CONTENTS FOR VOLUME II

CHAPTER VII

EXAMINATION OF PUNCTURE FLUIDS - 1221

General Considerations, 1221; Cellular Structure of Effusions, 1222; Aspiration Biopsies, 1227; Cerebrospinal Fluid, 1237.

CHAPTER VIII

FECES - 1261

General Considerations, 1261; Normal Findings, 1261; Examination of Stools, 1267; Bacteriology of the Stools, 1304.

CHAPTER IX

SPECIAL TESTS - 1305

C-Reactive Protein, 1305; Discussion of Hormone Assays, 1307; Laboratory Tests for Pregnancy, 1311; Urinary 17-Ketosteroids, 1323; The Vaginal Smear, 1326; Suction Curettage, 1329; Hypersensitiveness, 1336; Atopy, 1336; Semen Appraisal, 1363; Medicolegal Examination of Seminal Stains, 1366; Evidence in Suspected Sexual Assault, 1377; Deficiency Diseases, 1378.

CHAPTER X

BACTERIOLOGIC APPLICATIONS TO CLINICAL DIAGNOSIS - - - - - - - - - - - - 1388

General Considerations, 1388; Staining Procedures, 1399; Staining Technic, 1400; Bacteriologic Stains, 1401; Staining Methods, 1409; Culture Media, 1416; Reagents and Reactions, 1457; Culture Methods, 1462; Points in Identifying Bacteria, 1463; Special Culture Methods, 1469; Preparation of Vaccines, 1477; Inoculation of Experimental Animals for Clinical Diagnostic Purposes, 1480; The Preservation of Bacterial Cultures, 1482; Classification of the Pathogenic Bacteria, 1483; Description of Individual Bacteria, 1484; Neisseriae, 1497; Gaffkya, 1504; Mycobacterium Tuberculosis, 1505; Corynebacteria, 1510; Enterobacteriaceae, 1514; Brucella, 1538; Brucellosis, 1538; Bacilli, 1547; Genus Clostridium, 1548; Clostridia, 1554; Melioidosis, 1563; Hemophilus, 1564; Pasteurella, 1567; Vibrio, 1576; Lactobacillus, Listeria, etc., 1578; Erysipelothrix Rhusiopathiae, 1579; Pleuropneumonia Organisms, 1579; Bartonellaceae, 1579; Borrelia, 1580; Treponema, 1582; Leptospira, 1587; Collection and Examination of Specimens, 1596; Blood, 1597; Cerebrospinal Fluid, 1601; Pus From Localized Abscess, 1602; Material From Serous Cavities, 1603; Wound Secretions and Fistula, 1603; Sputum, 1604; Material From Ear and Mastoid, 1615; Nasal-Sinus-Nasopharyngeal Specimens, 1615; Cough Plate, 1620; Teeth, 1621; Skin, 1622; Eye Examination, 1622; Gastric Contents, 1627; Bile, 1629; Stool Examination, 1629; Urethral, Prostatic, and Cervical Material, 1639; Urine, 1645; Bacteriologic

Examination of Autopsy Specimens, 1648; Antibiotic Agents and Their Assay, 1648; Sanitary Bacteriology, 1654; Bacteriologic Examination of Glassware or China for Sanitary Quality, 1654; Bacteriologic Examination of Water, 1660; Bacteriologic Examination of Milk, 1675; Chemical Milk Analysis, 1684; Food Poisoning, 1687; Special Tests in Connection With Examination of Food Contamination by Chemicals and Spoilage, 1691; Examination of Flour for "Rope" Spore Content, 1695; Examination of Canned Food, Dressings, Needles, etc., for Sterility, 1696; The Testing of Disinfectants, 1702; Diseases Due to Rickettsiae, 1708; Rabies, 1716; Demonstration of Influenza Virus in Throat Washings, 1724; Etiological Agent of Infectious Hepatitis, 1725; Lymphogranuloma Venereum, 1726; Granuloma Inguinale, 1731; Yellow Fever, 1734; Dengue, 1735; Trachoma Bodies and Other Inclusion Bodies, 1736; Summary of the Laboratory Diagnosis of Viral Diseases, 1740; Preparations of Specimens in the Diagnosis of Viral Diseases, 1750; The Bacteriophage, 1758.

CHAPTER XI

MEDICAL MYCOLOGY - 1764

Histopathologic Methods, 1766; Collection of Specimens, 1766; Preparation of Cultures, 1767; Examination of Cultures, 1767; Animal Inoculations, 1768; Dermatophytosis, 1768; Trichophyton, 1771; Microsporum, 1773; Epidermophyton, 1775; Candidiasis, 1775; Actinomycosis, 1776; Mycetoma, 1778; Chromoblastomycosis, 1780; Sporotrichosis, 1782; Cryptococcosis, 1783; Histoplasmosis, 1784; North American Blastomycosis, 1786; South American Blastomycosis, 1788; Coccidioidomycosis, 1788; Aspergillosis, 1791; Mucormycosis, 1791; Rhinosporidiosis, 1793.

CLINICAL LABORATORY METHODS AND DIAGNOSIS

VOLUME II

VOLUME II

CHAPTER VII

EXAMINATION OF PUNCTURE FLUIDS

GENERAL CONSIDERATIONS

Puncture fluids should be obtained under all sterile precautions. The skin of the patient should be iodized and afterward rubbed with alcohol. The hands of the operator should be covered with sterile rubber gloves. The puncture instrument should be sterilized by dry heat at 170° C. for two hours.

1. **Amount** of fluid withdrawn should be noted. In cases of fluid accumulation in the pleural cavities, as much as 1.5 to 2 liters can be obtained; in abdominal ascites, as much as 10 to 20 liters.

2. **Gross Appearance.**—Note whether it is clear or cloudy; serous or chylous or purulent; colorless or colored; whether blood or bile stained. The presence of small pieces of blood clots does not change the appearance much. At times these small clots may be recognized after centrifugalization. It is only when hemolysis has taken place that the fluid takes on a red or yellowish color. In cases of biliary stasis, the fluid may be colored yellow. Where blood admixtures are present, eliminating the question of trauma, tuberculosis, or carcinoma of the serous surfaces must be considered.

3. A fetid **odor** is, of course, indicative of a severe inflammatory purulent infection.

4. **Specific Gravity** may be estimated by means of an ordinary urinometer. This investigation should be undertaken at once before precipitation of fibrin may alter the results. The specific gravity will enable one at times to differentiate between a **transudate** and an **exudate,** the borderline between the two being 1.018. Fluids with a low specific gravity are suggestive of a transudate (usually due to obstructive changes in circulatory apparatus), while higher specific gravities speak for exudates due to inflammatory processes. Practically all exudates are rich in fibrinogen, whereas transudates are usually poor in fibrinogen. When these exudates settle, the fibrin clots usually carry down with them some cellular elements.

5. **Albumin Content.**—Transudates are transparent, light yellow or light green; exudates are serous, bloody, purulent, or gangrenous. They also differ materially in their albumin content. Transudates contain from 1 to 3 per cent, or less, albumin, while exudates contain from 4 to 6 per cent, or more.

The quantity of albumin may be estimated by means of the Esbach method. (See Esbach Method in Urine Analysis.) It is best to dilute these fluids before the test, so that the albumin content will not be higher than 10 per cent. In other words, dilute them five to ten times, afterward mathematically correcting for the dilution. It is best to make the dilution with albumin-free urine instead of with water.

6. **The Rivalta Test.**—The Rivalta test is a simple qualitative determination of the globulin fraction of albumin present.

Add a few drops of 0.5% watery acetic acid solution by means of a pipette to a test tube containing the fluid to be examined. Add these drops slowly, one by one.

In fluids with a rich amount of globulin the precipitate appears in a form simulating cigarette smoke. A bluish cloudiness, which slowly falls to the bottom, develops in exudates; in transudates, where the globulin content is extremely minute, the cloudiness remains suspended in the fluid.

7. Determination of **bile** present may be carried out just as in urine, page 72.

8. **Microscopic Examination.**—The microscopic examination should be made very soon after the fluid is taken from the body before any clotting or precipitation occurs. If it is not possible to do this at once, it is best to add a small amount of 5 to 10 per cent sodium citrate or 4 per cent ammonium oxalate solution or a few crystals of hirudin to prevent clotting.

The nature of the cells present is very important. It is best to first prepare a smear direct from the fluid and stain just like a blood film. In tuberculous infections a great many lymphocytes are noted. The presence of neutrophilic leukocytes speaks of purulent or infectious processes. The presence of eosinophiles is of no particular importance except, possibly, as an allergic phenomenon.

Bacteriologic Investigations.—For bacteriologic investigations, refer to Chapter X.

CELLULAR STRUCTURE OF EFFUSIONS

The study of the cellular structure of effusions has been a neglected laboratory procedure. Possibly the most satisfactory method of study is that advised by Mandlebaum,[1] and popularized by Goldman.[2]

Mandlebaum Method.—

Place the fluid in a large Erlenmeyer flask. Allow to stand overnight in a refrigerator.

Decant the supernatant fluid.

Pour the sediment into a 50 c.c. centrifuge tube.

Centrifuge 20 minutes at moderate speed.

Again decant the supernatant fluid.

Harden the sediment with 1:10 Formalin or Zenker's fluid for 24 hours.

Carry through dehydrating and embedding steps as an ordinary tissue. Cut from above down so as to include all the cellular elements. Stain in hematoxylin-eosin.

Helwig Method.[3]—

Add enough Formalin immediately to the specimen to make a 4% solution of the fixative. This prevents bacterial growth and also cell degeneration.

---

[1] Mandlebaum, F. S.: Proc. New York Path. Soc., 1900, p. 178.
[2] Goldman, Alfred: Arch. Surg. 19: 1672, 1929.
[3] Helwig, E. B.: J. Missouri M. A. 39: 73, 1942.

Centrifuge as soon as possible.

There is a tendency for the block of sediment to crumble if sectioned immediately after fixation by formaldehyde; the entire mass of sediment is cut in a vertical plane when paraffin sections are prepared.

For further information on the preparation of stained sections of puncture fluids, see section on tissue cutting and staining, page 2156.

Goldman made an interesting report of fifty effusions prepared by this method from serous fluids in cases of malignant, cardiac, and tuberculous disease. The specific gravity was noted in all fluids. There were twenty cases of malignant disease in this series proved by autopsy, biopsy, or a palpable mass with gross characteristics of a malignant tumor. He studied the effusions from all these cases with particular reference to the presence or absence of tumor cells. Zemansky, in his series studied by this method, showed that in 60 per cent of fifty-five cases of carcinoma there were tumor cells in the effusions. In Goldman's report, 80 per cent of the effusions showed cells which were interpreted as being malignant. In other words, a positive diagnosis of tumor cells may be made with the highest degree of accuracy. A negative diagnosis does not, of course, rule out a malignant condition. Obviously, there must be contact between the tumor and the fluid before tumor cells are "shed."

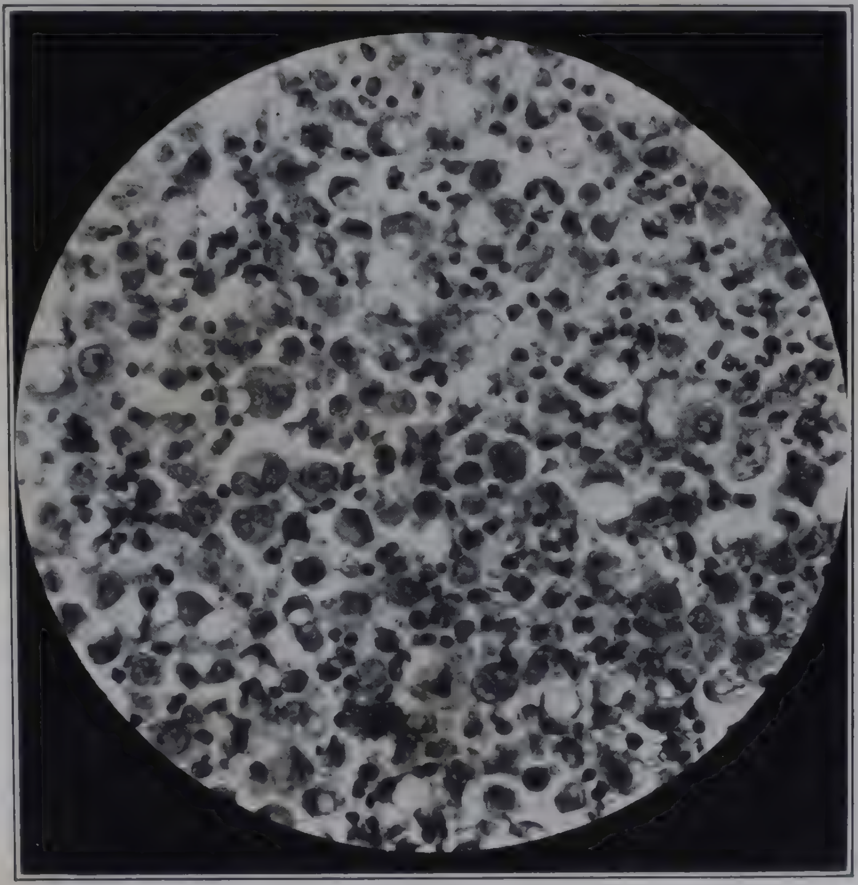

Fig. 296.—Paraffin section of pleural fluid showing carcinoma cells. (×400.)

Tumor cells, as has been pointed out by Zemansky and others, appear in two main forms: (a) fragments of tumor tissue often showing glandular or pseudoglandular arrangements or clumps of tumor cells, and (b) isolated tumor cells, the characteristics of which will be mentioned later.

The first type is easy to diagnose. The cell clumps stand out as large, deep-staining cells, amid various types of blood cells and mesothelial cells. Occasionally the tumor fragments may be seen almost exclusively at the bottom of the centrifuge tube.

It is in those cases in which individual tumor cells occur that one may have difficulty in making a diagnosis. There were three such cases in Goldman's series. Criteria for diagnosis here are large atypical deep-staining cells, with a large excentric nucleus or with several nuclei, sometimes showing mitotic figures, often vacuolated. Mesothelial cells which may or may not be clumped, occurring in transudates of long standing, are at times confusing. These must be carefully studied and differentiated by the criteria mentioned.

The cells often assume a glandular arrangement (eight cases). The tumor cells may thus resemble the original tumor. In one case both pleural and peritoneal fluids were obtained, and both specimens showed the same type of cell.

A fluid may be positive at one examination and later appear negative. A patient with carcinoma of the pleura in whom the condition had metastasized from a bronchial carcinoma developed an effusion which on the first examination revealed many tumor cells. Two months later, a second tapping was done in which no tumor cells were found. It is possible that the fluid obtained from the second tapping came from an encysted effusion and not from the large pleural effusion. The sputum in this case was treated by the same method and revealed no tumor cells.

Case 32 of Goldman's series shows the necessity of careful search for tumor cells. While in the majority of cases cells are present in abundance, in this instance only one group of cells was found on which the diagnosis of malignant disease was made. A biopsy of a tumor of the neck revealed a metastatic carcinoma probably from the bronchus.

Tumor cells may appear in an effusion soon after the appearance of the fluid.

Four cases in which a positive diagnosis of tumor cells was made came to autopsy. All showed direct contact of cancer tissue with the effusions which had developed. Apparently this is essential before tumor cells are "shed" into the serous cavity.

Four negative examinations occurred in proved cases of carcinoma. They were negative because there was no actual contact of tumor and fluid. Goldman states: "The appearance of the effusions varied from a clear straw-colored fluid as seen in transudates to turbid, bloody fluids. All specimens contained red blood cells in large amounts, more than in any other type of effusion. The specific gravity of the fluids ranged from 1.013 to 1.025; the average was 1.017. This figure is appreciably lower than that usually given in textbooks. There was no apparent relation between the specific gravity and the number of tumor cells present."

With respect to cardiac effusions, all contained numerous red blood cells, less than in the cases of tumor and more than in the cases of tuberculosis.

The predominating cell was the mesothelial cell; there were also a few macrophages containing blood pigment, similar to the "heart failure" cell in the sputum in cardiac cases. There were a few lymphocytes and occasional polymorphonuclear neutrophiles. Goldman warns against mistaking clumped mesothelial cells for tumor cells. The former are smaller, more regular, have a single nucleus, show no mitosis, and do not stain so deeply as do the tumor cells. The specific gravity of these fluids varied from 1.008 to 1.014, with an average of 1.012.

Tuberculous effusions showed lymphocytes as the predominating cell. In some cases, polymorphonuclear cells predominated. A few mononuclears were usually present; also a few red cells. Specific gravity ranged from 1.019 to 1.026. Goldman studied a number of miscellaneous cases with effusions. A pleural effusion in a case of Hodgkin's disease showed an equal mixture of lymphocytes and large mononuclear cells.

It is in carcinoma of the pleura that we have the greatest success in proving the diagnosis during life by this method.

One of the very important considerations in examination of fluids for carcinoma is that the carcinomatous cells show a very fine arrangement of mitotic figures. Fatty degeneration in the cells is likely to be found.

Helwig[1] reported on a study of sixty-five routine diagnostic fluids obtained from fifty-six patients. Paraffin sections were prepared and stained with hematoxylin and eosin. The sections were examined solely on a morphologic basis without knowledge of the history of the patient or of the cavity from which the fluid had been removed. Each specimen was recorded either as "positive for tumor cells" or as "negative for tumor cells." All the criteria which could be considered of possible significance for judging the presence or absence of tumor cells were listed on a chart. The criteria were recorded as plus or minus on each fluid. He utilized the following criteria: mitoses, abnormal mitoses, large nuclei, large or small nucleoli, multiple nuclei, position of the nucleus, irregularity of cell outline, vacuolization of the cytoplasm, acini, papillae, clumps of cells, fibrin, and red blood cells.

His results were as follows:

TABLE 132A.—SUMMARY OF SPECIMENS REPORTED POSITIVE

	PERITONEAL FLUID	PLEURAL FLUID	TOTAL
Total patients	23	33	56
Total specimens	29	36	65
Total reported positive	10	8	18
Proved correct[1]	4	2	6
Presumed correct[2]	3	6	9
Proved incorrect[1]	1	0	1
Unknown[4]	2	0	2

[1], [2], [4]See footnotes under Table 132B, p. 1226.

It will be noted that two cases showing the result "negative for tumor cells" were a primary carcinoma of the liver and the other a primary carcinoma

Unknown[4]	1	2	3

[1] Diagnosis established by examination of body cavity at operation or autopsy or by the identification of a specific etiologic agent in the cavity fluid.

[2] Diagnosis established by biopsy of malignant tumor in the patient or by roentgen-ray examination or by palpation of a mass when considered with the clinical course.

[3] Diagnosis established by the results of laboratory tests when considered with the clinical course.

[4] The exact nature of the disease was not established.

of the pancreas, the peritoneum being free from metastases at autopsy. Obviously, an examination of ascitic fluid from these two cases could not reveal the presence of a tumor which did not involve the peritoneum and the diagnosis of ''negative for tumor cells'' was actually correct for the specimen examined. He narrated that, in another case, a single examination of ascitic fluid failed to reveal the presence of identifiable tumor cells although an autopsy revealed a neoplasm involving the peritoneum.

His work emphasizes that in judging the accuracy of this type of test, it is necessary not only to know whether a neoplasm is present in the patient but also to know whether the serous surface of the particular body cavity from which the fluid was withdrawn is involved by the tumor. Even though a patient has a neoplasm, tumor cells cannot possibly be identified in fluid obtained from a cavity which is not involved by the neoplasm.

The criteria of Zemansky[1] in detail, which are useful in judging a fluid positive or not for neoplastic cells, are (1) fragments of tissue with a definite arrangement of cells and stroma, (2) multiple groups of large, deeply staining cells, giving the slide a mottled appearance, (3) finer cellular changes such as extreme irregularity of cell outline, excentricity of nucleus, extremely large size of nucleus, multinucleation, and typical or atypical mitotic figures. Foot,[2] some ten years after Zemansky's publication, attempted a diagnosis by means of measurement of the nucleolar-nuclear ratio. He refused to accept as evidence of neoplasia the presence of hyperchromasia, large and deeply stained nuclei, multinucleation, mitotic figures, or acinar-like arrangement of cells, changes which he believed might be presented by exfoliated mesothelial cells in fluids of long standing. Foot was correct in 60 per cent of the positive ascitic fluids and by using the nucleolar-nuclear ratio alone he was correct in 72 per cent. By utilizing this method, his record of accuracy for positive fluids fell far below those of Zemansky's but his results with negative fluids were appreciably more accurate. Quensel[3, 4] and Karp[5] emphasized that the ratio of nuclear to nucleolar size is high in cells of malignant tumors, thus agreeing with Foot. McCarthy* has emphasized, too, the difference in the nuclear-nucleolar area ratio of malignant and hyperplastic cells observed in unfixed tissue. As Helwig states, this is just the reverse of the nucleolar-nuclear ratio but gives the same ultimate results. Haumeder and McCarthy[1, 2] found the ratio of nucleus to nucleolus for the cells of regenerative breast to be 17 to 1 and for the malignant cells 11 to 1, whereas, Naidu[3, 4] working with similar organs in the same laboratory found the nuclear-nucleolar ratio for the cells of regenerative breast to be 21 to 1 and for malignant cells 17 to 1. Helwig states very properly that from these studies, it seems that the nucleolar-nuclear ratio is of least value in that group of fluids which is also most difficult to diagnose by a morphologic study of the cell.

Helwig's general conclusions were that the report of "tumor cells present" should carry with it a high degree of accuracy and that a report of "no tumor cells present" is of less diagnostic value. Further, he believes that atypical mitotic figures and bizarre multinuclear cells are indicative of malignant cells. He warns against confusing desquamated cells from the lining of the serous cavities with tumor cells. Cells arranged in clumps or acini should be accepted as tumor cells only when they exhibit pronounced pleomorphism.

Summarizing: (a) Effusions resulting from carcinoma show "cancer cells" in a large majority of cases, together with considerable blood; (b) cardiac transudates show a predominance of mesothelial cells. Red blood cells are abundant; (c) tuberculous effusions shows a predominance of lymphocytes, with a few red cells.

In addition to carcinoma, one may find in the fluid other important cellular material as follows:

(a) In actinomycotic fluids one often finds the characteristic particles which consist microscopically of a mass of fine radiating fibers. These accumulations are often calcified and must be decalcified with diluted hydrochloric acid. They must not be confused with fatty acid crystals.

(b) Puncture fluids frequently show echinococcus cysts.

(c) In addition to the cellular elements already seen, crystals may be found, especially in old fluids. Chlosterine crystals are found in purulent breakdown of ribs; hematoidin crystals are also likely to be found.

ASPIRATION BIOPSIES

In an evaluation of biopsy by needle puncture, the following questions must be answered[5]: Do the results justify the means? What can be learned by this procedure that cannot be determined by other methods? If there is a choice, is aspiration biopsy the method of choice? Does the simplicity of the technical procedure outweigh the possible danger to the patient?

Needle biopsy as a diagnostic procedure has proved to be practical, valuable, and reliable. It should be used if there is a deep-seated lesion located beneath normal tissue where the damage resulting from the surgical approach of the operation would outweigh the advantages gained. It should be used if the procedure can save time or expense, or prevent inconvenience or discomfort to the patient, and can furnish information of practical value to the physician. It is to be recommended whenever there is danger of postoperative infection of the aspiration wound, possible fungation of tumor through the incision, particularly in lesions of bones, nasal sinuses, breast, and subcutaneous nonencapsulated tumors.

The most important contraindications are[2] abnormalities in the clotting or bleeding time; danger of spreading and disseminating a disease process or infection of body cavities; unjustified aspiration, promising only information of doubtful value or having little more than academic interest; and an uncooperative patient.

The technics for aspiration biopsy may vary somewhat for the organs or regions concerned. Ordinarily an 18 gauge, long needle is used, but special devices have been advocated and have been successfully used. They will be hereafter described. Usually after Novocain infiltration of the skin and soft tissue, the skin is nicked with a scalpel and the needle is inserted. A 20 c.c. syringe is attached to the needle after the desired organ is entered, a vacuum is produced in the syringe, the needle is slowly advanced, and then gradually withdrawn, the vacuum being slowly released before the needle is entirely removed in order to avoid splashing of tissue into the barrel of the syringe. After the needle is withdrawn, the tissue block is forced out of the needle by pressure on the plunger of the syringe. Spreads can be made from small fragments, while most of the tissue cylinder is fixed for histologic examination.

Necessarily, only small pieces of tissue can be obtained.

The criteria for diagnosis should be sharply and exactly defined. The examiner must know how to differentiate primary from secondary tumors. It is sometimes difficult to differeniate inflammatory or degenerative lesions from neoplasms.

Biopsy of Liver[3]

Liver biopsy has a definite place in the diagnosis of obscure hepatic diseases. This is well pointed out by Sherlock.[4] Her technic is as follows:

Preparation of the Patient.—Jaundiced patients are given vitamin K preparations for three days before the puncture. If the jaundice is nonobstructive (urobilin present in the urine), two 5 mg. tablets of "Kapilon" are given by mouth three times a day. If the jaundice is obstructive, the vitamin must be administered intramuscularly; 5 mg. daily is a suitable dose.

In every case, before biopsy is performed, the patient's blood group should be known, and two pints of compatible blood should be readily available. Aspiration liver biopsy should not be performed unless adequate facilities for blood transfusion are available in case of complicating hemorrhage. A sedative is unnecessary before puncture.

[4] Sherlock, S.: Lancet 2: 397-401, Sept. 29, 1945.

Hepatic Puncture.—Have the patient lie supine in bed with the right side as near the edge of the bed as possible. A firm pillow may be placed under the left side in the hollow of the bed, so that the body is slightly tilted to the right. The right arm is placed behind the head. A site is chosen in the ninth or tenth intercostal space in the middle or anterior axillary line. After cleansing, anesthetize the skin with 2% procaine solution. Use a long fine-bore needle to infiltrate the pleura and then pass it through the diaphragm to anesthetize the peritoneum and the capsule of the liver. At least 10 c.c. of local anesthetic are needed. If the skin is tough, a preliminary nick may then be made with a scalpel. The cannula used is 15 cm. long and 1 mm. in bore. It is fitted with a handled trocar. Pass the instrument through the skin, and then instruct the patient to ''take a deep breath in, let it out, and then hold your breath.'' This displaces the lung upwards and insures apposition of diaphragmatic and costal pleura. Now push the trocar and cannula through the diaphragm into the right lobe of the liver. Do not withdraw the trocar until the instrument is fully half an inch inside the liver substance. Then punch out the cylinder of liver tissue by pushing the cannula on a further 4 to 5 cm. Connect a 20 c.c. ''Record'' syringe to the cannula and apply and maintain suction while withdrawing the cannula. Seal the puncture wound in the skin with collodion. The fragment of liver is usually found in the barrel of the syringe; occasionally it remains in the cannula. The aspiration of blood with the biopsy specimen need not occasion alarm.

Aftercare.—As a little local pain may follow puncture, morphine gr. ¼ or gr. ⅙ is given subcutaneously, according to the size and type of patient. This allays discomfort and prevents restlessness. If necessary, a further sedative, such as barbital soluble gr. 10, may be given in the evening. The pulse is charted hourly for the first 24 hours after biopsy; the physician should be called if the pulse rate shows a rise. Routine visits should be paid 4 and 8 hours after biopsy. A very careful watch must be kept on the patient, and if there is any sign of hemorrhage the cross-matched blood should be administered. Absolute rest in bed is essential for 24 hours. The patient can then be up and about and if desired can leave the hospital 48 hours after the liver puncture.

The procedure is attended with very little disturbance to the patient. During the puncture there may be a complaint of a drawn feeling across the epigastrium. Afterward some patients have a slight ache in the right side for about 24 hours, and some complain of a pain referred from the diaphragm to the right shoulder. Most patients agree that the discomfort compares favorably with that associated with sternal or lumbar puncture. Thirty patients had more than one biopsy; one had four.

Difficulties.—There may be failure to get an adequate sample of liver. Hoffbauer (quoted by Watson, 1944) had 40% failures with the Tripoli and Fader (1941) technic. Iverson and Roholm (1939) reported a 10 to 15% failure-rate; van Beck and Haex (1943), however, using the same method, state that the puncture failed only rarely. In Sherlock's first 126 biopsies there were 10% of failures; in the next 138 only 2%. Difficulties arise most often in hepatic cirrhosis, especially if there is associated ascites. In cirrhosis the tough liver is difficult to pierce and a few liver cells may be extracted leaving the fibrous framework behind. In ascites the liver is very ''ballottable'' and is difficult to transfix. A paracentesis abdominis should be undertaken before the liver biopsy is attempted, and the patient should lie well over on the right side during the puncture. This brings the liver into contact with the chest wall. Another source of difficulty may be pulmonary emphysema; the liver is pushed downward by the low diaphragm. It is very easy for the trocar to pass above the liver. If a low diaphragm is suspected before biopsy, the chest should be radiographed, and if necessary the puncture can be made through a lower intercostal space.

Inspection and Fixation of Biopsy Specimen.—Some information may be gained from inspection of the biopsy specimen. Fatty livers have a characteristic greasy look. Biopsy specimens of livers with excess fibrous tissue tend to crumble into fragments with a lobulated contour. If a malignant deposit has been punctured, the dull white appearance of the biopsy specimen is characteristic.

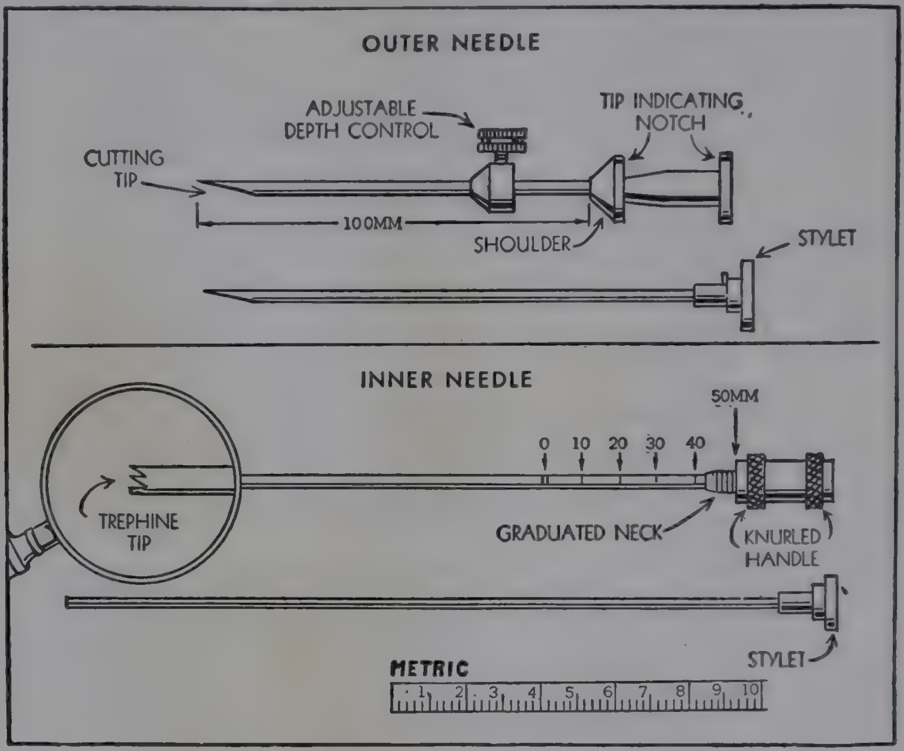

Fig. 297.—The Turkel standard liver biopsy set. (Courtesy Dr. Henry Turkel, Detroit, Mich.)

Fixation is best accomplished in absolute alcohol, which, while it dissolves the red cells, preserves the glycogen in the liver cells and enables Best's carmine stain to be applied. To demonstrate the elements of blood in the hepatic sinusoids, formol-saline is the most satisfactory fixative. Fat can be shown by fixing the material in Bouin's solution followed by 2% osmic acid. After fixation the specimen is embedded, sectioned longitudinally along the line of the cylinder, and stained in the usual way. If desired, the sample can be examined bacteriologically.

Reliability of Biopsy Specimens in Assessing Liver Histology.—Excluding the obviously localized conditions, such as malignant metastases, abscesses, and cysts, most other examples of human liver diseases have a reasonably uniform histology, and, therefore, biopsy specimens are likely to give good results. In Sherlock's experience, thirty cases came eventually to necropsy and in each the histology of the biopsy specimen was a fair sample of the liver as a whole.

Use of Biopsy Specimens in Diagnosis.—In regard to acute hepatitis, if the biopsy is performed early in the jaundiced phase, the acute liver inflammation presents a characteristic picture and diagnosis can be made. If the biopsy is postponed until convalescence, normal liver tissue may be observed and diagnosis is then impossible. In cirrhosis of the liver, clinical diagnosis may be aided by this liver biopsy study.

In obstructive jaundice, aspiration liver biopsy readily distinguished obstructive icterus of short duration from other types of jaundice.

In malignant disease of the liver without jaundice, very often a portion of a localized lesion is obtained for section, and it may indicate the site of the primary disease.

In connection with this information, attention should be called to the Turkel standard liver biopsy set. We recommend this for carrying out this technic. Fig. 297 shows the various parts of this equipment.

The outer splitting needle and stylet are forced through the skin, subcutaneous tissue, and liver; the liver is entered for a distance of about 5 mm. The stylet is replaced by the inner trephine needle which cuts the liver tissue to the desired depth. The inner needle is then removed and the biopsy tissue expressed with the stylet.

In connection with the use of this instrumentarium, the following **points on biopsy technic** must be observed:

1. Maintain asepsis
2. Instruments and materials:
    a. Liver biopsy set
    b. A 20 c.c. syringe (for retaining soft liver tissue within the inner needle)
    c. Abscess scalpel, syringe with local anesthetic (procaine)
    d. Biopsy sheet, dressings, antiseptics, gloves

Turkel suggests that *the most common points of insertion* are:

A. Anteriorly between mid-clavicular line and midline, just below the costal margin—only if the liver extends at least 4 cm. below the costal margin
B. Right mid-clavicular line—if liver is palpable 5 cm. below right costal margin
C. Between 9th and 10th rib on right side in anterior or mid-axillary line

In case of nodular liver where nodules are definitely palpable it might be advisable to take two specimens, one over the nodule and one in any non-nodular area for comparison.

Sherlock,* in her analysis of 264 biopsies, selected representative cases and gave six typical histologic pictures showing various diseases in which this method was used:

1. A typical case of hepatic cirrhosis following arsenotherapy jaundice.
2. Secondary hepatic squamous epithelioma with cell nests.

---

*Loc. cit.

3. Histiocytic medullary reticulosis showing increased nucleated cells in the sinusoids and portal tracts.

4. Amyloid disease showing heavy infiltration of hepatic sinusoids with pale-staining amyloid.

5. A case of kala-azar showing histiocytic accumulations scattered through the liver.

6. Another case of kala-azar showing Leishman-Donovan bodies lying within the histiocytes.

Aspiration Biopsy of Lung and Material in the Pleural Cavity

According to Smetana, Menetrier is credited with having made the first diagnosis of cancer of the lung by histologic examination after needle puncture, in 1886.[1] Other available literature on the subject of needle biopsy of the lung will be found in the work of Dutra and Geraci.[2] They call attention to the extreme difficulty in ascertaining the nature of lesions in the peripheral portion of the pulmonary parenchyma. Roentgenographic evidence of the presence of a region of increased density within the lung is always an indication for additional diagnostic procedures. For this purpose, the frequently utilized examinations are smears of sputum for organisms and malignant cells, cultures for bacteria and fungi, and bronchoscopy. All of these may fail to provide a definitive diagnosis, especially when the lesion is located distal to the secondary bronchi. There has been lately a tendency toward thoracotomy with biopsy resection of the lesion in such circumstances. At times neither is desirable nor practical. Craver[3] described a technic by which a needle passed through an intercostal space was used to obtain a fragment of diseased tissue from peripheral pulmonary lesions. Dutra and Geraci believe that there are cases in which needle biopsy is a valuable procedure and, if used only when indicated, the danger of complications will be negligible in relation to the information obtained.

Craver's technic was the introduction of a short-bevel No. 18 needle into the mass, followed by attempts to aspirate groups of cells from the lesion with a syringe. Recently there has been described the use of the Vim-Silverman biopsy needle for this procedure. This procedure is a simple one.

Use of the Vim-Silverman Biopsy Needle.—Have on hand a Vim-Silverman biopsy needle.

Use a barbiturate and morphine or meperidine hydrochloride solution as a premedication.

Under fluoroscopic control, locate the tumor, and by rotation of the patient determine the point where the lesion is nearest the chest wall.

Mark this area of the chest wall with Merthiolate, light the room, and infiltrate the skin and subcutaneous tissues with 1% solution of procaine hydrochloride.

Insert the biopsy trocar and sheath through the skin and appropriate intercostal space in the direction of the tumor.

With the patient again before the fluoroscope, pass the trocar into the lung tissue and the periphery of the tumor mass.

---

[1] Craver, L. F., and Binkley, J. S.: J. Thoracic Surg. 8: 436, 1939.

[2] Dutra, Frank R., and Geraci, Charles L.: J. A. M. A. 155: 21, 1954.

[3] Craver, L. F.: Surgery 8: 947, 1940.

Then withdraw the trocar from the sheath and insert the cutting blades down the sheath into the tumor mass.

Drive the blades forward to the hilt with a slight twisting motion. This carries them approximately 2 cm. beyond the sheath and into the tumor tissue.

Rotate the blades completely several times to sever the core of tumor tissue and then withdraw the blade. The core of tumor tissue is found between the blades.

Drop it into a 4% solution of formaldehyde (10% Formalin).

Needle biopsy of the lung should be employed when there is evidence to suggest the patient has a malignant tumor of the lung that could not be cured by resection. Its use should be restricted to cases in which other diagnostic methods have failed to identify the pulmonary lesion. The procedure should be done only in cases in which the following criteria are met: (1) the chest films reveal one or more opaque lesions in the peripheral pulmonary tissue; (2) examination of several smears and cultures of sputum and gastric washings have been done without isolating *Mycobacterium tuberculosis;* (3) evidence of a malignant neoplasm cannot be obtained by the technics of exfoliative cytology or by bronchoscopic examination and biopsy; (4) there is clinical evidence of incurability of the lesion.

Biopsy of Prostate*

Prostatic biopsy has been a much neglected procedure since it has not been possible to obtain a satisfactory specimen in many instances. The Turkel standard prostate biopsy set No. SBP 1214-100-50 consists of: One outer sheath or splitting needle gauge 12, 100 mm. long with its obturator or stylet; one adjustable depth control guard; one inner sheath or trephine needle gauge 14, extending 50 mm. with its obturator or stylet.

It serves as an excellent method of obtaining material from prostate for diagnosis.

Technic.—

Force the outer sheath or splitting needle and obturator through the skin until the tip of the needle partly enters the gland. Replace the obturator with the inner sheath or trephine needle which cuts the glandular tissue to the desired depth. Then remove the inner sheath and express the tissue.

If only biopsy is to be performed, the patient may be anesthetized with Pentothal sodium or by deep infiltration with a local anesthetic since the entire procedure may last only about five minutes.

If major operative procedures are contemplated, the patient may be given spinal anesthesia or whatever type of anesthesia may be decided upon.

There are certain points to be remembered; first, always maintain asepsis and, second, have all instruments and material ready for biopsy.

Assemble the following material:

Trephine prostatic biopsy set.
An empty 20 c.c. syringe for retaining fluid or soft tissue within the inner sheath.
Abscess scalpel, syringe with anesthetic.
Biopsy sheath, dressings, antiseptics.

The patient is put in the lithotomy position and sterile preparation of the entire field is done.

Make a nick with an abscess scalpel to facilitate entrance of the outer needle.

---

*J. Urol. 51: 66, 1944.
Year Book of Urology, page 280, 1944.

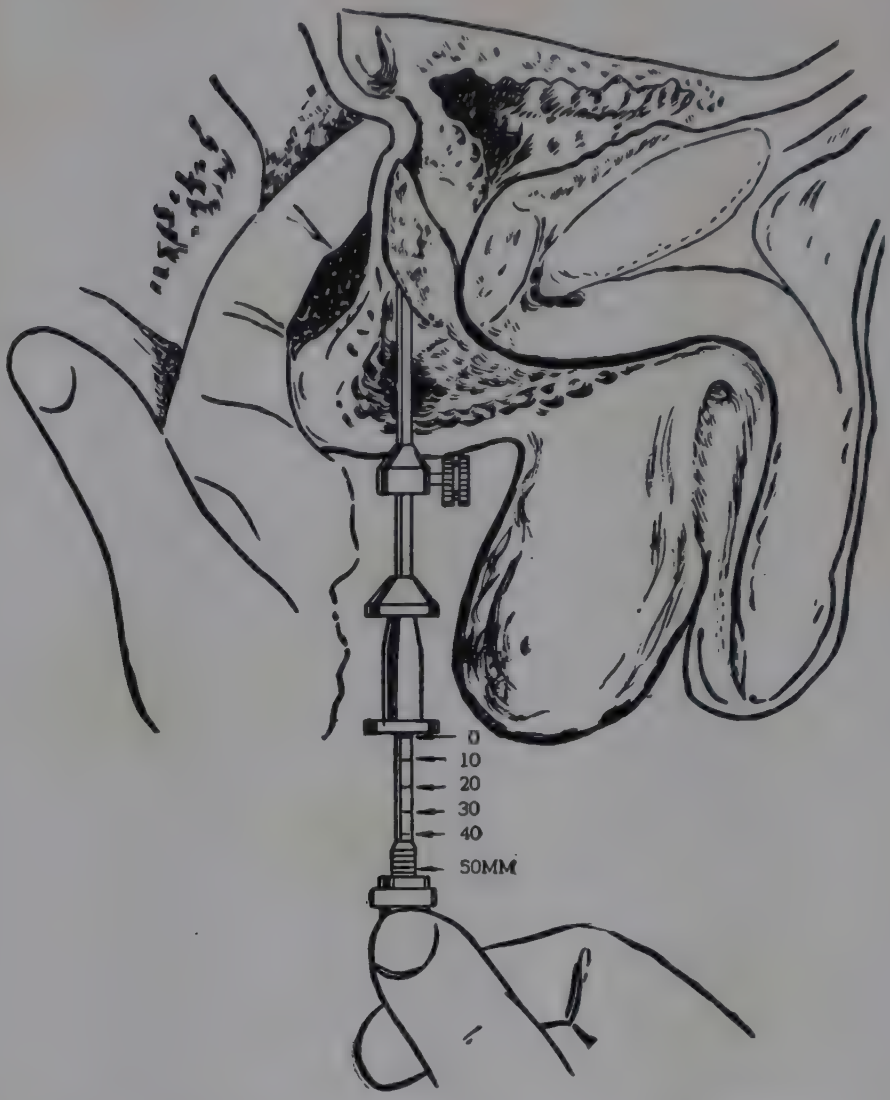

Fig. 298.—Aspiration biopsy of the prostate. The rectal finger is passed to the proximal portion of the prostate and hooked above. (Courtesy Dr. Henry Turkel, Detroit, Mich.)

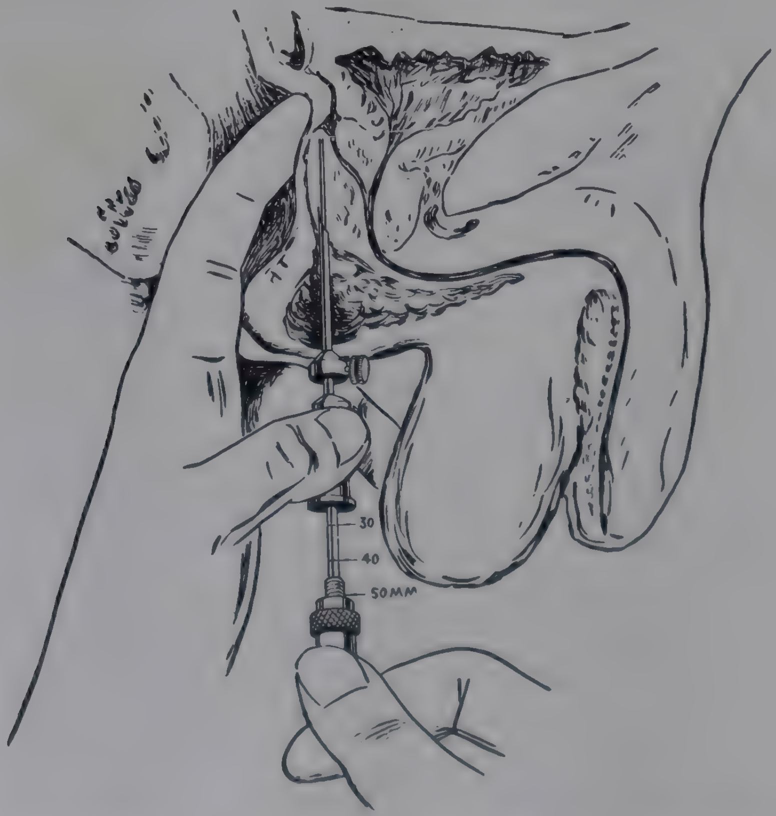

Fig. 299.—Aspiration biopsy of the prostate. Advance the inner trephine sheath through the gland with a to-and-fro motion. (Courtesy Dr. Henry Turkel, Detroit, Mich.)

With the index finger of the left hand in the rectum, the outer sheath with its obturator is inserted through the perineum and guided with the rectal finger until it just enters the prostate.

One may or may not move the depth control guard close to the skin and tighten the screw.

At this point, withdraw the obturator and insert the empty inner trephine sheath. It is important that the rectal finger now be passed to the proximal portion of the prostate and hooked above (Fig. 298). This is done in order to give counter-resistance to the cutting section.

Advance the inner trephine sheath through the gland with a to-and-fro motion, Fig. 299. When the desired amount has been cut, turn the trephine sheath with a clockwise rotatory motion in order to separate the specimen from the remainder of the gland.

Should the tissue (gland) be soft or contain fluid, suction should be applied with a 20 c.c. syringe to the inner trephine sheath in order to retain the tissue within the inner sheath.

Remove the inner sheath while applying suction. Insert the inner obturator into the inner sheath and force the specimen into a bottle containing a fixative.

Look for tissue in the outer sheath since the section occasionally falls into this portion during removal.

Cover the point of insertion with an antiseptic dressing. Occasionally there may be a slight bleeding but this can be disregarded because gland compression will stop it after removal of the sheath. Coagulation of the channel may be done through the outer sheath with a special electrode attached to a Bovie or similar apparatus.

Biopsy of the Sternum

Biopsy of the sternum is discussed on pages 937 ff.

Needle Biopsy of the Central Nervous System

Needle puncture of the central nervous system has been employed by many neurosurgeons as a routine procedure since the early part of the century. Unsatisfactory results of neurological examinations for determination of the nature and site of disease of the central nervous system are indications for its use. This applies to tumors, cysts, abscesses, hemorrhages, and other lesions, including disorders of the choroid plexus, tumors of the meninges, adenoma of the pituitary gland, glioma, neurinoma, and even capillary hemorrhages on an arteriosclerotic basis. It is also employed for therapeutic purposes, such as relief of increased pressure of the cerebrospinal fluid, localization and drainage of extradural hemorrhages, pachymeningitis, if the blood is still liquid, and drainage of abscesses and cysts. The danger of spreading the process through the central nervous system, for instance, during the puncture of a tubercle or an abscess, does exist; but such a complication is uncommon, according to Smetana.[1] The implantation of tumor tissue along the puncture canal is also possible. The greatest danger is infection of the meninges.

Aspiration Biopsy of the Spleen

With proper precautions, the application of acceptable technics, and correct assessment of the indications, splenic puncture can be regarded as devoid of danger if the procedure is restricted to enlarged organs (Smetana). It should never be carried out in patients suffering from hemorrhagic diathesis, in the presence of an acute splenic tumor, or in comatose patients. Splenic puncture should be performed only during full inspiration, and penetration into the pulp should not exceed 1 to 2 cm. The material obtained may be studied cytologically or histologically. It has many applications in the diagnosis of hematologic disorders, in metabolic diseases such as Gaucher's disease or Niemann-Pick disease, in kala-azar, in malignant lymphomas, in leukemias and other conditions. Together with bone marrow puncture, it can be of diagnostic value in some hematologic and metabolic conditions.

---

[1] Am. J. Clin. Path. 24: 395, 1954.

Aspiration Biopsy of Bone

Aspiration biopsy of bone has certain advantages, namely, the simplicity of technic for obtaining material for study, the slight inconvenience to the patient who need not be hospitalized, and trauma of such minor degree that operations or treatment can be instituted at the site without waiting for wound healing.

If aspiration biopsy is contemplated for general conditions, such as myeloma, leukemia, and metastatic carcinoma, the iliac crest is regarded as the best site for aspiration. Sternal puncture (see pages 937 and 939) has been the method of choice for many workers, but we have had signal success by aspiration of iliac crest (see page 940).

Good diagnostic results of aspiration biopsy have been reported in cases of primary and secondary tumors of bone. Hodgkin's disease is not easily diagnosed by aspiration, nor is this method satisfactory in cases of osteitis deformans. The method may serve to exclude an apparent malignant tumor. Bone cysts are not suitable material. On the other hand, the Hand-Schüller-Christian, Gaucher, and Niemann-Pick diseases, eosinophilic granuloma, myeloma, and histiocytic lipomatosis can be diagnosed from material obtained by needle puncture.

Aspiration Biopsy of the Kidney

Aspiration biopsy of the kidney has been mainly used in the study of medical diseases, and therefore its use has been rather limited. It is thought to be a valuable adjunct, however, for the study of disorders rarely seen at autopsy in their active clinical phase. It is predicted that needle biopsy of the kidney will be instrumental in contributing to understanding such diseases as acute uremia, effects of shock, lower nephron nephrosis, and the effects of poisons. In this manner, the effects of damage to the kidneys can be evaluated and the histopathologic background correlated with the data on renal function. This also applies to the study of the natural history of the nephritides, hypertension of renal origin, interstitial nephritis, pyelonephritis, urolithiasis, and many other conditions of the kidney of which only the terminal phase is known and the pathologic picture of the early and intermediate stages is assumed.

The technic described by Iversen and Brun is the same as that for needle punctures elsewhere. X-ray examinations are essential to determine the presence and location of the kidney. An intravenous pyelogram with the shadow of the kidney outlined on the skin from at least two planes serves as a guide for the needle. The right side is preferred because of the presence of large venous channels on the left.

Iversen and Brun have reported success in 42 of 66 cases, with occasional transient hematuria 6 to 12 hours after puncture as the only complication.

Studies on renal biopsies were repeated by Parrish and Howe, using the Turkel biopsy needle, 12 gauge with a 75 mm. shaft and 100 mm. inner cutting needle. If there was abnormal clotting time or the prothrombin value was less than 70 per cent of normal, no biopsy was performed. The results reported by these authors were encouraging, being positive in 29 of 50 attempts in 41 patients.

These authors conclude that renal aspiration biopsy is a valuable adjunct in the diagnosis of renal diseases, and if necessary can be repeated in the same patient. It is contraindicated in congestive heart failures with elevated venous pressure, in bleeding diathesis, in the presence of only one kidney, and if perinephritis or perinephritic abscess is suspected. It is indicated in instances of undiagnosed renal disease, albuminuria, and hematuria of renal origin and obscure etiology.

Aspiration Biopsy of Miscellaneous Sites

Smetana describes the use of the Silverman biopsy needle in cases of suspected thyroiditis, struma lymphomatosa and Riedel's struma, in inoperable carcinoma, and in the study of the uptake of radioactive iodine.

Conventional biopsy of the pancreas is often unsatisfactory, because tumors are deep in the parenchyma and difficult to reach, the tissue is very vascular, inflammatory changes are frequent along the surface layers, and injury to ducts may produce a pancreatic fistula.

Occasionally aspiration biopsy has been performed on the testis and the epididymis for diagnosis of suspected tumor or other obscure clinical conditions. Similarly, such needle biopsies have been reported after puncture of masses found in soft tissue or in body cavities at operation, or of enlarged lymph nodes in various situations.

Summary

Aspiration biopsy constitutes a valuable means for securing histologic information concerning diseased conditions and the presence of neoplasms in many organs and areas. The indications vary somewhat for different organs and include inaccessibility of undiagnosed conditions for conventional exploration, after unsatisfactory results of clinical examination, search for the presence and type of neoplasms, follow-up studies of the course of disease, and the effect of treatment, and search for unrecognized systemic diseases. In addition, there are certain economic considerations.

The principal contraindications are the presence of states of hemorrhagic diatheses, the possibility of dissemination of infection, a spread and implantation of cancer cells, uncooperativeness of the patient, and lack of justification for, or poor chance of, success of aspiration.

CEREBROSPINAL FLUID

The examination of spinal fluid is a very important procedure in connection with many medical and surgical cases. For the method of withdrawing spinal fluid from the living subject, we are indebted to Heinrich Quincke who first treated two cases of hydrocephalus by means of withdrawal of the spinal fluid. In 1893 Lichtheim called attention to spinal puncture as a valuable aid in diagnosis, and in 1895, Fubringer reported 107 punctures in eighty cases. Since that time, spinal puncture has been generally adopted as a routine procedure for diagnostic and therapeutic purposes.

The ventricles of the brain which contain fluid slightly different in composition from that of the spinal fluid were first tapped by Middeldorpf in 1856. Occipito-atlantoid drainage of the cisterna magna in man was first performed by Parker in 1893. Cistern puncture has been developed mainly in this country. In 1919, Wegeforth, Ayer, and Essick performed the operation in man, using a needle for the puncture. Sicard, in 1923, was the first to introduce Lipiodol into the cistern as a roentgenographic aid in the diagnosis of cord tumors.

The cerebrospinal fluid is contained in the ventricles of the brain and in the subarachnoid space of the brain and cord. There are five ventricles, two lateral, and the third, fourth, and fifth. They are intercommunicating. The cerebrospinal fluid in the ventricles of the brain communicates with the fluid in the other ventricles through the various apertures connecting them. The only exception to this is the fifth ventricle which contains very little or no fluid. The fluid in the lateral ventricles flows into the third through the foramina of Monro; the fluid in the third communicates with that in the fourth by means of the aqueduct of Sylvius. The cerebrospinal fluid of the subarachnoid space communicates with the fluid in the ventricles of the brain through the foramen of Magendie which opens into the posterior part, and the two foramina of Luschka which open into the lateral recesses of the fourth ventricle and through numerous other apertures which open into the lateral ventricles. It is denied by some, however, that there is any communication between the cerebrospinal fluid in the ventricles of the brain and the fluid in the subarachnoid spaces of the brain and cord. But the best evidence that a communication exists between the ventricles of the brain and the subarachnoid spaces is the commonly observed fact that in hemorrhage into the ventricles the fluid obtained by lumbar puncture contains blood. It is also known that when a dye is injected into the ventricles, it can be recovered by lumbar puncture in a few minutes; and, vice versa, if the colored fluid is injected into the cisterna magna it can be recovered from the lateral ventricle.

In order to understand the diagnostic features of cerebrospinal fluid, something must be said of the physiology of this fluid. No one has yet determined the rate of formation under normal conditions. Equally uncertain are the data on the rate of absorption of the spinal fluid, but it has been shown that absorption probably occurs through the perivascular lymphatics directly into the blood stream.

The function of the cerebrospinal fluid is mechanical. The fluid forms a water bed around the cord and brain and prevents jarring from external trauma. It also equalizes the pressure between the brain and the cord. It is probable that the chorioid plexus, which is in the ventricles of the brain, is responsible for the secretion of the cerebrospinal fluid, although the evidence brought forward to prove this point is not altogether convincing. There is some evidence pointing to the assumption that the fluid is a direct product of the blood or of the brain tissue.

Method of Obtaining Spinal Fluid by Lumbar Puncture

Cerebrospinal fluid is obtained by lumbar puncture. The puncture is made between the third and fourth lumbar vertebrae. The type of needle used varies with different operators, but a strong needle 18 gauge, 3½ inches long suffices. The needle and stylet, which goes within the needle, are prepared as follows:

Place the needle with a small piece of cork inserted into the point into a test tube with a piece of gauze protruding over the edge of the test tube. Cork securely. Needles prepared this way are placed in the dry heat sterilizer and heated to 170° C. for two hours. They may then be kept indefinitely in these containers and are ready for use whenever required. Boiling is not recommended for the reason that it may not always kill spore-forming bacteria.

The patient is placed on his side on a firm operating table or in a bed. He is directed to draw up both knees and bow the head down so that the presenting vertebral column will have as much curve as possible, thus widening the spaces between the lumbar vertebrae so as to freely admit the spinal puncture needle. The so-called "soft spot" or opening between the vertebrae is found by the finger, and the entire area prepared with iodine followed by alcohol. The table and edges of the operating field are covered with a sterile sheet or towels. The operator with sterile rubber gloves now prepares the skin and subcutaneous tissue by local anesthesia, injecting a few drops of a 1 per cent solution of Novocain at the point selected for the puncture. In order that the spinal puncture may be successfully performed the patient's back must be at a perfect right angle to the plane of the bed or operating table, and the patient must be cautioned not to move from this position. With the finger, one finds the "soft spot" which is readily obtainable by dropping a line perpendicular from the crest of the ilium across the skin. The needle is then quickly inserted in the midline at a right angle to the long axis of the vertebral column and at a right angle to the lateral surface of the skin of the back. If the needle is properly introduced in the midline, it will go through the soft tissues quickly until it reaches the tough spinous ligaments where it meets with a little resistance. One can feel the "jump" of the needle as it leaves the tough tissues and punctures the dura of the spinal canal. The stylet of the needle is then removed, and if the puncture is properly made, fluid will begin to flow at once. If it does not flow, it is possible that the needle is blocked by a small piece of the dura. This can be dislodged by slowly and gently twirling the needle around.

Normal pressure of spinal fluid varies between 70 and 180 mm. of water. Values over 200 mm. are definitely high. Low pressures are found in patients with a subarachnoid block. High pressures are found in meningitis, brain tumor, brain abscess, and intracranial hemorrhage. Pressure is increased in patients with meningism, congestive heart failure, uremia, and aseptic meningeal reaction, also in neurosyphilis, cerebral trauma, and encephalomyelitis.

Under normal conditions, the spinal fluid comes out of the needle drop by drop; if the amount of pressure is very great, it may spurt out. The fluid may be collected in the sterile test tube in which the needle was prepared. It is well to have several other sterile test tubes on hand. The first few drops are received in the first tube and succeeding drops in the second and third tubes.

The presence of blood in the spinal fluid indicates either a traumatic injury above, or is the result of a faulty puncture. Faulty punctures are very common and are due to inexperience or to the use of needles that are too large. It is highly objectionable to contaminate the fluid with blood because this blood vitiates investigation for cytology, globulins, and even for the complement fixation tests. About 10 c.c. of fluid should be withdrawn for all purposes for which the fluid is tested.

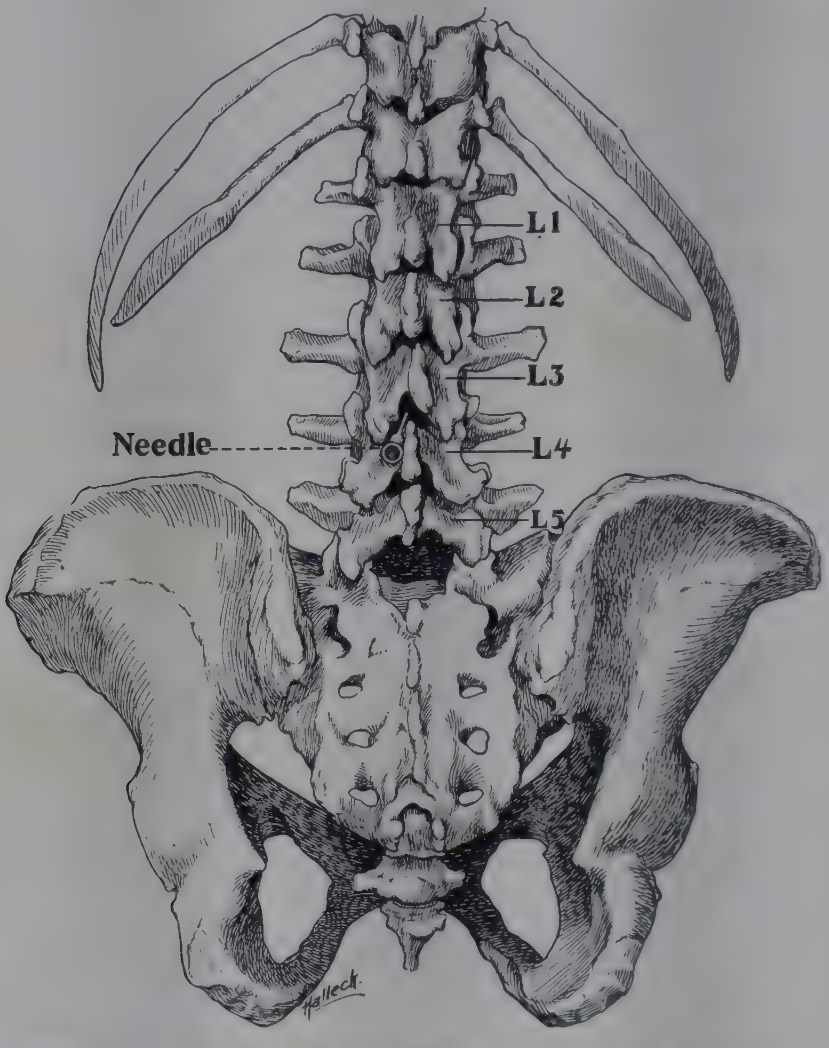

Fig. 300.—Position of the needle in a spinal puncture.

After the puncture, the patient is requested to lie in bed for twenty-four hours.

The reactions which follow spinal puncture vary in different individuals from a slight pain in the back of the neck to a very severe headache. This headache may be very persistent and last for a number of days, or it may disappear within twenty-four hours. There is no conclusive explanation as to the cause of this headache. Caution must be exercised in the practice of the spinal puncture on any patient suspected of having any new growth in the head, because the sudden release of spinal fluid below from a spinal puncture needle is likely to drive the contents of the cerebrum too suddenly against the foramen magnum with serious or even fatal results. In the presence of brain tumors especial care must be exercised in performing a spinal puncture.

The examination of the fluid should take place as soon as possible after withdrawal. It consists of the following tests: the *macroscopic* test; *bacteriologic* tests for tubercle bacilli, the various pus-producing bacteria (pneumococci, influenza bacilli, meningococci) and trypanosomes; *chemical* tests for globulin and sugar; *cytologic* examination for total white count, lymphocytes, and various cells which indicate disease changes; *serologic* examination, or complement fixation and precipitation tests for syphilis; the mastic test; and the Lange *colloidal gold* test. The study of the hydrogen ion concentration, cataphoreses, the Lange colloidal gold test, the ninhydrin reaction, and the precipitation tests, all of which are based on physiochemical principles, have clarified our understanding of the diseases of the central nervous system in general, and on the composition of the spinal fluid in particular.

If acute infections are suspected, complete bacteriologic examinations are necessary.

Characteristics of Cerebrospinal Fluid

Amount.—The amount of fluid normally present in the ventricles and in the subarachnoid space varies according to different authors from 60 to 150 cubic centimeters.

Color.—Normal cerebrospinal fluid is clear and colorless, provided no blood has been removed with it during the puncture. On standing it may become contaminated by bacteria or moulds, in which case it becomes turbid.

A very interesting condition which is called ''xanthochromia'' may sometimes be found. In this condition, the spinal fluid is a clear yellow color with rapid and marked coagulation, large amounts of globulin, and no blood pigments by chemical tests. It is generally the result of compression by a tumor of the cord or vertebrae with interruption to the flow of cerebrospinal fluid and formation of a pocket of greater or less extent in which the fluid stagnates.

Transparency.—Normal spinal fluid is clear. In acute meningitic infections, the fluid may vary from slight cloudiness to almost pure pus. It is absolutely clear in tuberculous meningitis.

Pellicle Formation.—In many acute cases of meningitis a pellicle or a net of fibrin and blood cells forms in the fluid on standing. In suppurative meningitis, the pellicle forms in a very short time; in tuberculous meningitis, it takes from twelve to twenty-four hours to form. Pellicles have been observed in poliomyelitis and in general paresis only rarely. The pellicle is formed by the separation of the heavier elements of the cerebrospinal fluid, so that microscopically one sees in the pellicle many leukocytes on a fibrinous background. Fig. 301 shows the forms of pellicle in various diseases as observed early, before autolysis takes place. There is considerable controversy as to whether or not the pellicle is dependent for its formation upon the presence of fibrinogen. The point has not been definitely established.

Lack of Sediment.—Normal fluid forms no pellicle or sediment. This lack of sediment is helpful in differentiating normal fluid from fluid in cases of meningitis in which a sediment is often present.

Specific Gravity.—The specific gravity varies according to different authors from 1.001 to 1.010.

Reaction.—Reaction of cerebrospinal fluid is alkaline, the alkalinity usually amounting to half that of the blood.

Levinson[1] states that the *hydrogen ion concentration* ranges from pH 7.4 to 7.6.

Total Solids.—Total solids vary between 1.200 and 0.876 gm. per 100 c.c.

Calcium.—Calcium content of the spinal fluid varies from 2.5 (figures of Depisch and Richter-Quittner) to 11.2 (Yvon) mg. of calcium in 100 c.c. cerebrospinal fluid.

Magnesium.—Magnesium content of spinal fluid is greater than that of blood, 3.0 mg. of magnesium to 100 c.c. of blood.

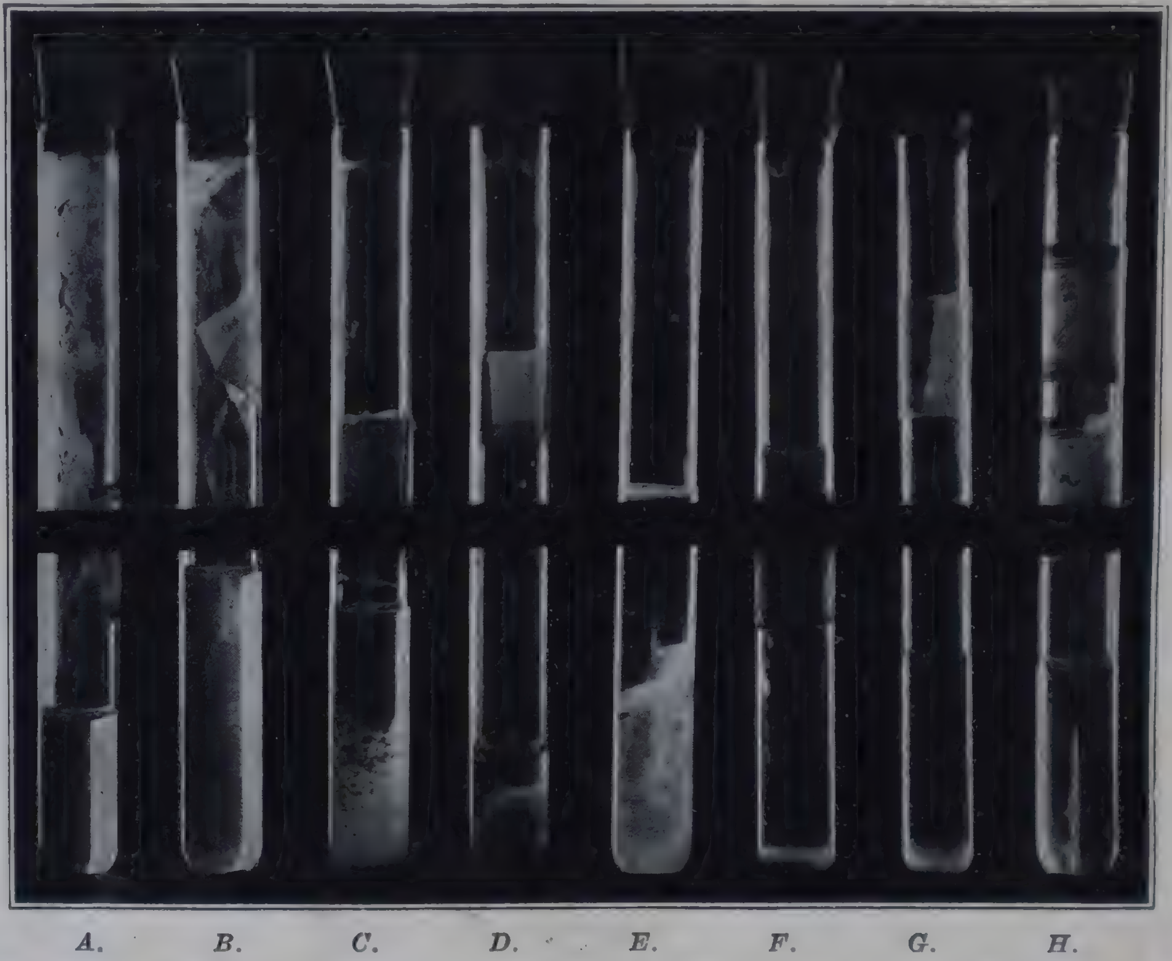

Fig. 301.—Pellicle-formation in meningitis. *A.* Normal. *B.* Meningococcus meningitis, fairly early. *C.* Meningococcus meningitis, advanced (sulphurlike granules). *D.* Meningococcus meningitis, late in disease. *E.* Meningococcus meningitis, severe, on road to recovery. *F.* Pneumococcus meningitis, fatal. *G.* Pneumococcus meningitis, fatal. *H.* Tuberculous meningitis. (From Levinson: Cerebrospinal Fluid in Health and in Disease, ed. 3, St. Louis, 1929, The C. V. Mosby Co.)

Chlorides.—Normal spinal fluid contains more chlorides, expressed as sodium chloride, than does blood plasma. The normal value for adults as NaCl is 720 to 750 mg. for each 100 c.c. of spinal fluid. In children, the normal range is from 625 mg. to 760 mg. per 100 c.c. The chloride content (in terms of Cl) is 390 to 460 mg. per 100 c.c., with a mean value of 450 mg.

The normal milliequivalent per liter is 110 to 130.

In acute meningitis, the amount of chloride may be reduced in adults to 625 mg. per 100 c.c. and to 575 mg. per 100 c.c. in children. In tuberculous meningitis, still smaller amounts are found. High values may be found in conditions in which the value for the plasma chloride is increased.

Cytology of Spinal Fluid

Most writers are of the opinion that the normal cell count in spinal fluid varies from none to two per cubic millimeter. As a rule, we consider anything up to 5 normal.

Type of Cells Found.—The cells of spinal fluid are leukocytes, principally small lymphocytes. The nucleus of the lymphocytes of normal spinal fluid is round or slightly oval, seldom irregular. Large lymphocytes occur very rarely. Polymorphonuclear or segmented leukocytes are usually absent in normal fluids. The origin of the cells in normal spinal fluid has not been fully determined. The cell count should be made as soon after withdrawal as possible. Always shake the tube before diluting the spinal fluid.

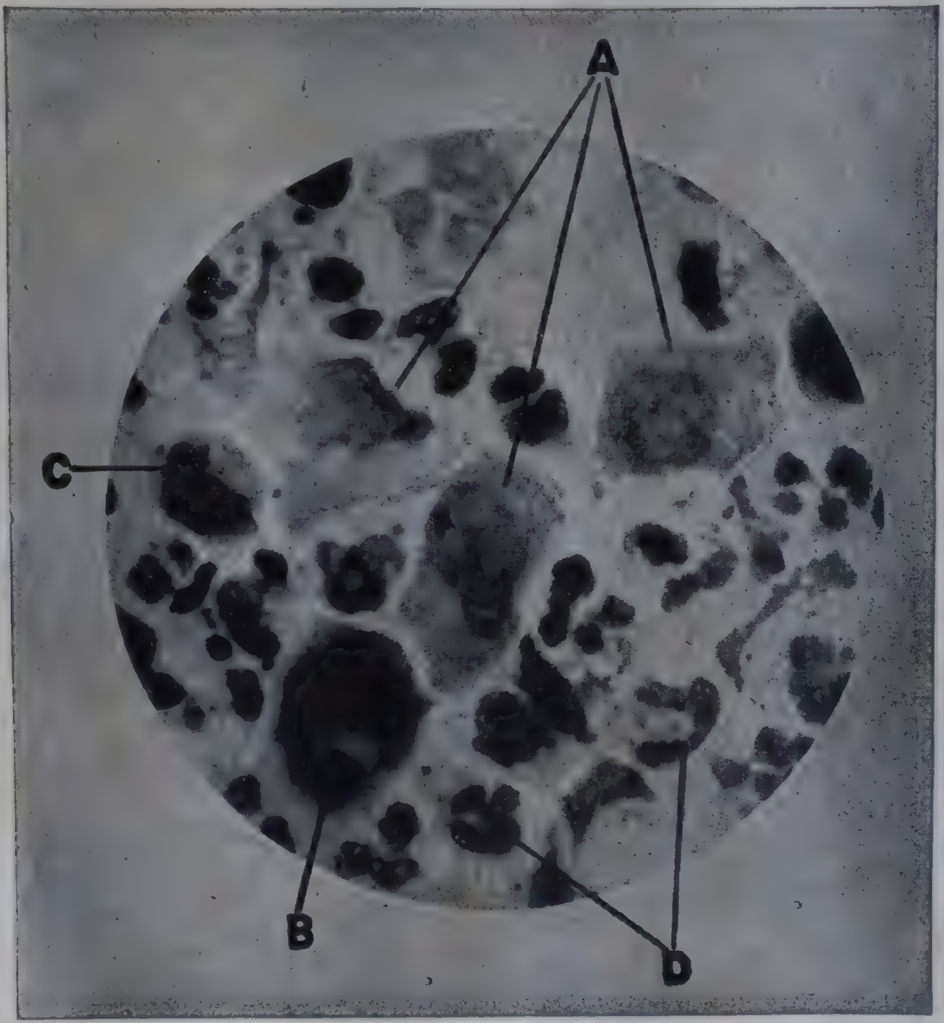

Fig. 302.—Photomicrograph showing types of cells in pathologic cerebrospinal fluid. (× 1,000.) *A*, Desquamated endothelial cells. *B*, Monocyte which has engulfed a polymorphonuclear leukocyte. *C*, Large mononuclear cell. *D*, Polymorphonuclear leukocytes. (From Levinson: Cerebrospinal Fluid in Health and in Disease, ed. 3, St. Louis, 1929, The C. V. Mosby Co.)

Method of Cell Counting in Spinal Fluid

Spinal Fluid Counting Solution (Tuerk's Solution).—

Glacial acetic acid	1 c.c.
Distilled water	99 c.c.

Add a few drops of alcoholic gentian violet to color. Filter several times.

Technic.—(With any counting chamber.)

Diluting the spinal fluid.—Draw the *spinal fluid counting solution* to the 0.5 mark and the *spinal fluid* to mark 11 in a white counting pipette. Mix thoroughly.

Filling the counting chamber.—Blow out two or three drops of the diluted spinal fluid before filling the counting chamber. Place the cover glass over the ruled area.

Allow the diluted spinal fluid to run under the cover glass so that it exactly fills the space between the cover glass and the counting chamber.

Making the count. Focus under the low power dry objective without the Abbé condenser.

Count all the cells in the entire ruled area which represents nine fields.

Divide by 9 and multiply by 10 to obtain the number of cells per cu. mm.

Make similar counts on two more drops of diluted spinal fluid.

Average the three counts for the report.

To correct for the slight dilution of the spinal fluid, divide the final result by 19 and multiply by 20. Do not report a fraction of a cell.

Example.—

1st drop	2d drop	3rd drop
9 | 18	9 | 20.0	9 | 18
2	2.2	2
10	10	10
20	22.	20
22		
20		
3 | 62		
19 | 20.6		

1.08 × 20 = 21.6 or 22 cells per cu. mm. of spinal fluid.

Normal 0 to 5 cells per cu. mm. (see below).

Counting of Spinal Fluid Contaminated by Blood.—The problem of whether or not an accurate cell count can be made of bloody spinal fluid may be answered in the following words—to date no reliable or absolutely accurate method can be recommended for estimation of pleocytosis in the cerebrospinal fluid if the fluid is contaminated by blood. An attempt has been made to do this by staining the fluid lightly with Unna's polychrome methylene blue and calculating all of the red cells and all of the white cells present in one cubic millimeter. Correction for the number of white cells present in the fluid as a result of the blood can then be made on the basis of the red and white blood count in the peripheral vessels. According to Merritt,[1] "while this method is not absolutely accurate there is usually no trouble determining a pleocytosis in the cerebrospinal fluid of twenty-five or more cells."

The author does not care to make a diagnosis of pleocytosis in bloody spinal fluid.

Making the Differential Count of Spinal Fluid.—This count can be made if there is a total blood cell count of over 500 cells per cu.mm. If the cell count is below this, the sediment may be procured by centrifuging the fluid in an open bottom centrifuge tube with a rubber stopper in the bottom. By centrifugalization the cells are thrown down onto the rubber stopper.

Technic of procuring the cells is to discard the supernatant fluid and spread the cells on a glass slide. In either case, whether the direct count or count of this centrifuged specimen is to be made, proceed in exactly the same manner in which a differential count of the leukocytes in blood is made.

As stated above, the normal cell count in the spinal fluid is 0 to 10 cells per cu.mm. in adults. In children under one year of age, 30 cells would be considered normal. From one to four years, 20 cells are found, and from five years to puberty, 10 cells.

---

[1] Merritt, H. Houston: Personal communication.

Increased cell count is due to inflammatory lesion of the brain, spinal cord, or meninges. An increased count is found in cerebral tumors but no relationship can be drawn between the type or location of the tumor and the cell count. An acute process will show an increase in the segmented neutrophiles. This is especially true of pus infections. In chronic infections and toxic conditions, there is usually an increase in lymphocytes. A slight increase, say from 10 to 100, especially of the lymphocytes, occurs in early tuberculous meningitis, neurosyphilis, anterior poliomyelitis, encephalitis lethargica, and multiple sclerosis. As many as 1000 cells, principally lymphocytes, have been found in late tuberculous meningitis, poliomyelitis, and acute syphilitic meningitis. The author recalls a case of paresis many years ago with a cell count of 600. Naturally, over 1000 cells are found in purulent meningitis, influenza meningitis, and brain abscess. There is no increase in cells to any extent in uremic or diabetic coma.

Tests for Protein

These tests are commonly called tests for globulin, but they are really tests for protein since the methods used depend upon the precipitation of both albumin and globulin.

Normal concentration of cerebrospinal protein is between 15 and 40 mg. per 100 c.c. of fluid. In inflammatory conditions of the meninges, the choroid plexus, which is the barrier of the passage of the proteins, breaks down and permits these to enter the spinal fluid. In some other conditions, such as typhoid fever, uremia, and convulsive states, protein fluids are found. The increase in the proteins of the spinal fluid in suppurative diseases of the meninges is due to the accumulation of the protein of the polymorphonuclear leukocytes. In acute suppurative meningitis, protein concentration values may be as much as 1300 mg. per 100 c.c. Tuberculous meningitis shows values between 200 and 1000 mg. In tetanus there is an increase in the protein concentration, and an increase has been noted shortly after epileptic seizures. In such syphilitic diseases as paresis, tabes dorsalis, and other forms of cerebrospinal syphilis, values between 20 and 200 mg. have been reported. In epidemic encephalitis, protein concentrations vary between 50 and 300 mg. per 100 c.c. In cerebral hemorrhage, thrombosis, or embolism, there is an increased protein content. There are increased protein contents in brain abscesses and brain tumors, also in multiple sclerosis. In the disease known as "the Froin syndrome," in which there is complete obstruction of the meninges of the spinal cord, there is a difference noted in the protein concentration above and below the point of obstruction. For instance, a lumbar puncture may show in such a case as much as 1000 mg. per 100 c.c., and fluid taken from a cisternal puncture may show practically normal values. In myxedema, protein varies between 30 and 220 mg. Table 133[1] shows the changes in the pathologic conditions in respect to protein concentrations.

---

TABLE 133.—CEREBROSPINAL FLUID PROTEINS

CONDITION	CHANGES IN SPINAL FLUID PROTEIN TO BE EXPECTED	CONCENTRATIONS OBSERVED (IN MG. PER 100 C.C.)
Normal	0	20-40
Pathological:		
Brain tumor or abscess	+	30-100
*Cerebral hemorrhage	+	20-220
*Cerebral thrombosis	+	20-140
*Cerebrospinal syphilis	+	20-160
Epilepsy	+	20-80
*Epidemic encephalitis	+	50-300
*Froin syndrome	++	100-2100
Meningitis:		
*(a) meningococcic	++	150-750
*(b) pneumococcic	++	180-1300
*(c) streptococcic	++	150-900
*(d) tuberculous	+	50-200†
*Multiple sclerosis	+	
Myxedema	+	30-220
*Paresis	+	30-190
Serous meningitis (from influenza, otitis media, mastoiditis, pneumonia, typhoid fever, uremia, etc.)	0 to +	20-90
Spasmophilia or tetany	+	
*Tabes dorsalis	+	40-200
Tetanus	+	
Uremic convulsions	+	

*Diseases in which the determination may be of clinical value.
†Values as high as 1000 have been reported but such concentrations are rarely found.

The first test described below, the Nonne-Apelt or Ross-Jones test, is a test for globulin, while the Pandy and Noguchi tests are really protein tests.

A. QUALITATIVE TESTS

Nonne-Apelt Method (Ross-Jones)

Reagent.—

Nonne-Apelt (Ross-Jones) Reagent.—Saturated solution of ammonium sulphate, filtered after saturation has been reached.

Technic.—

Place 1 c.c. Nonne-Apelt (Ross-Jones) reagent in a test tube.
Stratify 1 c.c. spinal fluid on the reagent.
A white ring at the point of contact indicates the presence of globulin.
If the spinal fluid contains blood, the test cannot be made.

Pandy Method

Reagent.—

Pandy's Reagent.—

Dissolve 10 gm. of carbolic acid crystals
in 150 c.c. distilled water.
Place in the incubator and shake frequently for several days. Filter. The reagent must not become turbid upon shaking. It may become pink.

Technic.—

Place 1 c.c. Pandy's reagent in a test tube. Add a few drops of spinal fluid. Shake. A turbidity develops if globulin is present.

Noguchi's Method

This test is so delicate that it often detects globulin in normal spinal fluids.

Reagent.—

Butyric acid	10 parts.
0.9% sodium chloride	90 parts.

Technic.—

In a small test tube place 0.5 c.c. of Noguchi's reagent.

Add 0.1 c.c. spinal fluid.

Bring to a boil over a flame.

Add 0.1 c.c. N/1 NaOH.

A flocculent precipitate appears in a few minutes if globulin is present in large quantities. The precipitate may take a few hours to form, if the quantity of globulin is low.

Normal spinal fluids show a slight opacity. Traces of proteins are normally present in spinal fluid. A great increase occurs in acute inflammations, in tuberculous meningitis, and in syphilitic and parasyphilitic affections.

The chief protein is globulin, tests for which are outlined above. Because of the presence of serum globulin in blood, a globulin test is valueless if the spinal fluid is contaminated with blood.

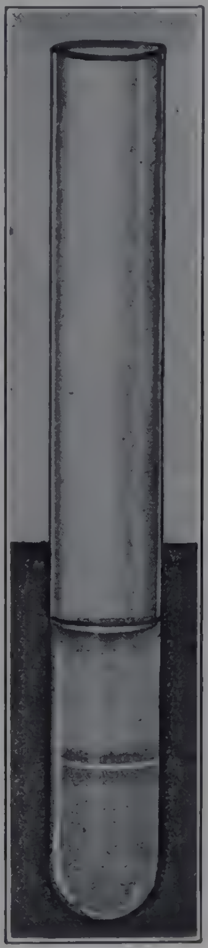

Fig. 303.—Nonne-Apelt test for globulin in spinal fluid, positive reaction.

The Weichbrodt Method

To 0.7 c.c. of spinal fluid in a test tube, add 0.3 c.c. of a 1% solution of bichloride of mercury.

A positive reaction is seen by opalescence or cloudiness.

Alcohol Test

A drop of cerebrospinal fluid is added to a test tube containing 0.5 c.c. of 95% alcohol. A very slight turbidity is normal, but a heavy white cloud or flocculation indicates a high protein content.

B. QUANTITATIVE TESTS

Method I

Technic.—

Measure 2 c.c. of spinal fluid into a 15 c.c. centrifuge tube, and add 3 c.c. water and 1 c.c. 20% trichloroacetic acid. Centrifuge out the protein precipitate, and pour off the supernatant fluid. Dissolve the precipitate in 0.25 c.c. of 10% sodium hydroxide and heat one-half hour in a water-bath. Then add 3.75 c.c. water, 0.5 c.c. Folin phenol reagent (page 305), and 1.5 c.c. saturated sodium carbonate solution. Mix by inversion, and read in a half hour in a colorimeter, setting the standard at 10 mm.

Standard.—Two standards should be made, one containing 1 c.c. 20 mg. % tyrosine and 7 c.c. water, and the other 2 c.c. standard and 6 c.c. water. Then add 1 c.c. phenol reagent and 3 c.c. saturated sodium carbonate solution to each tube.

Calculation.—

Standard 1

$$\frac{10}{B} \times \frac{0.2}{2.0} \times \frac{100}{2.0} \times 13.0 = \text{mg. protein per 100 c.c.}$$

$$\text{or} \quad \frac{650}{B} = \text{mg. protein.}$$

Standard 2

$$\frac{10}{B} \times \frac{0.4}{2.0} \times \frac{100}{2.0} \times 13.0 = \text{mg. protein per 100 c.c.}$$

$$\text{or} \quad \frac{1300}{B} = \text{mg. protein.}$$

Method II

Reagents.—

Standard Protein Solution.—Dilute 20 c.c. of normal human blood serum to 200 c.c. with a 15% solution of sodium chloride.

Filter.

Estimate total nitrogen of this filtrate by macro-Kjeldahl method, using 40 c.c.

Estimate nonprotein nitrogen in the original undiluted serum by the micro-Kjeldahl method of Folin. Divide this figure by 10 and subtract from the total nitrogen to obtain the protein nitrogen content of the concentrated standard solution. The protein nitrogen multiplied by 6.25 gives the protein content of the concentrated standard solution. Dilute concentrated standard solution with sufficient distilled water to make a dilute standard solution containing 30 mg. of protein per 100 c.c. Add thymol crystals and keep in refrigerator.

Sulphosalicylic Acid.—Dissolve 5 grams of sulphosalicylic acid, Merck, in 100 c.c. distilled water.

It has been recommended by Irvine[1] that this estimation can be carried out very conveniently by using small detachable cups and plungers in the Duboscq colorimeter or any other standard colorimeter. In other words, these attachments consist of a pair of all-glass cups of 1 c.c. capacity, solid glass plungers with a threaded adaptor, and holders for 1 c.c. cups. These parts are easily interchangeable with the standard ones. A special diaphragm with a smaller opening is used in the eyepiece.

Technic.—

This method has been described by Ayer, Dailey, and Fremont-Smith.[2] This is a modification of the method previously described by Denis and Ayer.[3]

Place 0.6 c.c. of cerebrospinal fluid in a test tube.

Add 0.4 c.c. of distilled water.

Add 1 c.c. of a 5% solution of sulphosalicylic acid.

Mix by inversion.

Let stand five minutes.

Read the turbidity in the colorimeter against that produced by a standard protein suspension prepared at the same time as the unknown.

---

[1] Irvine, M. D.: The Cerebrospinal Fluid. Merritt and Fremont-Smith, p. 259. W. B. Saunders Company, 1937, Philadelphia.

[2] Ayer, J. B., Dailey, M. E., and Fremont-Smith, F.: Arch. Neurol. & Psychiat. 26: 1083, 1931.

[3] Denis, W., and Ayer, J. B.: Arch. Int. Med. 26: 436, 1920.

Preparation of the standard protein suspension:

Mix 3 c.c. of the dilute standard solution containing 30 mg. of protein per 100 c.c. and 3 c.c. of a 5% solution of sulphosalicylic acid.

Calculation:

$$\frac{\text{Standard}}{\text{Unknown}} \times \frac{30 \text{ (number of mg. in 100 c.c. of standard)}}{\text{c.c. of spinal fluid used}} = \text{mg. protein per 100 c.c.}$$

Method III

Kingsbury, Clark, Williams, and Post described a method for the quantitative determination of albumin in urine. The method is very satisfactory for the quantitative determination of total protein in the spinal fluid.

Equipment.—

The equipment consists of a set of standard tubes filled with clear gelatin mixed with varying amounts of Formalin, which represents the turbidity produced by mixing a 3% solution of sulphosalicylic acid with known amounts of protein in serum. The standards keep for some years, although they should be checked from time to time for accuracy. They may be prepared according to the method which has been described by the originators of the method (see page 148).

Reagent.—

3% Sulphosalicylic Acid.—3 gm. in 100 c.c. of distilled water.

Technic.—

Place 1 c.c. of spinal fluid in a tube measuring ½ by 4 inches.

Add 3 c.c. of the reagent and mix thoroughly.

Allow the mixture to stand 5 minutes and compare the degree of turbidity with that of the permanent standard tubes.

The **normal amount of protein** in spinal fluid is usually about 30 mg. per 100 c.c.

Quantitative Test for Chlorides

Method of Osterberg and Schmidt

Reagents.—

Silver Nitrate Solution.—

(1 c.c. is equivalent to 1 mg. of chlorine.)

Dissolve 4.791 gm. of chemically pure silver nitrate in distilled water, and dilute to 1 liter in a volumetric flask.

Preserve in a brown bottle.

Potassium Thiocyanate Solution.—

Dissolve about 3 gm. of potassium thiocyanate in 1 liter of distilled water. Standardize against the silver nitrate solution so that 5 c.c. exactly equal 5 c.c. of the silver nitrate solution. Refer to page 434.

20% Ferric Ammonium Sulphate Solution.—

Dissolve 20 gm. ferric ammonium sulphate in distilled water and dilute to 100 c.c. with distilled water.

Dilute Nitric Acid Solution.—

Add 1 part of concentrated nitric acid, c.p., to 3 parts of distilled water.

Technic.—

Place 1 c.c. of spinal fluid in a 125 c.c. Erlenmeyer flask.

Add slowly 10 c.c. of dilute nitric acid from a burette, agitating the flask to form a white, flocculent preipitate.

Add 5 c.c. of silver nitrate solution and 1 c.c. of 20% ferric ammonium sulphate.

Titrate the excess of silver nitrate with the solution of potassium thiocyanate.

Calculation.—

5 − c.c. of potassium thiocyanate used × 100 = mg. of chlorine per 100 c.c.

To obtain the mg. of sodium chloride per 100 c.c. of spinal fluid, multiply by 1.65.

To change to meq./L., consult page 28.

Normal.—See page 1242.

Mastic Test (Cutting)

The mastic test has been proposed as a substitute for the gold test, but it is not as useful a test in the differentiation of the various types of syphilitic diseases of the nervous system. Complete precipitation of the mastic corresponds to complete decolorization of the colloidal gold reagent; while partial precipitation of the mastic corresponds roughly to the purple or blue of the colloidal gold test. The method used by Cutting follows:

Reagents.—

Mastic Solution.—

Gum mastic, U.S.P.	0.20 gm.
Absolute alcohol	20.0 c.c.
Freshly distilled water	80.0 c.c.

Dissolve the gum mastic in the absolute alcohol and centrifuge to clear.

Pour the filtrate rapidly into the distilled water and mix well.

Alkaline Saline Solution.—

Potassium carbonate, reagent grade	5.0 *mg.* (0.005 gm.)
Sodium chloride	1.25 gm.
Distilled water	100.0 c.c.

Dissolve the salts in the water.

Technic.—

Arrange a series of six small test tubes. In the first, place 1.5 c.c. of the alkaline-saline solution and in each of the others place 1 c.c. To the first tube add 0.5 c.c. of the spinal fluid, which must be completely free from blood. Mix by sucking the fluid up into the pipette and expelling it, and transfer 1 c.c. to the second tube. Again, mix and transfer 1 c.c. to the third tube and continue down to the fifth tube, discarding the 1 c.c. portion which is removed from this, and leaving the sixth tube with alkaline-saline solution alone to serve as a control. Finally add 1 c.c. of the mastic solution to each tube. Mix well and set aside at room temperature for twelve to twenty-four hours, or in the incubator for six to twelve hours. Tubes in which the reaction is complete will show a heavy precipitate with clear supernatant fluid.

Interpretation.—As stated before, this reaction is read as we read the Lange colloidal gold test reaction. If there is no precipitation of the colloidal suspension in any of the tubes, this is a negative reaction. Any precipitation is considered a positive reaction and the characteristics of the precipitation in the various tubes determine the interpretation of the localization of the syphilitic process; e.g., most precipitation in the first tubes is read as paretic zone; precipitation in the center tubes as luetic zone; and in the last tubes as meningitic zone.

Sugar Estimation in Spinal Fluid

It is generally believed that the sugar values in spinal fluid vary between 45 and 85 mg. per 100 c.c. Estimation of the amount of sugar in spinal fluid is important because a low sugar content is diagnostic of certain conditions.

For instance, there is a low sugar content in acute and subacute meningitis due to the glycolytic action of the organisms present. It also has been noted that there is a low sugar content in cerebrospinal fluid containing blood. This is due to the action of glycolytic ferments which are present in the blood, which serve to reduce the normal sugar content of the fluid. A low sugar content has been seen in cases of so-called aseptic meningeal reaction due to the glycolytic action of cells in vivo.

Technic.—

One may use the same method described elsewhere in this book by Folin and Wu for glucose determination in blood.

Reagents.—

Five Per Cent Sodium Tungstate Solution.

One-Third Normal Sulphuric Acid Solution.

Standard Sugar Solution, No. I.—See page 231.

Alkaline Copper Solution.—See page 230.

Phosphomolybdate Solution.—Place 35 gm. of ammonia-free molybdic acid, 5 gm. sodium tungstate, 200 c.c. of 10 per cent sodium hydroxide solution, 75 c.c. water in a Pyrex beaker. Boil vigorously until the fumes coming off fail to turn red litmus blue. Cool. Add 125 c.c. of concentrated (85 per cent) phosphoric acid. Dilute to 500 c.c. Be sure that any glassware used in making this solution, which has been previously contaminated with copper, is washed with nitric acid and rinsed thoroughly with water before being used.

Technic.—

Place 2 c.c. of the protein-free filtrate in a Rothberg-Evans sugar tube.

Place 2 c.c. standard solution in a similar tube.

To each tube add 2 c.c. of alkaline copper solution.

Boil for 8 minutes in usual way.

Place in cold water bath.

Add 2 c.c. of phosphomolybdate solution at once.

Cool.

Dilute the standard to 25 c.c. and the unknown to match it.

In cases where the sugar content is very low, one may make the standard dilution up to 50 c.c.

Read in a colorimeter. Set the standard at 20 and read the unknown.

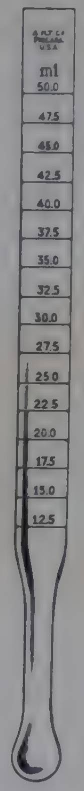

Fig. 304.—Rothberg-Evans tube.

Calculation.—

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \frac{\text{Dilution of unknown}}{\text{Dilution of standard}} \times 10 \times 10 = \text{mg. glucose per 100}$$

c.c. cerebrospinal fluid.

Be sure to make the sugar determination as soon as possible after the spinal fluid has been removed.

Lange Colloidal Gold Test

The method which is recommended for the preparation of Lange's colloidal gold solution is that suggested by Levine.[1] He had previously[2] described a method for this preparation using gold chloride, potassium carbonate, and formaldehyde. At that time, he suggested the use of triply distilled water and a block-tin or resistant-glass distilling assembly. In 1934, Borowskaja[3] found that sodium citrate could be used in the preparation of gold sol instead of the potassium carbonate and the formaldehyde. She found, further, that sodium citrate stabilized the reaction sufficiently so that once-distilled water could be employed with safety. Levine made a study of Borowskaja's reaction and found that the time which it took for the reaction to reach its completion varied in duration from five to thirty minutes and occasionally even longer, and that the sensitivity of the final sol to precipitation by positive spinal fluids varied accordingly. But he found that by the addition of a few drops of a fresh solution of 3 per cent hydrogen peroxide instead of bubbling air or oxygen through the hot water, the reaction began immediately and reached completion within a few seconds. The method which is here advocated is that originated by Levine.

---

[2] Levine, B. S.: Am. J. Syph. 16: 103, 1932.

[3] Borowskaja, D. P.: Ztschr. f. Immunitätsforsch. u. exper. Therap. 82: 178, 1934.

Glassware should be chemically cleaned. While it is recommended that once-distilled water be adjusted to pH 7.2 to 7.4, this is not essential.

Technic.—

To prepare 500 c.c. of gold sol the following formula is recommended:

Distilled water	460 c.c.
Gold chloride (1% solution)	5 c.c.
Sodium citrate (1% solution)	25 c.c.
Hydrogen peroxide (fresh 3% solution), 3 to 5 drops, diluted in 10 c.c. of distilled water.	

Heat the distilled water to brisk boiling.
Remove from the hot plate.
Add the 5 c.c. of the 1 per cent gold chloride solution.
Shake for a few seconds.
Add the 25 c.c. of the 1 per cent sodium citrate solution.
Shake for 10 or 15 seconds.

While shaking, add the 10 c.c. of distilled water which contains the five drops of hydrogen peroxide. Continue shaking for a few seconds. Let the flask rest on the table until the reaction is completed. This usually takes from one-half to one minute.

The advantages of this method are resident in the fact that, first, it is not necessary to use triply distilled water; second, that the reaction of the water does not have to be adjusted; third, this method can be used to make as little as 100 c.c., can be made with the same ease and with as high a degree of reliability as larger volumes. In Levine's experience, however, the reaction proceeds in a more regular manner in large volume manufacture, say, 500 or 1000 c.c.

Note: The prepared solution ordinarily requires no special treatment for neutrality. It is advisable, however, to test it with known normal and known paretic spinal fluids. It must give no reactions beyond the red-blue color with a known normal spinal fluid, and a typical paretic zone curve with the known paretic spinal fluid. The neutrality of the colloidal gold solution must be controlled; this may be carried out with alizarine red. Place 10 c.c. of the colloidal gold fluid in a clean flask, add one or two drops of a 1% solution of alizarine red in 50% alcohol. Titrate with N/50 sodium hydroxide until neutral. With this solution of alizarine, acid reaction shows lemon yellow; neutral, brown red; alkaline, reddish purple. After estimating the quantity of acid or alkali necessary to neutralize the 10 c.c. sample, add enough of one or the other to neutralize the entire amount of colloidal gold reagent that has been prepared.

A special set of glassware should be kept for the making of the reagent and the test. This glassware should be chemically cleaned, and care should be exercised in preventing contamination of the spinal fluid with dyes or chemicals before it is tested. Glassware should also be cleaned in 50% **aqua regia** (3 parts HCl, 1 part HNO_3, 4 parts water) to remove precipitated gold.

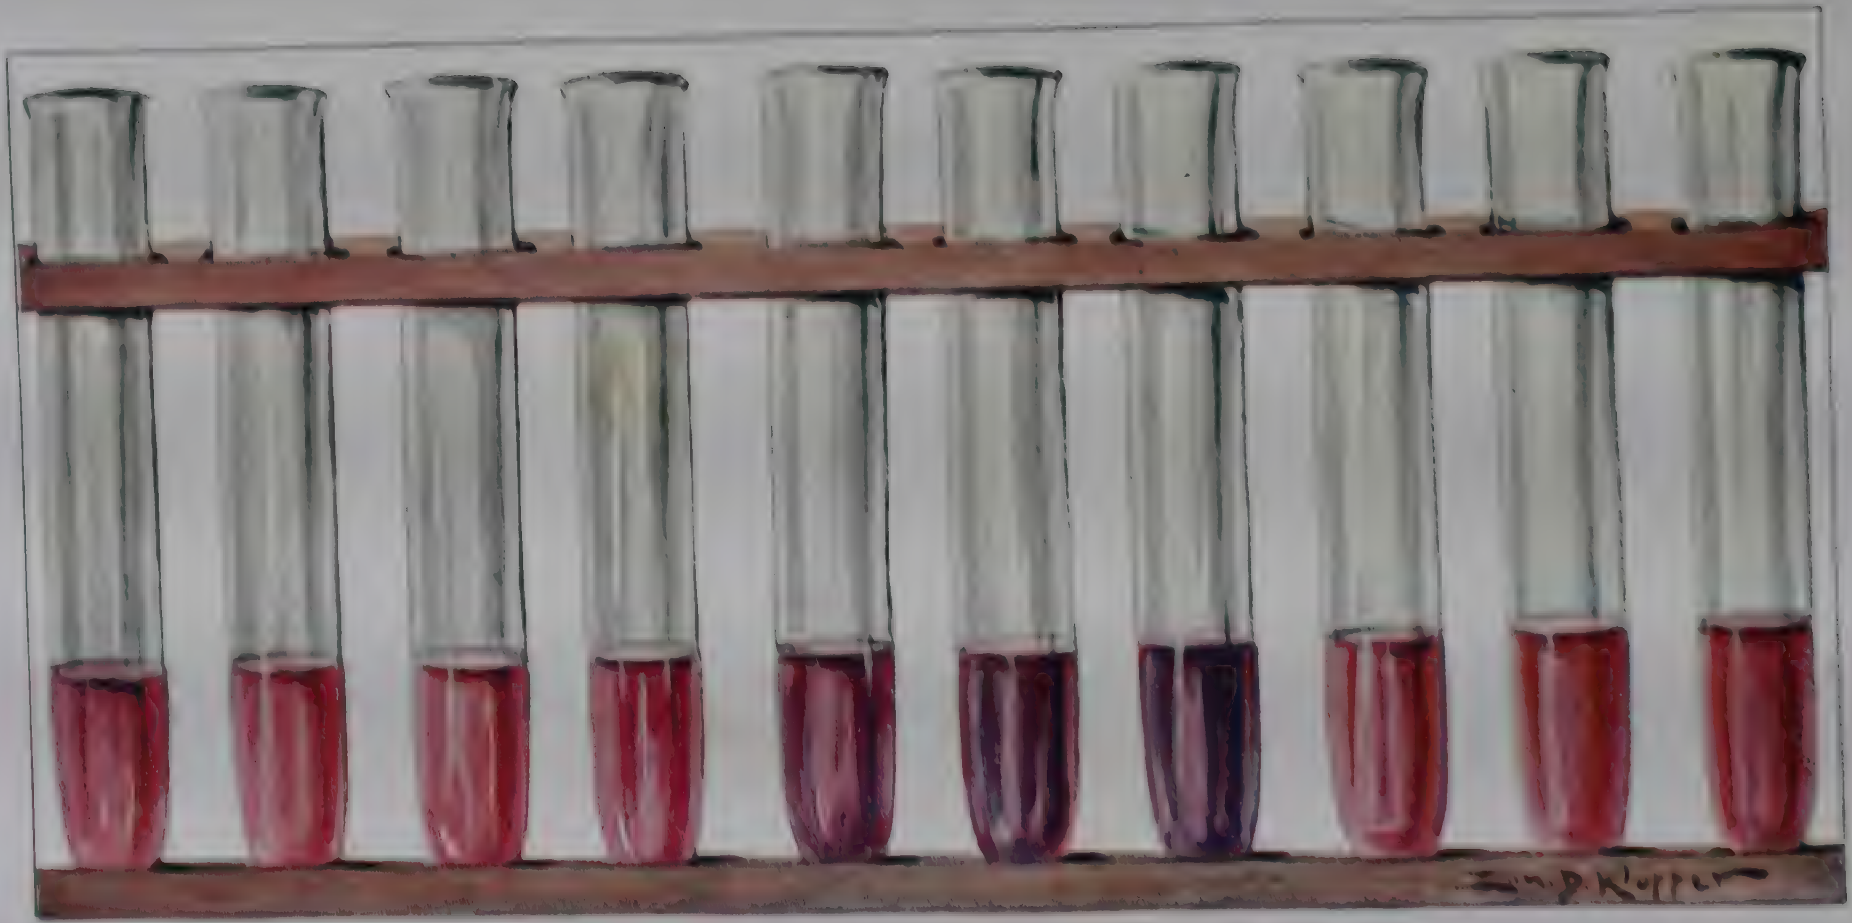

PLATE XXXIII. COLLOIDAL GOLD REACTION IN A CASE OF TUBERCULOUS MENINGITIS.
(From Levinson: Cerebrospinal Fluid, The C. V. Mosby Co.)

Glassware.—

1—1000 c.c. Pyrex beaker, free from scratches.
1—1000 c.c. cylinder graduated in 10 c.c.
1—1000 c.c. brown glass-stoppered bottle for storing the reagent.
1—100 c.c. cylinder graduated in 1 c.c.
1—25 c.c. volumetric pipette.
1—10 c.c. pipette, graduated in 0.1 c.c.
2—1 c.c. pipettes, graduated in 0.01 c.c.
2—5 c.c. volumetric pipettes.
Several test tubes, kept especially for use in testing the reagent.
Eleven test tubes for the actual test, 1 cm. in diameter, and 10 cm. long.

Technic of the Test.—

Test tubes, 1 cm. in diameter and 10 cm. long, the same size as Wassermann test tubes, are needed for the test. In addition, two 1 c.c. pipettes, graduated in 0.1 c.c., and one 5 c.c. volumetric pipette are required.

Physiologic saline is diluted to double volume for the test, as a 0.4% sodium chloride solution is used.

Place the 11 test tubes in a Wassermann test tube rack.

Leave one space between the tenth and the eleventh tube. Tube 11 is a control over the glassware and the reagent. It receives no spinal fluid.

Place 1.8 c.c. of 0.4% sodium chloride solution in Tube 1 and 1.0 c.c. in each of the remaining tubes, including Tube 11.

Add 0.2 c.c. spinal fluid, free from blood cells, to Tube 1.

Mix by drawing in and out of the pipette many times.

Withdraw 1 c.c. of the mixture in Tube 1, and place in Tube 2. Mix the contents of Tube 2 in the same manner, withdraw 1 c.c. and place in Tube 3. Mix the contents of this tube; withdraw 1 c.c.; place in Tube 4. Continue in this manner through Tube 10.

After mixing the contents of Tube 10, withdraw 1 c.c. of the mixture and discard. Tube 11 receives no spinal fluid.

Place 5 c.c. Lange colloidal gold in each of the 11 tubes.

Mix thoroughly and allow to stand at room temperature for 24 hours. Record the results according to the charts on page 1254 or record the numbers represented by the color changes in each tube according to the charts on page 1254.

The color scale, with corresponding numbers, is as follows:

5	colorless
4	pale blue
3	blue
2	lilac or violet or purple
1	red blue or very slight change
0	red, no change in the color of the reagent

The **principle** upon which this test is based is as follows: if a cerebrospinal fluid is diluted in geometrical progression with a weak neutral electrolyte and five volumes of clinical colloidal gold are added to each successive solution, a series of precipitation colors may be obtained which when ascribed numerical values from 0 to 5, and the values plotted as ordinates against the dilutions as abscissae, will give a curve whose contour is characteristic for certain of the infectious diseases of the central nervous system.

The recording of the color values or ordinates is then plotted on coordinated paper against the dilutions or abscissae. Multiply the abscissae values by some convenient factor to elongate the curve formed by connecting the points in a continuous line. A convenient factor is 5/3.

The color of the colloidal gold is red. No change in the color of the reagent is, therefore, red, or ''0'' on the color scale. Complete precipitation of the gold is accompanied by a change in color of the reagent from red to colorless, the color changes between red and colorless depending on the amount of precipitation.

Interpretation of Results

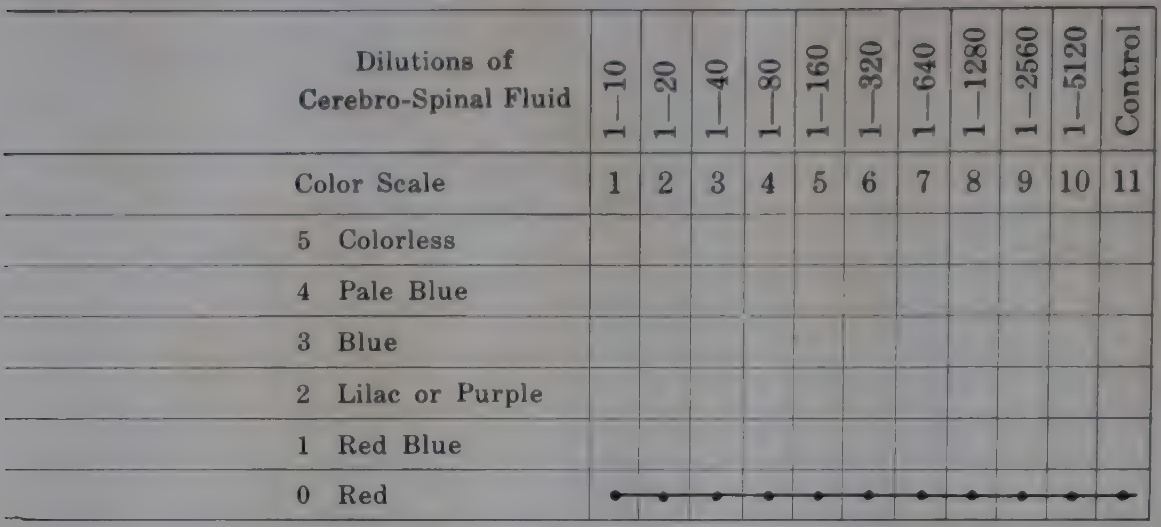

Chart I.—Normal curve 0000000000.

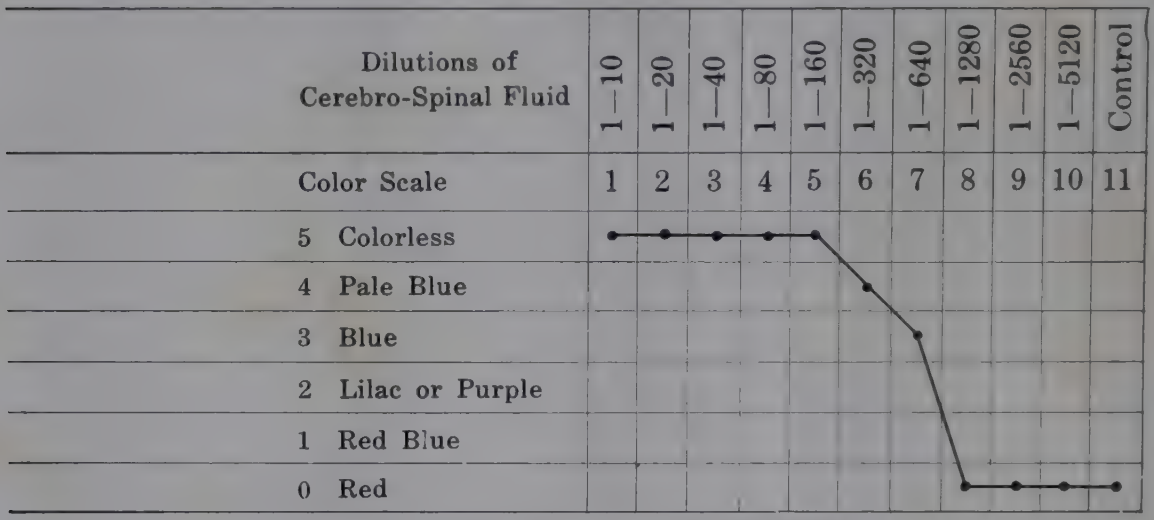

Chart II.—First-zone curve 5555543000.

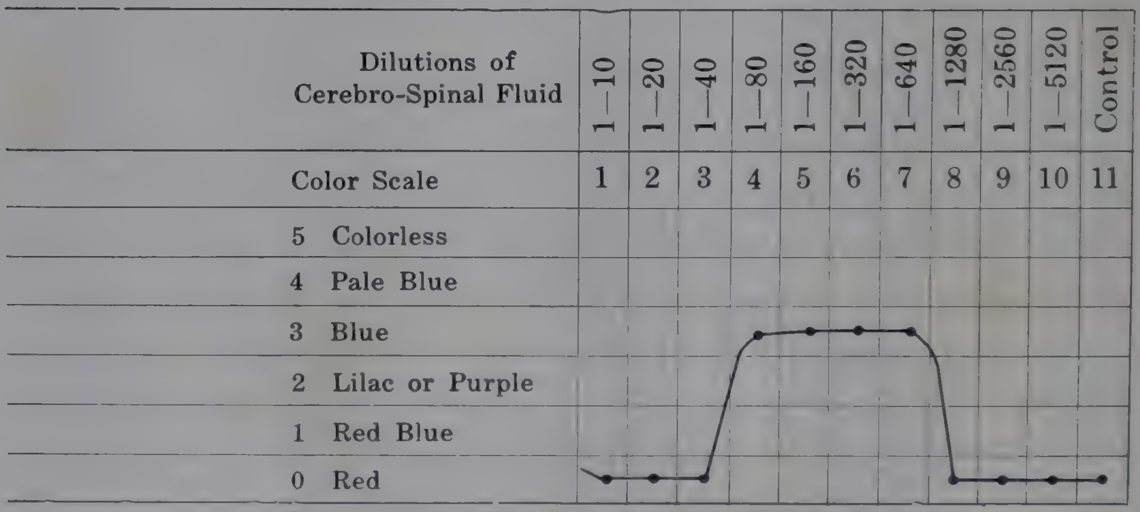

Chart III.—Mid-zone curve 0003333000.

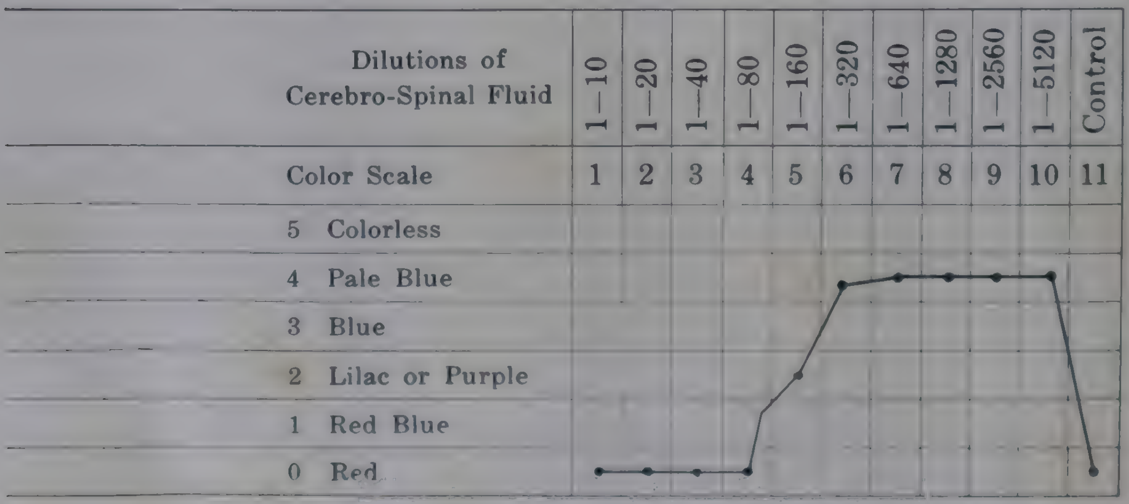

Chart IV.—End-zone curve 0000244440.

Interpretation of the Lange Colloidal Gold Reaction

It has been generally believed, ever since Lange brought out this reaction in 1912, that it is diagnostic of syphilis of the nervous system and particularly that various types of neurosyphilis could be distinguished by changes in this reaction. The weight of opinion at the present time, however, is to discard the terms "paretic," "cerebrospinal luetic," and "meningitic curves" and replace them by terms which indicate the tubes in which the greatest precipitation of the colloidal suspension occurs—"first-zone," "mid-zone," and "end-zone." This test indicates an abnormality in the protein content of the cerebrospinal fluid and does not necessarily have any particular diagnostic value. Kafka[1] and others have shown that the changes produced in colloidal suspensions of spinal fluids are related to the albumin-globulin ratio and to the total protein content of the fluid. In other words, the globulin fraction of the protein of the cerebrospinal fluid is most active in the precipitation of the colloidal suspension, while the albumin fraction has a protective action; this protective action depends not only on the albumin-globulin ratio but also on the total amount of protein in the fluid. A fluid with a high protein content and a high albumin-globulin ratio would produce no change in the colloidal suspension, but dilutions of it would cause a precipitation.

A normal curve results in no change of the colloidal gold suspension except possibly a slight change to lilac.

The "first-zone" curve is seen in the cases of paresis but is not necessarily diagnostic of this condition because it has been seen in multiple sclerosis and other conditions. (See illustration curves, page 1254.)

The "mid-zone curve" (see illustration, page 1254) may be found in any abnormal fluid and cannot be used as a specific indication of any particular type of cerebrospinal syphilis.

The "end-zone" curve (see page 1254) was formerly called the "meningitic curve," but really means a fluid with a very high protein content with an especially high albumin-globulin ratio. It is naturally found in cases of acute purulent meningitis, subarachnoid block, and extravasation of blood in the subarachnoid space.

It is perfectly reasonable, therefore, to find changes in the colloidal gold test without any other signs of syphilis in the nervous system. Too much emphasis has been laid in the past on the specific value of this test alone as a differential diagnostic measure in cerebrospinal syphilis.

Precautions With the Lange Colloidal Gold Reaction.—It must be remembered that the colloidal gold solution contains only 1 part of gold in 20,000 parts of water, and therefore the presence of even a minute trace of contaminant may have a disastrous effect on the proper precipitation color. It was shown by Zsigmondy[2] that when 0.5 c.c. of a 10% solution of sodium chloride is added to 5 c.c. of a gold solution containing 0.25 mg. of gold, more than 0.0025 to 0.005 mg. of gelatin or 0.003 to 0.02 mg. of alkali albumin[3] will prevent the change from red to violet.

Probably all the errors made in connection with this test are due either to inadvertent protection of the gold solution before or after use, or inadvertent precipitation afterward. One must be sure to prevent the intrusion of even traces of foreign disturbing substances into these solutions. The spinal fluid must be received into specially prepared test tubes which contain no traces of gelatin or albumin. Using the salt solution in this test, it is advisable to pour out the quantity which is going to be used from the stock bottle into a separate clean container, so that repeated insertion of the same pipette or different pipettes into the stock bottle can be avoided. The same precaution should be followed with the colloidal gold solution; namely, pour out about 60 c.c. of this material from the stock bottle and reject the surplus.

Attention must be called to the fact that the smallest amount of saliva flowing into the pipette and touching the gold solution will inhibit normal precipitation of the colloidal gold solution. It has been found, too, that the soluble sizing from toweling used to dry a beaker has pronounced protective powers.

In order to check the gold solution and the salt solution, the addition of 0.4 c.c. of a 1% salt solution to 5 c.c. of the gold solution should produce no precipitation after standing at room temperature eighteen hours, while the addition of 1.7 c.c. should produce complete precipitation of the gold in the same period of time. The addition of 1 c.c. of a 1% solution of sodium chloride to 5 c.c. of the gold solution should produce, upon standing overnight, a color change adjudged to be midway between a "1" and a "2" reading. The ultimate test, of course, is to use the spinal fluid from a known paretic, which will give the typical curve of the paretic zone. If the gold solution should exhibit evidence of protection, a fresh 0.4% salt solution must be prepared with which the gold solution must again be tested. If the same results are obtained, it is probable that the gold solution has become protected through contamination; if an improved result is obtained, contamination of the original salt solution by a protectant is indicated; on the other hand, if an undue tendency for the gold solution to precipitate is found, and an improvement is then noted with the fresh salt solution, the presence of a precipitant in the original salt solution may be inferred.

The Test of Spinal Fluid for Syphilis

See discussion in Chapter XIII, Serology.

Bacteriologic Examination of Spinal Fluid

Spinal fluid is examined for the presence of tubercle bacilli, meningococci, various pus-producing organisms, influenza bacilli, and trypanosomes, viruses, etc. Refer to page 1601.

Examination of Spinal Fluid for Tubercle Bacilli

(See page 1602 for further information.)

According to many writers, the spinal fluid in tuberculous meningitis is clear, is under increased pressure, has a high cell count with lymphocytes predominating, shows decreased sugar and chlorides; it contains increased globulin; and one should be able to demonstrate tubercle bacilli by the special method which will be later described. Levinson contends that different kinds of protein in the spinal fluid distinguish tuberculous from "suppurative" meningitis. He uses a chemical test to differentiate meningitis due to the tubercle bacillus from other types of meningitis. In "suppurative" (nontuberculous) meningitis sulphosalicylic acid gives a precipitate three times as great as mercuric chloride. According to Levinson's experiences, in tuberculous meningitis the bichloride precipitate is supposed to exceed that of the sulphosalicylic acid.

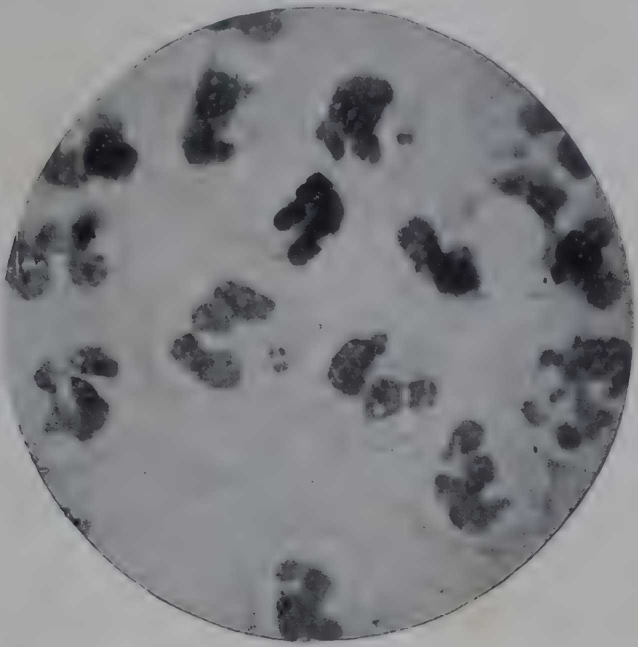

Fig. 305.—Photomicrograph showing direct smear from cerebrospinal fluid of case of meningococcus meningitis.

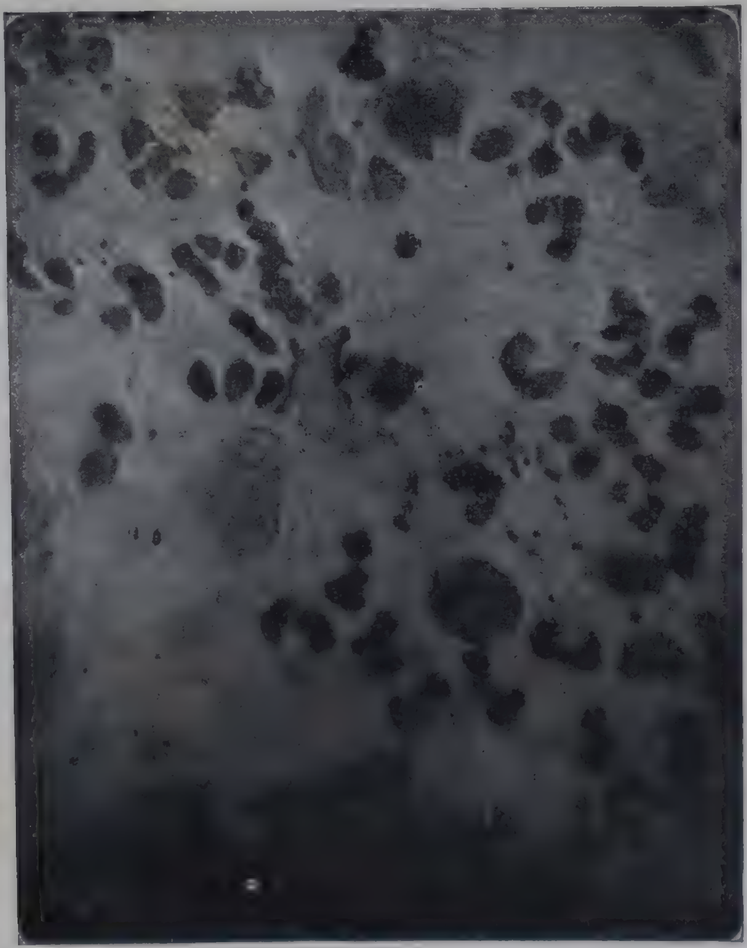

Fig. 306.—Direct smear of cerebrospinal fluid from another case of meningococcus meningitis. (From Levinson: Cerebrospinal Fluid in Health and in Disease, ed. 3, St. Louis, 1929, The C. V. Mosby Co.)

Some writers contend that the cells in spinal fluid of tuberculous meningitis are neutrophilic. Very few of the textbooks agree with Sahli[1] that the spinal fluid in unmixed tuberculous meningitis may be cloudy or turbid and contain an excess of neutrophiles. Traut[2] found in 113 proved cases of this condition, the spinal fluid was cloudy in 10% and neutrophiles constituted more than 50% of the cells in 10% of the cases.

In 17 of these cases, tubercle bacilli were isolated from the spinal fluid; the cases were also proved by autopsy. In 35 cases the diagnosis was made from the presence of tubercle bacilli in the spinal fluid. In 66 cases the diagnosis was confirmed by culturing tubercle bacilli from the spinal fluid on Herrold's medium,[3] and later by autopsy. In one case the tubercle bacilli were seen microscopically and cultured on Herrold's medium. In five cases the tubercle bacilli were seen and produced tuberculosis in guinea pigs. In three cases a positive guinea pig inoculation was the only proof. In one case tubercle bacilli were found only on guinea pig inoculation. This patient later showed tuberculous meningitis at autopsy. In all, autopsies were obtained in 76 cases. The records of 111 patients were obtained from the Cook County Hospital and the Presbyterian Hospital of Chicago. Two patients were in the West Suburban Hospital.

It is obvious, therefore, that one cannot expect to find clear spinal fluid in all cases of tuberculous meningitis, nor can one expect to find predominance of lymphocytes in all cases.

The examination of spinal fluid for tubercle bacilli is carried out as follows:

About 15 or 20 c.c. of spinal fluid should be withdrawn.

Direct Method.—

(1) Place 5 or 10 c.c. spinal fluid in a test tube. Centrifuge at high speed for ten minutes. Decant the supernatant fluid and discard. Smear the sediment on slides in egg albumen or serum. Allow to dry. Fix in the flame. Stain with Ziehl-Neelsen stain. Examine for tubercle bacilli.

(2) Incubate the spinal fluid for thirty minutes at 37° C. Fibrin threads will develop. Pick out the fibrin threads with a platinum loop, or centrifuge the specimen. Mount on slides in egg albumen or serum. Fix in the flame. Stain with the Ziehl-Neelsen stain. Examine for tubercle bacilli.

Cooke's Method.—

J. V. Cooke, of the Department of Pediatrics, Washington University School of Medicine and St. Louis Children's Hospital, has still a different method for demonstrating tubercle bacilli in spinal fluid. It is true that it is difficult to demonstrate tubercle bacilli because they are often present in very small numbers. It is probable that the thin fibrinous pellicle or clot which forms in these fluids enmeshes the bacteria and that stained specimens of this pellicle offer the best chance of finding the organisms. Cooke has found that the method he described facilitates the transfer of the fibrinous pellicle to the slide with a minimum of handling and distortion and has consequently helped to demonstrate tubercle bacilli. The test tube containing the spinal fluid with the pellicle is shaken gently to detach it from the sides or bottom of the tube, and the entire contents of the tube are poured on the surface of a clean glass plate, about 3 by 6 to 8 inches. Such plates may be made from discarded x-ray plates from which the emulsion has been removed.

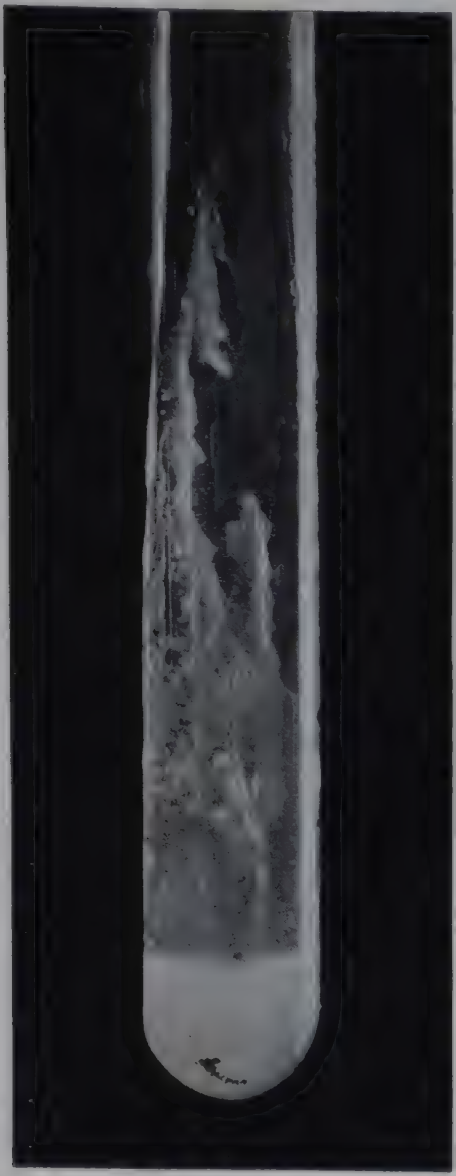

Fig. 307.

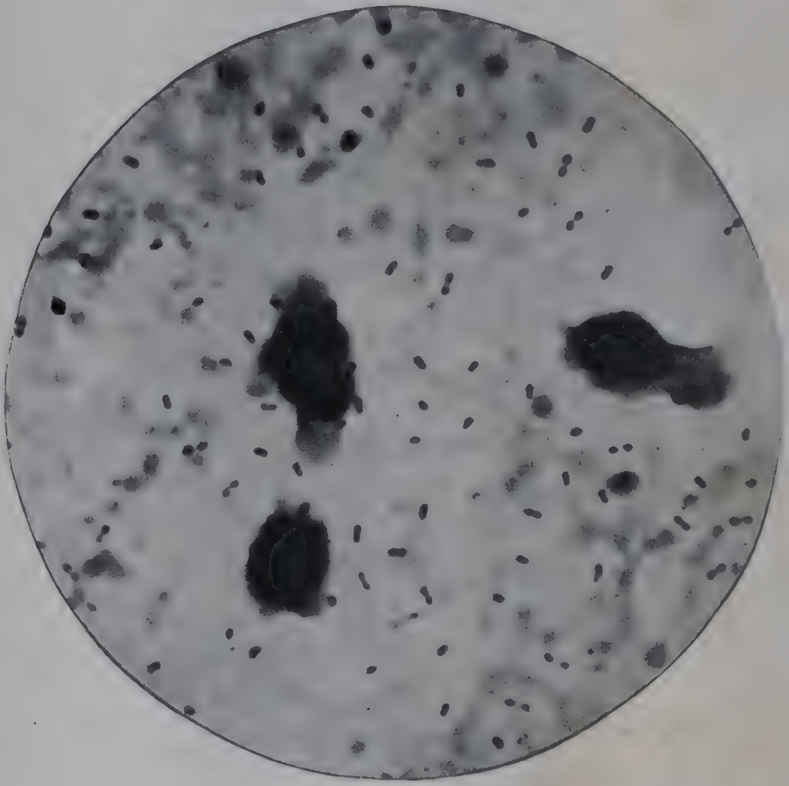

Fig. 308.

Fig. 307.—Twenty-four-hour culture of meningococci grown on ascitic dextrose agar. The culture which has been originally obtained from a case of meningococcus meningitis has been transplanted several times on artificial media, hence the heavy growth in twenty-four hours. (From Levinson: Cerebrospinal Fluid in Health and in Disease, ed. 3, St. Louis, 1929, The C. V. Mosby Co.)

Fig. 308.—Photomicrograph of smear from cerebrospinal fluid of pneumococcus meningitis. (From Levinson: Cerebrospinal Fluid in Health and in Disease, ed. 3, St. Louis, 1929, The C. V. Mosby Co.)

Five to ten c.c. of the liquid will not over-run the edges of such a plate if moderate care is used in pouring it out. The fibrin film is not distorted and floats in the liquid on the flat surface of the plate. The excess of spinal fluid may be drained off with a pipette or blotting paper. After drying in the air, the film is stained in the usual manner (Ziehl-Neelsen method). Since the plate is too large to be satisfactorily placed under the microscope or to be satisfactorily used on the ordinary microscope stage, that portion bearing the stained film is cut down to 1 by 3 inches for observation.

Petroff's Method.—

To about 10 c.c. spinal fluid add 2 drops of 5% tannic acid solution. Shake thoroughly, until a precipitate forms. Centrifuge immediately at high speed for five minutes.

Decant and discard the supernatant fluid. Use one portion of the sediment for smears (made in egg albumen or serum); one portion for inoculation of appropriate medium (page 1647); and one portion for injection into guinea pigs.

Tests for Tuberculous Meningitis.—There are two special tests for tuberculous meningitis, the Levinson test and the tryptophane test. Neither of these tests is specific for tuberculosis but they are of some importance in an exclusion way.

Levinson Test.—

Place 1 c.c. of cerebrospinal fluid in each of two serologic tubes of equal size. Add 1 c.c. of 2 per cent aqueous mercuric chloride solution to the first tube, and 1 c.c. of 3 per cent aqueous sulphosalicylic acid to the second tube. Stopper tubes. Mix solutions and allow to stand upright at room temperature for 24 hours. Measure the height of the sediment in the two tubes and compare.

Normally, the sediment in both tubes is less than 2 mm. If there is an increase in proteins, the sediment in both tubes is heavy. The sediment in the mercuric chloride tube is light and feathery and forms slowly. The sediment in the sulphosalicylic acid tube is compact and heavy and forms rapidly.

It is claimed by the advocates of this test that in tuberculous meningitis the height of the sediment in the mercuric chloride tube is 2 mm. or more, and is two or more times that in the sulphosalicylic acid tube. In suppurative meningitis the sediment in the sulphosalicylic acid tube is greater than in the mercuric chloride tube.

Tryptophan Test.—

A positive reaction with this test occurs in bloody fluids, in purulent and xanthochromic fluids, whatever the cause; hence the test has no value in fluids of this character. In clear cerebrospinal fluid, the purple ring is demonstrable in most of the cases of tuberculous meningitis but the reaction is negative in encephalitis, poliomyelitis, brain tumor, and syphilitic meningitis. This is an extremely delicate test and its interpretation should be carried out very guardedly.

Technic.—

Place 2 to 3 c.c. of spinal fluid in a medium-sized test tube. Add 15 c.c. of concentrated hydrochloric acid and 2 to 3 drops of 2 per cent formaldehyde. Shake mixture and allow to stand for 5 minutes. Add 3 c.c. of 0.06 per cent aqueous sodium nitr*ite* by overlaying.

A negative reaction is characterized by absence of color change at the junction of the two fluids or by a faint yellowish color. A positive reaction is shown by a delicate violet ring which may take several minutes to become visible and which persists for fifteen minutes or longer.

Chick Embryo in Examination of Spinal Fluid

Refer to pages 1473 ff.

Trypanosomes in Spinal Fluid

Spinal fluid examinations are much used in tropical medical practice for diagnostic and prognostic purposes. Trypanosomiasis shows a high cell count in the spinal fluid indicative of the onset of nervous symptoms. The trypanosomes may be readily identified in the spinal fluid by routine smear of the sediment obtained by centrifugalization. The sediment is stained with Giemsa stain after preliminary fixation for five minutes in methyl alcohol. (See Plates XLVII and XLVIII.)

CHAPTER VIII

FECES

GENERAL CONSIDERATIONS

The examination of the feces, while generally stressed by clinical teachers as a very important means of diagnosis in medical and surgical cases, is seldom thoroughly performed. The leading gastroenterologists are undoubtedly examining stools, just as they are giving barium enemas, and making roentgenologic examinations of the canal, but the rank and file of the profession has not fallen into the practice. We do not, by any means, insist that there should be a routine chemical, bacteriologic, and microscopic examination of the stools of every patient who consults his physician, but we do believe that, in certain selected cases, a review of the stools will aid the examiner considerably. The microscopic examination can be quickly made, likewise the more important chemical tests; to wit, the search for occult blood by the benzidine test, and the examination for bilirubin and hydrobilirubin by Schmidt's method. A little time devoted to washing the stools in looking for gallstones will repay the effort. A search for pathogenic amebas is frequently indicated.

Physicians make exhaustive examinations of all parts of the patient but the anus and rectum; in most cases this part of the physical examination is superficial, and consequently much valuable information is overlooked. The indifference to the possibilities of help from routine stool examinations, lack of concise information as to technic and interpretation, and esthetic objection to handling the material, all have conspired to make this field of laboratory work practically a *terra incognita* to most workers and students.

In southern states we find more interest and more real work being done on stools than in any other section of the country, because of the prevalence of intestinal parasitism in that district and the impossibility of making a diagnosis definitely in any other way. We find a growing interest in stools, too, on the part of pediatrists, but in the main, we believe much more emphasis must be placed on this department than has been in the past.

NORMAL FINDINGS

It must be remembered that what constitutes the "normal" stool is quite a variable factor. There is no normal standard regarding either the frequency or absolute character of the stools; many factors enter into a consideration of what shall be the number, the character, the weight, the consistency, and the color of the passages; these factors must be accurately ascertained in every individual case before one can draw reasonable and proper deductions therefrom.

In order to appraise the individual case, certain fundamentals must not be overlooked. The feces consist of the indigestible and undigested remnants of food, plus certain constituents such as material secreted by the intestinal wall, plus certain bacteria which may or may not belong to the group of normal intestinal flora. The food remnants, together with intestinal parasites and their eggs, are intimately mixed with bacteria and excretions from the intestinal mucosa. It is claimed by Strassburger that ordinarily the feces consist of one-third bacteria; in pathologic conditions, this percentage may be markedly increased. There are many factors in the normal metabolism and habits of the individual that will determine the character and amount of the stool. Therefore, in summing up the data from this standpoint, the individual must always be considered. In some individuals one stool a day might be considered diarrhea; in others, constipation; in still others, normal. Diarrhea is usually considered to be an increase in the individual's frequency of evacuations; these may be from one to fifty a day.

The usual amount of stool is from 100 to 200 grams a day, but this quantity is dependent upon the amount and character of food ingested. Besides the diet, the amount of feces passed depends upon the adaptability of food to the peculiarities of the individual's digestion, the rapidity of intestinal absorption, the amount and character of the digestive juices, such as the bile and pancreatic fluids, the amount of mucus discharged by the intestinal mucosa, and the biologic characteristics of the bacterial flora of the canal. The age of the patient, his habits, whether he leads an active or a sedentary life, his occupation, etc., all influence the number and weight of the stools. Only an extended study of the individual will permit one to take these factors into serious consideration in an estimation of the status of intestinal activity.

Proper attention to the diet is necessary in computing the data from the weight of stools. Harley and Goodbody (The Chemical Investigation of Gastric and Intestinal Diseases, 1906) found that of a series of 118 cases on the same amount of mixed diet, the amount of the stool varied from 30 to 282 grams, an average of 102.8 grams. On a mixed diet weighing 150 grams, it is said that an individual ought to pass from 30 to 37 grams of fecal material, but owing to the factors already enumerated, this is by no means a constant figure. A diet rich in vegetable and starchy elements will increase the weight of feces, while one made up largely of protein, such as meat, tends to decrease this quantity.

The stools of patients with diarrhea lasting several days show undigested muscle tissue if they have been eating meat, also unchanged connective tissue elements. The predominant ingredient of a stool that is associated with inflammation of the small intestine is mucus, thoroughly mixed with food remnants.

Collection of the Specimen*

In order to make the best possible examination of the stool, the material must be properly collected and submitted to the analyst as rapidly as possible. This is particularly true with respect to ameba examinations, where, in order to detect their motility, the stool is examined, while still warm, with the aid of a warm stage. For routine bacteriologic and chemical examinations this is not vital. The best results for all purposes are obtained where conditions are such that no preservative need be added. For long distance transportation, a chemical preservative must be added; this sacrifices some of the data obtained from the fresh, unchanged specimen.

---

*Refer to pages 1629 ff. for fuller details.

Physicians, as well as laymen, are prone to send both sputum and feces specimens in unwieldy, impracticable, and dangerous containers. The Post Office Regulations in this country very properly compel one to see to it that disease is not communicated through the medium of infectious material in the mails. Material is made safe for mailing if the proper bottles are selected, and if they are placed in double, tightly closed metal containers. The stool should be collected in a wide-mouth, chemically clean and sterile bottle. (We recommend throughout our work the sterilization of all glassware at 170° C. for two hours in the dry heat sterilizer.) The container must be chosen with the idea in mind of exactitude in diagnosis; first, to keep the material in much the same condition as it was when passed from the patient; second, to withstand the violence to which it may be subjected in transit. Despite reasonable care in transit, many very severe strains are placed upon such containers; they must be carefully packed so as to withstand the severest of ordeals in shipment. Sometimes the delay caused by the breaking of a specimen in transit may offset the necessity of an examination; at other times, the patient or examining or referring physician refuses to submit another specimen.

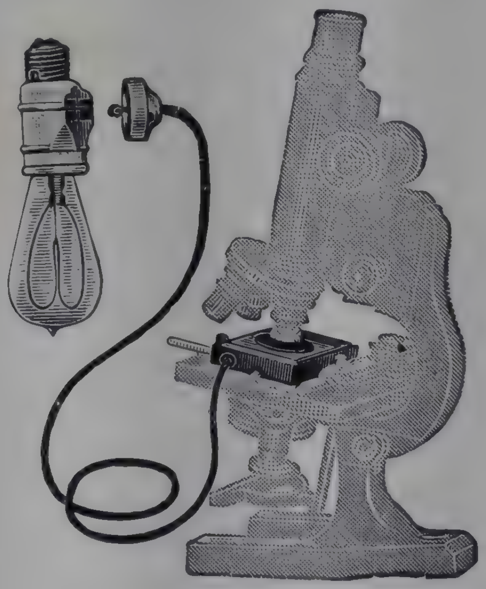

Fig. 309.—Warm stage. (Courtesy E. H. Sargent Co., Chicago.)

The receptacle and its packing must be so prepared that it will be neither a menace to the health of those handling it, nor offensive to the sensibilities of those who must examine it. Containers leaking fecal material from all sides, as from a Mason jar, for instance, require great care and time on the part of the laboratory worker to prevent infection and contamination of laboratory material. Above all, paper receptacles are to be condemned and never used.

Fill the bottle only about one-third full so as to allow ample space between the stopper and the top of the fecal contents to prevent the stopper from being forced out by gas formation. The stopper should be of cork and should fit tightly enough to prevent leakage. It should be long enough to project well above the bottle so as to facilitate ease of removal. It is well to tape the top of the bottle with adhesive strips after it has been closed.

The use of 20 per cent glycerin in physiologic saline solution has been suggested by Cumming who claims that it has an inhibitory effect on the growth of the colon bacillus and other fecal microorganisms. His solution is made by adding 20 c.c. glycerin to 80 c.c. of 0.9 per cent sodium chloride. To 20 c.c. of this solution, a mass of feces about the size of a split pea is added. Shake well to make uniform suspension. Do not use a greater amount of feces as the inhibition of *Escherichia coli* may not be controlled when larger amounts are used. According to Hazeltine[1] this method gives admirable results on specimens artificially contaminated with laboratory cultures of *Salmonella typhosa* and should be applicable in practice.

When the stools are to be examined in a hospital laboratory adjacent to the hospital-domiciled patient, they may be received directly into a clean sterile granite-ware bowl and taken immediately to the laboratory.

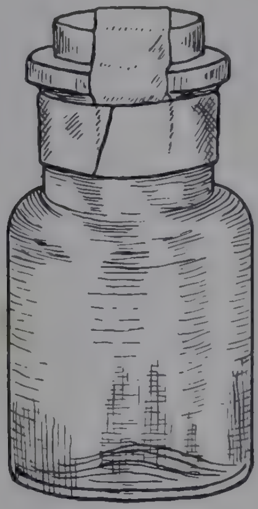

Fig. 310.—Taped bottle for collecting specimen of feces.

Stools intended for the demonstration of living amebas are examined while still warm. Preferably send the patient to the laboratory and procure and examine the stool there at once. Patients with dysentery due to pathogenic amebas may show these parasites only during the activity of the process when the patient has frequent bloody or purulent passages. The material should be examined at once, using a warm stage. If the patient cannot come to the laboratory, or the laboratory worker cannot take his microscope and other material to the bedside, then it is best to have the attending physician make half a dozen slides from the fecal matter, allow them to dry, and ship them to the laboratory. An examination of the stained specimen can be made for cysts; this is the most reliable method of diagnosis. In cases in which an examination is being made of the feces for amebas in a fresh state, the bottle or receptacle containing them should be placed in the incubator and kept warm while the technician is adjusting the microscope and warm stage. Refer to Chapter XII for details relative to examination of stools for intestinal protozoa.

---

[1] Hazeltine, H. E.: U. S. P. H. S. Reports 32: No. 48, 1917.

In general, feces should be examined as expeditiously as possible because of the rapid tissue and bacterial changes. The isolation of *Salmonella typhosa*, for instance, increases in difficulty in proportion to the age of the stool. A specimen that has been quickly examined for typhoid bacilli will often show a good culture, whereas the same stool kept for a while and then cultivated will show no growth of typhoid. Certain changes of decomposition take place in the stool; the overgrowth of one or more hardy microorganisms prevents the growth and recognition of *Salmonella typhosa* in the stools of suspected carriers. The administration of a cathartic increases the number of bacilli in the stools. It is good practice, therefore, to precede the search for typhoid bacilli in suspected carriers by the administration of a saline cathartic. Bacteriologic examination of stools is discussed in detail in Chapter X.

As Cammidge has pointed out, the feces of infants have generally to be scraped off diapers and are therefore contaminated more or less with material derived from dusting powders or ointments which have been applied to neighboring parts. This must be taken into account in the chemical and microscopic examinations of infants' stools. The feces should be free from urine, to prevent interference with the reaction, the ammonia content, chloride estimation, etc. With adults it is not difficult to prevent the contamination of stool with urine. In the case of infants, the nurse may prevent contamination by placing a large pad of absorbent cotton over the urethral orifice while collecting the stool for the analyst. A stool that is strongly alkaline or that has an ammoniacal odor with a well-marked reaction for chlorides can be instantly proved to be contaminated with urine because the stool never shows more than a bare trace of chlorides. The presence of urine can be quickly proved as follows:

Test for Urine in Stools.—

Make a concentrated watery extract of the stool with boiling distilled water. Filter. Acidify with nitric acid and add a 10% solution of silver nitrate, adding this drop by drop. An uncontaminated stool will show only a slight opalescence due to the formation of silver chloride. If a heavy white precipitate forms, indicating a large amount of chlorides, this stool contains urine.

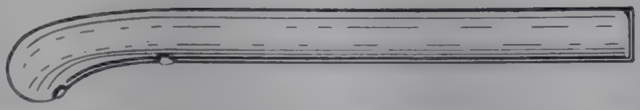

Fig. 311.—Appliance for removing stools from infants for bacteriologic examination.

In reference to stools intended for bacteriologic examination, as noted above, it is often advisable to give a sterile enema, plus a purgative, but this is not necessary or advisable when making a chemical analysis only. Stools intended for chemical analysis should not be contaminated by any oil or soap enemas. It is imperative for the analyst to know what drugs, if any, the patient has been taking; particularly, iron, bismuth, liquid paraffin, olive oil, etc. If these are being used, they should be discontinued a few days before the chemical analysis is undertaken.

The stool of an infant should be obtained for bacteriologic analysis by means of a special sterile feces collector directly from the lower end of the rectum. Such tubes have been devised by Cohnheim and Sato. This glass instrument, previously sterilized, is lubricated with sterile vaseline and introduced into the lower end of the canal, turned about, and a small amount of the stool caught in the eye of the instrument, then quickly withdrawn and the material examined bacteriologically.

Only a small amount of feces is necessary for the usual routine stool analysis. In cases in which an elaborate chemical analysis is desired, the stool must be collected for several days and a large quantity submitted. We do not recommend a complete chemical analysis of stools except under special conditions, where a complete metabolic study of the individual is being made. For instance, to determine the metabolic changes in a given case, we might make such a chemical analysis in conjunction with the estimation of the chemical intake of food, the study of the blood chemistry of the individual, and the chemical study of the urinary constituents. As a rule, the stool examination should consist of a determination of certain essential factors, macroscopic and microscopic. Under special conditions this examination may be varied to include a complete bacteriologic study, qualitative and quantitative.

Test Meals

In order to test the income and outgo of nitrogen and other elements, it is customary in food and metabolism experiments to put the patient upon a certain definite quantity of food, together with the ingestion of some substance at the beginning and at the end of the experiment which differs enough in color and consistency from the surrounding feces to render easy the differentiation of the feces of the ''experimental period'' from that immediately preceding and succeeding it. A method which is very serviceable is to give a gelatin capsule containing 0.2 gm. of powdered *charcoal* at the beginning and end of the period under observation. This causes the appearance of two black zones to map off the intermediate period of nutrition which we are engaged in studying. *Carmine* in 0.3 gm. capsule may also be used in the same way, thus producing two dark red zones.

The test meal of Schmidt[1] is possibly the most useful:

> One liter of milk, 100 grams of zwieback, 2 eggs, 50 grams butter, 125 grams beef, 190 grams potato, 1 gram oatmeal, sodium chloride 2 to 3 grams. This contains 102 grams albumin, 111 grams fat and 191 grams carbohydrates, representing 2,234 calories. The material may be divided as follows:
>
> *Breakfast*—0.5 liter milk, 50 grams zwieback, 0.5 liter oatmeal. Gruel made of 40 grams meal, 10 grams butter, 200 grams milk, 300 grams water, and one egg, and enough salt to make it palatable.
>
> *Luncheon*—125 grams chopped beef (Hamburg steak) with 20 grams butter lightly baked so that it is practically raw, plus 250 grams potato soup made of 190 grams mashed potato, 100 grams milk, 10 grams butter, and salt.
>
> *Afternoon Luncheon.*—0.5 gram milk, 60 grams zwieback.
>
> *Evening Meal.*—0.5 gram of morning oatmeal, gruel, with the same amount of butter, milk, water, and egg and salt.

---

[1] Die Funkstionprufe des Darmes mittels der Probekost, ed. 2, Wiesbaden, J. F. Bergmann, 1908.

This diet is given for three days or longer, until one can be assured that the patient is passing a stool composed of the remnants of this food. The test meal produces a normal stool which can be identified by giving 0.3 gm. carmine to color the stool at the beginning of the transition from the normal diet. If the milk produces diarrhea, cocoa may be substituted in the same quantity, made by mixing 20 gm. cocoa, 10 gm. sugar, 100 gm. milk, and 400 gm. water.

EXAMINATION OF STOOLS

The examination of stools is divided into five studies: first, macroscopic; second, microscopic; third, microchemical; fourth, chemical; and fifth, bacteriologic.

Macroscopic Examination

The macroscopic identification of parasites may be summed up as follows: the proglottids of the tapeworms, *Ascaris lumbricoides, Enterobius (Oxyuris) vermicularis* all are likely to appear spontaneously in the stools. *Ancylostoma duodenale* and *Trichuris trichiura* appear only as a result of definite therapeutic attempts to expel them. Rarely we find insects and their larvae. I recall a case near St. Joseph, Missouri, where the stools repeatedly showed the larvae of flies, and where the physician and patient both stoutly maintained that all chance of contamination after the stools were expelled had been excluded. We were never able to prove this. Workers must be sure that stools are not contaminated *after* their expulsion either accidentally or purposely, by malingerers or psychopathic individuals.

The number and variety of foreign bodies that have been found in stools are legion. They may vary from meat skewers, splinters of wood, eggshells, garden earth (from imperfectly cleaned vegetables), kernels of nuts and fruits, pieces of tobacco leaf, tea leaves, etc. It is remarkable to note that sharp instruments may pass the entire length of the canal and may be expelled without injury to the wall, such as needles, pieces of a knife blade, glass balls. It must not be forgotten that some of these foreign bodies may be placed in the anus by psychopathic persons.

The macroscopic examination is very important.

Place a portion of the stool on a flat dish. Note the color, consistency, quantity, mixture with large mucous particles, blood, and undigested food remnants. For closer examination, some of the stool should be mixed with water and this diluted material should be put in a Petri dish with a dark background. The brown particles which will then be noted should be examined microscopically.

Pathologic macroscopic findings are as follows:

1. Undigested food remnants; such as connective tissue, remnants of potatoes and meats, and pieces of fat.
2. Mucus, pus, or blood.
3. Pieces of human tissue.
4. Intestinal stones and gallstones.
5. Worms.

The **Physical Characteristics** of the stool should be investigated as follows:

Color.—Under normal conditions the color of the stools may be light yellow to blackish blue, dependent in a measure upon the character of the food ingested. Exposure to the air and to light causes the stool to become blacker. The fecal color is due to bile pigment, plus the presence of foreign pigments of foods and drugs. The ingestion of blackberries or huckleberries causes black stools; chocolate gives them a dull gray color; cocoa makes them light gray. The effect of starchy food is to produce a yellow stool; of chlorophyl from vegetable material, a greenish shade. Fats produce the classical "clay-colored" stool. Certain drugs, such as bismuth and iron, produce a black stool; senna, rhubarb, santonin, and calomel give a yellowish green cast.

The normal color of the fecal material is due to the presence of hydrobilirubin derived from the bilirubin of bile; the intestinal bacteria convert bilirubin into hydrobilirubin. Neither of the bile pigments, bilirubin nor biliverdin, is ever normally encountered in a stool unless the bile is passed unchanged down the intestinal tube by unduly rapid peristalsis. The darkening of the stool after exposure to the air is probably due to the conversion by bacteria of hydrobilirubinogen into hydrobilirubin. The *color* of *stools* is mainly dependent upon the character of the *diet*. If one is to be influenced by color of the stool in estimating a fault in health, then he must inquire very carefully as to the diet taken, whether mixed, whether it contains vegetables or fruit or what not. An inquiry of this kind will usually explain the color.

Blood.—Blood is not easy to identify in the stool because the bright red color is lost after the blood remains some time in the intestine, changing in color to the brown of hematin. A large quantity of blood gives the appearance of cooked tea. If blood comes from the lower bowel, it will usually appear on the surface of the stool and can be detected by the naked eye. It is always red if it comes from the rectum and is darker if it comes from a point higher up. When summing up the evidence presented by either the macroscopic or the chemical analysis for blood in stools one must know whether there are any hemorrhoidal changes present, also whether there is a rectal fissure, as well as polyps, rectal adenomata, carcinoma, or ulcer. Attention should be called to the gross appearance of stools contaminated with large quantities of blood coming from points higher up, notably the "tarry" color of duodenal ulcer, typhoid stools with bleeding, or in severe dysenteric conditions.

Resort must be had to the microscope and the chemical test to identify blood.[1] Blood mixed with pus is seen in dysentery. Mucus and blood are seen mixed in cases of invagination and polyposis intestinalis. Blood is found, too, in cases of embolism of the mesenteric arteries. In simple catarrh, blood may be found just as it is found in so-called stagnation colitis (hemorrhoidal bleeding). Nothnagel noted bleeding in tuberculosis without ulcers and without catarrh.

Form.—The form of the fecal material gives an idea of certain conditions. The stools in prolonged constipation are hard and often ball-shaped, sometimes grooved by the intestinal bands. There is a characteristic scybala formation called "goat-droppings" seen in cases of spastic constipation or we may see pipe-stem or ribbon-shaped stools. In general it may be said that the formation of scybala, due to small bulk of feces and lack of moisture, is evidence of spastic constipation.

---

[1] See pages 1290 ff. for occult blood tests.

Liquid and semisolid stools are indicative of irritation in the intestinal tract, all comprised under the general term of "diarrhea." There are varieties of these liquid formations, sometimes spoken of as characteristic of certain definite disease states, such as the "pea-soup" stools of early typhoid, and the brilliant red stool of the later period. In cholera the so-called "rice-water" stools are seen.

Odor.—The odor of feces is due to the presence of indol and skatol which are formed as a result of the putrefactive processes that normally occur in the intestine. These putrefactive processes result from the action of bacteria upon protein present in intestinal contents. The most important products formed are indol, skatol, paracresol, phenol, para-oxyphenyl-propionic acid, para-oxyphenylacetic acid, volatile fatty acid, hydrogen sulphide, methane, methylmercaptan, hydrogen, carbon dioxide, proteoses, peptones, peptides, ammonia, and amino acids. Of these products indol and skatol in the feces give the disagreeable odor, while indol, skatol, phenol, and paracresol appear in the urine as ethereal sulphuric acids. Methane, methylmercaptan, and hydrogen sulphide may add to the disagreeable odor produced by indol and skatol. The more meat digested by the patient, the more the odor; it is less marked in stools from a vegetable diet and hardly noticeable in stools from a milk diet. This explains the fact that stools of infants on milk diets are practically odorless except under pathologic conditions.

Casts.—Casts of the bowels are occasionally found. They may be passed in shreds, or in the form of a complete cast of the intestine. This condition has been designated by Nothnagel as "enteritis membranacea" or "colica mucosa." They may be a foot or more long and may be passed, accompanied by severe tenesmus, without any fecal material. These cases are seen more commonly in women than in men, and have been regarded as indicative of hysterical or nervous disorders. They are found according to Greene[1] associated with two conditions aside from the causes mentioned; namely, impairment of general nutrition, and spastic constipation. The nature of these casts may be determined by Pariser's method:

Treat them with sublimate alcohol and then with Ehrlich's triacid stain; they turn green if mucoid, whereas, if fibrinous, they turn red. Details of the test are given on page 1271.

Undigested food particles may be seen and identified by the naked eye. Pour liquid stools into Petri dishes. Thick pasty stools are best stirred with water and then poured over a fine shred sieve. The sieve described by Einhorn is very useful to detect concretions. Another method without the use of a special sieve consists of tying a double thickness of cheesecloth over a ring of wood or on to the edge of a pail. Kemp has described a method which is simple and practical. A circular wire is fitted to the toilet seat and to this is attached a bag made of double thickness of cheesecloth which dips into the pail. The patient defecates into the bag. Water is poured through until only the more solid parts remain. These are then scraped off and examined. The same thing may be accomplished by means of a colander over which is laid a fine meshed wire screening.

---

[1] Medical Diagnosis, Philadelphia, 1926, P. Blakiston's Son & Co., p. 865.

Undigested food particles, pieces of bone, cartilage, and muscle may be seen as undigested food remnants. Starchy foods leave no residue that can be distinguished by the naked eye, but raw vegetables such as cucumbers, lettuce, onions, radishes, asparagus, and string beans, and fruits, such as cranberries, nuts, and currants, pass through the intestinal canal and appear intact. It is difficult to recognize the residue of cooked vegetables unless they are very poorly masticated. Among other products which may be recognized with the naked eye are the epidermis of fowl, fish scales, pieces of lobster shell, or eggshell. The connective tissue and sarcolemma of "old hens" may be recognized also. The ingestion of considerable fat may be recognized in the stool, according to Nothnagel.

In general the process of cooking of food is reflected in the condition of the food remnants in the stools. There is a more thorough disintegration of meat fibers from long-continued stewing and boiling than there is from baking. Small pieces of brownish baked meat and even particles of fried eggs may be recognized by the naked eye.[1] The cooking of vegetables in "hard water" makes the cellulose tougher, so that there are distinct food remnants in the feces.

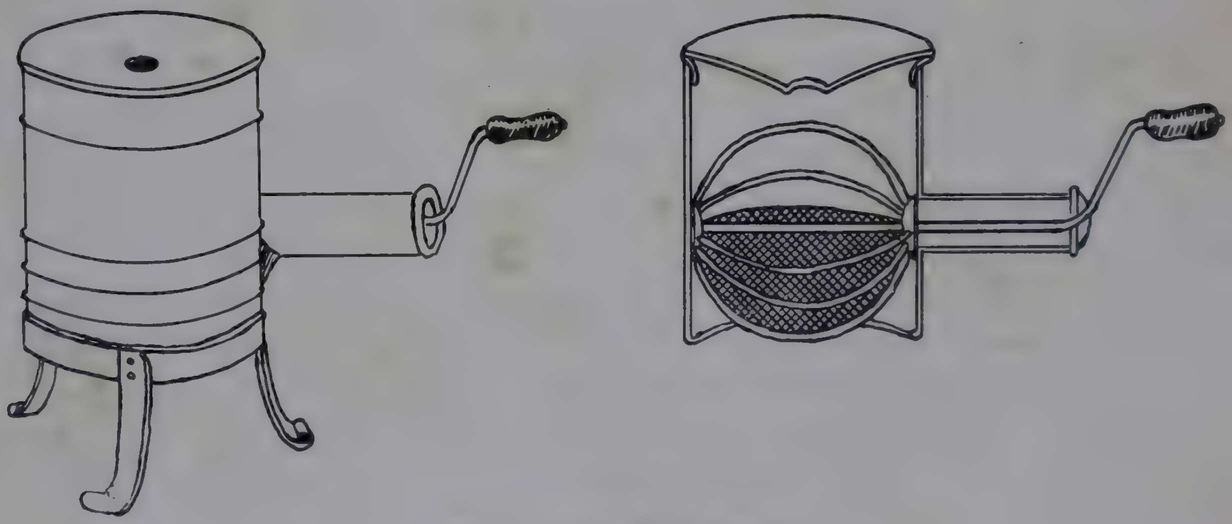

Fig. 312.—Einhorn sieve.

The factors of imperfect mastication of food and deficiency in the motor functions of the gastrointestinal tract are important in a consideration of food remnants in the stools. The influence of chemical insufficiency of the gastric and intestinal juices is also important. Ogata introduced raw meat in dogs directly into the duodenum and found the connective tissue of the meat in abundance in the stools. The same result is seen in cases of achylia gastrica. Schmidt noted in all cases where there was a deficiency of the gastric juices that connective tissue residue of meat predominated in the passages. Faber found in cases of achylia and hypoacidity that fish bones and small spicules of bone appeared constantly in the stools, but not so in health. Insufficiency of the pancreatic function is seen in albuminous and fatty changes in the stools; masses of fluid fat appear, which become hard when the stool is exposed to the air, so that it becomes covered with a fatty crust. Deficiency of the biliary function also causes a disturbance in fat digestion, with much fat in the stool. Deficiency in the resorption powers of the gastrointestinal tract is also responsible for food remnants in stools. Schmidt reported a case of tabes mesenterica with visible muscle remnants in the stool.

---

[1] Van Ledden-Hulsebosch: Macro u. mikroscopische Diagnostik der menschlichen Excremente, Berlin, J. Springer, 1899

The entire question of food remnants in the stool, from a diagnostic standpoint, must revolve around the determination of what is normal or abnormal for the particular individual. Confusion often exists in the minds of beginners in examination of stools; they often mistake one kind of food remnants for another, and for parasites. The microscope must be constantly at hand to correct such errors. Small pieces of muscle may be mistaken for bile-stained fat and vegetable residue, or even clumps of mucus. Pieces of orange skin have been mistaken for parasites. The pieces of mucus found in enteritis membranacea have been mistaken for actual pieces of intestinal mucosa. We should search, especially in the stools of infants, for white masses formed from milk. They occur in gastrointestinal disturbances in infants and are formed from casein, according to Monti; often from fat, according to Widerhofer.

Referring to the test diet (see page 1266) the following directions may be formulated: if there are particles of chopped beef in the stool there is derangement in gastrointestinal digestion. If connective tissue remnants are seen, the stomach is at fault. If muscle particles are visible and no connective tissue, it is an intestinal condition, probably a fault in pancreatic juice digestion. If both connective tissue and muscle remnants are seen, then both stomach and intestine are involved. We term a condition with undigested visible food remnants "lientery."

The determination of the state of gastrointestinal activity from the presence of undigested *vegetable remnants* is much more difficult than is the case with meat. Ledden-Hulsebosch stated that in health, food made of flour, white bread or potato leaves no residue visible in the stool, but that raw vegetables such as radishes, cole slaw (cabbage), pickles, onions, etc., pass out unchanged. The hard vegetables such as asparagus, rhubarb, string beans, as well as poorly cooked or poorly cut up beans, peas, lentils, and the like, are readily seen in properly functioning gastrointestinal tracts. Bean soup, spinach, and the like are unrecognizable. Fruits, such as berries, currants, etc., nuts, are unchanged, as well as the skins of plums and apples. Under a test diet, cooked vegetables are not to be seen in the stools. The cellulose fibers of vegetables may be seen in a general diet, but no data can be drawn from their appearance.

Mucus.—Mucus that appears in the stool is usually visible macroscopically. In very small quantity it is difficult to find, but in larger quantity it can readily be seen and grasped with the forceps. Cases in which it is found only with the aid of a microscope are rare, but do exist. Our interest, therefore, is in mucus that can be found macroscopically.

Tests for mucus may be made as follows: A few particles of the supposed mucus are washed in water and stored in a test tube with 2½ per cent mercuric chloride in alcohol, using a glass rod. The larger particles are thrown down by the hardening effect of the mercuric chloride in alcohol. Sediment the specimen, add distilled water with a few drops

FOOD TECHNOLOGICAL RESEARCH INSTITUTE

LIBRARY
3990

of Ehrlich's triacid stain, sediment again, wash in water, and examine microscopically. The mucus particles, provided they are not too rich in cells or fat, are stained bluish green or green; all other animal cells are stained red.

Mucus is precipitated with acetic acid. The precipitate is not redissolved by an excess of this acid. Mineral acids added slowly cause a precipitate; added rapidly they dissolve the mucus. Alkalies cause it to swell and dissolve. Alcohol causes shrinkage. Thionin stains mucus violet, other tissue remains blue. In order best to obtain this reaction, take care that there is not too much mixture with other material, and that the reaction of the specimen is neutral. Other aniline colors stain only the cells present. Iodine stains a diffuse yellow color. Hecht's method[1] is a mixture of brilliant green (2 per cent) with neutral red (1 per cent). Stain a few minutes. This gives a light red color to mucus, which is in sharp contrast to the rest of the field, which is green. Nuclei and cell membranes appear reddish violet.

The amount of mucus present in stools may range from very small particles to enormous masses. We have seen pieces of mucus in cases of membranous colitis as long as 40 cm.

The mucus is usually present in clumps or small masses which, in water, appear to have irregular edges. At times there are the so-called boiled sago nodules, the composition of which has been much in dispute. The consistency of mucus masses varies from extreme softness to leatherlike hardness. Pure mucus masses are usually soft, the harder particles consisting of other material as well as mucus; namely, albumin, fat, and many cells. Mucus is transparent, but when contaminated with other substances, such as fat or albuminous material, it becomes cloudy. It imitates the color of the fecal mass in which it is found, varying from the brown color of hydrobilirubin to the orange red and green color of bilirubin and biliverdin; blood elements, of course, make mucus reddish or red brown.

Washing the stool gently with water makes it comparatively easy to find the small microscopic particles where the macroscopic view fails to reveal them. Mucus appears under the microscope as structureless material, more or less transparent, in which may be imbedded epithelia, pus cells, red blood cells, bacteria, protozoa, air bubbles, detritus, food remnants, and crystals. Mucus from the upper tract is more likely to be entwined with food residue than when it is from a point low down. The bacterial contents vary, being very scant from cases of mucous colitis. The greater the transparency of the mucus, the less the contaminated bodies bound up with it. Note two points of interest, the irregular lines that traverse it, and the irregularity of its boundaries.

Only visible mucus is found under pathologic conditions. The exceptions to this are the meconium and the stools of young infants. Caramer[2] noted the presence of mucus in the first meconium of newborn children. In constipated individuals, the hard stools literally scrape off particles of the mucosa.

The bodies described by Nothnagel, which he terms "yellow mucous granules" or hyaline mucous islands, are not mucous in character, but are of an albuminous or fatty nature. They are minute pinhead particles which may be present in very large numbers, yellowish brown, and soft. Pressed under the microscope, they spread out and are homogeneous, free from cells or other structures, thereby differing from mucus which is frequently combined with cellular material. They originate high up and, being bile stained, certainly indicate an ileitis or jejunitis, as claimed by Nothnagel.

---

[1] Wien. klin. Wchnschr., 1908, No. 45.

[2] Deutsch. med. Wchnschr., 1907, No. 12.

The most important consideration in the study of mucus is its *source*. Usually, *mucus comes from the large intestine.* The small intestine does not produce mucus with the same facility as the large bowel. If mucus is found in diarrheal stools very finely subdivided, as in typhoid fever, tuberculosis, and cholera, it may be assumed that it comes from the small intestine. Further proof of the small intestine as the source of the mucus is the impregnation of the mucus with unchanged bilirubin.

The manner in which mucus is mixed with stools may indicate the source; if the well-formed stool is covered with mucus or if the mucus dips down between the scybala, it is coming from the lower end of the large intestine. The ribbonlike masses that are called membranous colitis mucus come from the sigmoid flexure of the colon. If mucus is intimately mixed with a ''soupy'' stool, the material comes from the upper part of the large intestine; in fact, the smaller the particles and the more intimately they are mixed, the higher up their source.

The pathologic process underlying the undue pouring out of mucus into the intestinal canal is usually a catarrhal process, with increase in the glandular activity and a diffuse inflammatory change in the entire mucosa. Mucous colitis is a mysterious disease entity which has been placed in the class of hypersecretion of the mucous glands with a nervous basis (a secretion neurosis).

The degree of inflammation may in a measure be determined from the transparency of the particles of the mucus. Our conception of a very severe attack is a mucus which is very cloudy, due to the content of epithelial and pus cells. There may, however, be a catarrhal inflammation without mucus in the stool, so that absence of mucus does not exclude inflammation. The appearance of the sagolike clumps of mucus occurs in the stools of children as an evidence of severe mucous inflammation. Heubner, in explaining this formation, thinks that the nodules of mucus are formed from the follicles in the intestinal wall, while Kelsch believes they are pieces that are squeezed out of the Lieberkuhn follicles. The presence of a large amount of pus with mucus indicates ulcerative inflammation; with blood, a diagnosis of ulcerative enteritis (dysentery).

Fibrin.—It is difficult to identify fibrin in the stools with the naked eye, or even chemically. Autopsy findings of fibrin are common in dysenteric patients, but there it is attached to the walls of the intestine. It is logical to assume that it is cast off and appears in the stool, but it cannot be proved by an examination of the stools. Fibrin masses are found especially in membranous colitis.

Tissue Remnants.—Tissue remnants emanate either from tumors of the intestinal wall or from necrotic mucous membrane changes. In the first group we note polypi, pieces of hemorrhoidal nodes, carcinoma, and occasionally lipoma. Necrotic pieces are seen in ulcerative processes; such as, invagination cases, typical dysentery, twisted off pieces of adenomatous polypi, or pieces of ulcerative neoplasms.

Very small necrotic masses have been seen in stools of typhoid fever in the second or third week. Occasionally we have received solid particles from a distance, which a physician thought was a piece of tissue. Usually these are artefacts or food remnants which passed out in undigested form. We have been asked to make sections of such pieces as well as sections of distinct blood clots. If we section the tissue and find actual glandular material we may well think of invagination.

The greatest stumbling block to an attainment of a good working knowledge of the material commonly seen in stools is the presence of nonpathologic substances or artefacts. These are fly larvae, unusual pieces of food, pieces of goods, pieces of apparatus, and other objects which may come in contact with the stools or containers. This must constantly be borne in mind; in fact, a microscopic study of all such foreign matter is very good preliminary practice in preparing oneself for coprological expertness.

Other Organic Material.—Other organic material may be parasites or various calculi. Among *calculi* are gallstones which are identified by their smooth and facetted surfaces and their light weight. Chemical means will fully identify them. While all sizes of gallstones may be found, the two extremes, very large and very small stones, are rare: the very large stones lead to obstruction and are not passed; the small stones are so easily broken up that they are no longer recognizable when they reach the lower end of the canal. The rare pancreatic stones have no known characteristics to make their identification with the naked eye easy. According to my old teacher Fleiner of Heidelberg, their surfaces are facetted and rough.

Enteroliths must be differentiated from so-called coproliths or fecal mass. Leichtenstern divided enteroliths into three classes: (1) heavy round stonelike masses with concentric layers when viewed in cross-section, showing centrally usually a foreign body as a nucleus; (2) light, irregular, porous stones, consisting of fecal and calcium salts with undigested vegetable food remnants; (3) concretions resulting from long-continued use of medicines, such as lime salts, benzoic acid, bismuth, salol. A curious habit of young girls of chewing the ends of their braided hair may lead to a fecal concretion with this hair as a nucleus. Very minute sandy particles of unknown origin have been reported in stools by the French authorities such as Dieulafoy.

The literature gives an occasional reference to the occurrence of *intestinal sand.* In 1903 Mitchell[1] reported a patient who passed sandy particles on a milk diet, the sand disappearing when the patient was put on a general diet. The sand was composed of calcium phosphate and carbonate. No bile or salts were present. Bedford[2] reports a case with severe mucocolitis coincident with the passage of sand. The analysis of the sand showed: moisture, 5.2 per cent; calcium phosphate, 28.68 per cent; calcium carbonate, 5.20 per cent; magnesium phosphate, 0.46 per cent; organic matter, 60.45 per cent. He states that the true intestinal sand, which is of mineral origin as opposed to false sand which is of animal origin, contains a higher percentage of inorganic salts than the false variety in which about 2 per cent is found. Delphine at the London Pathological Society in 1890 first called attention to the tendency of pears, figs, and bananas to produce false sand. He thought there was some relation between true sand and gout, but could not account for the absence of uric acid deposits. Crombie[1] reported several cases and stated that it is more commonly found in India because it is the custom there to wash all stools in the search for parasites. J. McNamara[2] looked at the condition from an evolutionary standpoint and suggested that the formation of sand is a reversion, in the mammal, to the eggshell forming function of birds and goes into comparative anatomy to prove his theory. J. S. Myer and J. E. Cook,[3] of St. Louis, reported a case of possibly false sand. They could not experimentally produce sand by the ingestion of vegetables. They produced it, however, by giving the patient one or two bananas, finding the sand twenty-four hours later in the stool. Fuller reported a case that he observed for a number of years, a married woman with diarrhea of many years' standing. She passed stringy mucus, and later passed two to three ounces of gritty sand. The sand was hard, crystalline, and yellow gray. It was partly soluble in nitric acid, turning to a bright orange color. It was insoluble in potassium hydroxide. The chief salts present were calcium phosphate and carbonate. It contained no bile salts. It could be washed from every stool. This writer concluded that most of the cases reviewed have been of a nervous disposition. He does not believe that diet has much to do with the condition, although false sand can be produced by large quantities of certain fruits. He suggested very properly that in all cases with persisting colicky pains the stools be washed and strained through gauze. This he believed will show a great many more cases than have previously been found.

Microscopic Examination of the Stool

The microscopic examination of the stool may be made either a very simple procedure or a very complicated one. It depends upon how far we wish to go, and upon the object of our investigation. We may simply wish to survey the crystals present, or the food remnants, or to verify our naked eye judgment; or to prove the presence or absence of eggs of the more common parasites such as the hookworm or the tapeworm; we may wish to make a simple smear for tubercle bacilli, or to make a smear for other microorganisms; in short, our microscopic examination may be directed to the solution of one problem or a great many. We usually are given a clue from the clinician as to what he particularly wants investigated.

Preparation of the Specimen.—In general, the following material is needed for a microscopic examination of stools: glass slides and cover glasses; teasing needles; a good centrifuge; test tubes and small funnels, pieces of sterile gauze for filtration; sterile Petri dishes; culture media for identification of the more common varieties of bacteria such as the colon and typhoid bacilli.

---

[1] London Lancet, 1902, p. 314.

[2] Brit. M. J., 1903.

[3] Am. J. M. Sc., 1909.

It is inadvisable to add any chemical substance to the stool to reduce the odor as these substances always cause a distortion of the picture and render the examination of doubtful value.

The simplest examination consists in taking a small piece of the stool on a toothpick and rubbing it on a glass slide, covering with cover glass and examining. Portions from various places should be taken, from the solid parts, and from softer and more liquid parts. Be sure the specimen is as fresh as possible to eliminate the question of alterations from standing. If the stool is not particularly fresh, take the specimen from the inside of the masses rather than from the outside. In exerting pressure on the cover glass elastic tissue and watery material will not remain pressed out, mucus and fat containing stools remain pressed out. If a grittiness as of glass against glass is noted crystals or sand may be present. Thin watery stools may be sedimented and thicker heavy stools may be slightly diluted with water or saline in making this examination. The mixture may be made on the slide. Examine with the low and high power dry lenses. To isolate certain parts of the stool, wash repeatedly, shake, sediment, and pour off the supernatant fluid. Remove the large particles which are visible to the naked eye and examine the sediment.

Sedimentation can best be accomplished with the use of a centrifuge tube very much like that devised by Hopkins for the counting of bacteria. Run the centrifuge at moderate speed. Note a sharp line of separation between the sedimented portion and the supernatant fluid. In the cloudy portion just above the sediment the various bacteria and the fatty acid needles are found in fat stools. Note foamy fat on the surface in cases with much fat in the stools. In this upper portion are seen small particles of vegetable material, mucus with air bubbles, and particles of connective tissue cells. In the deeper portions of the sediment are crystals of large size such as triple phosphates, the hairlike covering of vegetables, the large muscle remnants.

There are a number of other more elaborate methods of washing and sedimenting the stool for microscopic study but we feel that the above method will amply suffice for all practical purposes. We refer those who desire a much more elaborate method of separation of the various elements of the stool to Van Ledden-Hulsebosch's work.[1]

Microscopic Findings.—

Epithelia.—Epithelial cells from all portions of the tract are naturally likely to find their way into the stool. The character of the cell points to the origin, but pure histologic pictures as they occur in the mucosa do not exist in the stool because the digestive juices have a powerful effect in changing the morphology. There may be pure unchanged stratified squamous epithelial cells from the region of the anus but even this is rare. They appear, however, less changed than cells from points higher up; for instance, the cylindrical cells from the small and large intestines. These squamous cells closely resemble the cells that fall into saliva from the mucosa of the mouth. They are very large nucleated cells, and are not to be confounded with the nuclear-free cells of meconium and infant stools which have originated from the vernix caseosa. Pure types of squamous cells are rubbed off, unchanged, from the anal orifice by passage of the stool. Cylindrical cells from points higher up are seen as slightly distorted cells, found in washings of the gut or in thin soupy stools of typhoid, diarrheas of children, tuberculous enteritis, and cholera. They have clear nuclei and granular cytoplasm. They may appear singly or grouped as they are in the intestinal wall, arranged side by side. These cells are sometimes swollen with fat droplets. One may see the cells described by Nothnagel as ''vanishing'' or epithelial cell ''ghosts'' bound up with mucus particles. They are supposedly degenerated cells according to Leube, or amyloid cells according to Lambl. They are small, homogeneous, and have no nuclei. They are refractile, and apparently have lost their granules. They are frequently spindle shaped. Nothnagel believes they are cells which are changed by abstraction of water. Kitagawa, however, stated that he found these cells in watery stools in diarrhea and that they are the result of a degenerative process, either hyaline or coagulation necrosis. Schmidt[1] showed that they are caused by an inhibition with soaps, because, after adding acetic acid and gently warming the slide, fat droplets exude; further warming causes these drops to run together in a fatty film. Epithelial cells in the feces are usually not stained. Rarely are they yellow colored from bile. Nothnagel believed that the staining with bile is an intervital process and does not occur postmortem.

---

[1] Makro u. microscopische Diagnostik der menschlichen Excremente, Berlin, J. Springer, 1899.

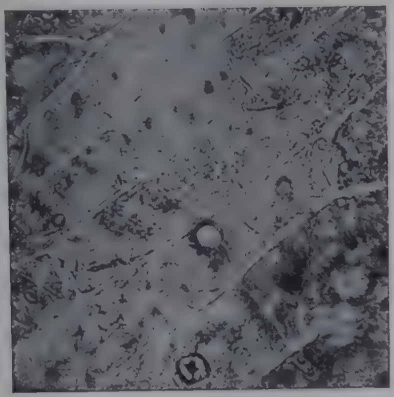

Fig. 313.—Vegetable cells in feces.

A sharpness in outline of the cytoplasm of the epithelial cells may be produced in the usual way by the addition of acetic acid. Osmic acid will stain fat granules black.

The diagnostic significance of epithelial cells in abundance is their indication of the existence of catarrhal processes. The occurrence of a large amount of mucus and a paucity of cells evidently shows that the derangement is more a result of a nervous irritability of the intestine than a true inflammatory process. This is especially true in cases of enteritis membranacea. Toxic disturbances of an intense nature, as in cholera, cause a great exfoliation of cells. One cannot conclude simply because the epithelial cells are bile stained that the disturbance is in the small intestine. Other signs must be at hand to make this diagnosis. The presence of the ''vanishing ghost'' cells does not prove their source the large intestine; when mucus is present as well, this is probable. The presence of half digested cells with mucus indicates a small intestine disturbance, especially if the cells are bile stained. This picture is seen in typhoid fever and tuberculous enteritis, where pus cells are also present.

---

[1] Deutsch. Arch. f. klin. Med. 65: 2440, 1900.

Leukocytes.—Leukocytes are not commonly found in feces. They are abundant naturally where there is pus formation, as in ulcerative conditions in the tract. One may have difficulty in identifying them under the microscope but they may present a perfect contour, with granular cytoplasm and single or multiple nuclei. Eosinophilic granules may be seen; particularly is this true when Charcot-Leyden crystals are found in cases of parasitism. Leukocytes that are large enough to be designated giant cells have been seen in feces. They are much larger than the flat cells found in the mucosa of the mount. They show vacuoles. They are seen in tuberculous enteritis. Schmidt noted phagocytes in a case of dysentery. The shadows of leukocytes are sometimes seen. Small, broken down leukocytes are frequently seen enmeshed in mucous particles. The presence of a few leukocytes in conjunction with epithelial cells in infantile stools indicates an irritation process.

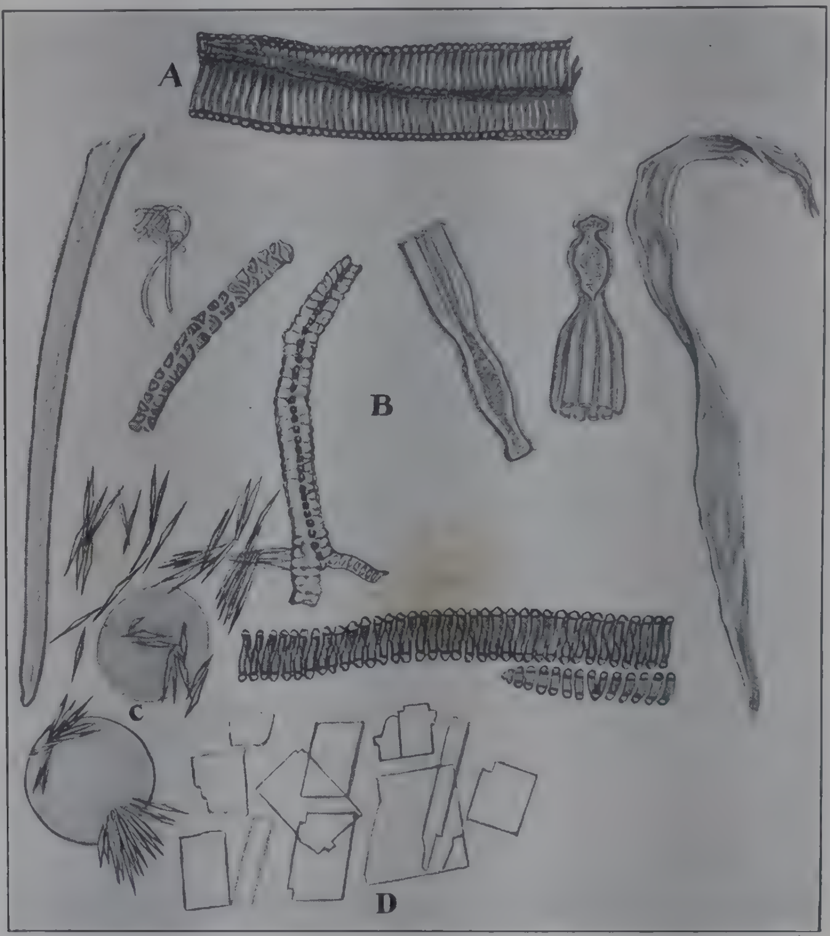

Fig. 314.—Microscopic findings in feces: *A* and *B*, vegetable fiber remnants; *A*, banana, commonly mistaken for tapeworm section; *C*, fatty acid crystals; *D*, cholesterol crystals.

Pus.—Macroscopically the grayish masses which microscopically prove to be collections of pus cells may be observed. If we actually see the yellow material which is unmistakably pus, we must think of para-intestinal pus pockets in the region of the large intestines. Pus coming from a point higher up in the small intestine would naturally undergo such changes before being expelled with the stool mass that it would not be readily recognized macroscopically. In the various ulcerative processes of the large intestine and even of the small intestine, such as dysentery, colitis ulcerosa, syphilis, neoplasms, tuberculosis, and typhoid, pus may be intimately mixed with the stool and is difficult to recognize as such.

Pus cells do not appear in feces in abundance in catarrhal states, as is the case in sputum of catarrhal inflammation of the respiratory tract. The presence of much pus always indicates an ulcerative pathology with but one exception; namely, colitis with severe inflammatory changes, with pus, blood, and mucus in the stools, without ulceration. One must remember that there are certain types of ulceration without pus; for instance, the perforation of typhoid ulcers. The various grades of proctitis with pus, blood, mucus, and Charcot-Leyden crystals have already been noted.

Erythrocytes.—Blood must be very fresh in order that the cells be seen in intact form under the microscope. Even then we usually see the crenated or crabapple form, due to the acid reaction of the stool. Only a large number such as are expected in an ulcerative or intensely inflammatory condition will yield shadow forms, which show no color. The finding of red cells in feces usually indicates ulceration. Exceptionally they are found in venous stagnation. Well-preserved corpuscles are seen in cases of hemorrhage from stasis low down (hemorrhoidal vein bleeding).

Detritus.—Besides the various elements already described, there are found in stools microscopic particles which are extremely small and impossible to identify. This material is called "detritus." It is intimately digested muscle remnants, plant cells, bacteria, epithelia, and isolated nuclei too far changed by the digestive juices to be recognizable. The presence of a large quantity of detritus is a good indication of the chemical and mechanical efficiency of gastrointestinal digestion.

Crystals.—Many crystals are found in feces, some derived from food, others from chemical changes in the intestine.

Triple phosphate or ammonium magnesium phosphate crystals are the commonest. They vary in size, some so small that they can be covered by calcium oxalate crystals, others very large. The best developed crystals are seen in fluid stools. Their shape is that of the "knife-rest" or "coffin-lid" but some are more or less irregular (see Figs. 33 and 34). Some are so large that they cover two microscopic fields, in which case they can be seen in the specimen with the naked eye, as a small white point on the slide. They sometimes appear as three- or four-cornered splinters representing breaking down of the "coffin-lid" formation. Triple phosphates are never bile stained. They are freely soluble in dilute acetic and other acids. They are insoluble in ammonium carbonate solution which distinguishes them from neutral phosphate crystals which they closely resemble. Some claim that they are found in normal and abnormal stools. Szydlowski found them absent in but one condition constantly; namely, icterus. Lynch states that they are never found in meconium. When found, we must be sure that there is no urine contamination.

Di-calcium phosphate or neutral phosphate of lime crystals appear in the form and size of those found in urine; namely, larger or smaller sheaves, with the points lying together. They may occur as rosettes. They are occasionally bile stained, whereas triple phosphates are never bile stained. A homogeneous transparent variety is seen in milk stools, this form being a combination with fatty acids. They are freely soluble in acids and in ammonia, as well as ammonium carbonate solution. They are found in normal stools, particularly when alkaline stools have been allowed to stand for some time. They have no diagnostic importance.

Neutral magnesium phosphate or trimagnesium phosphate crystals are found in stools showing ammoniacal decomposition. They occur as irregular sheaves, never as in urine as light refracting long rhombic plates. They are soluble in acetic acid, and become opaque when ammonium carbonate solution is added.

Calcium carbonate crystals appear as round or dumb-bell shaped crystals or amorphous granules. The addition of acetic or other mineral acids dissolves them with gas formation. Sulphuric acid causes them to assume a sheaflike form. These crystals are commonly seen in the stools of milk-fed children.

Calcium oxalate crystals are found in ingested vegetables that contain them; such as rhubarb, tomatoes, spinach, etc. They are not seen on a milk or meat diet. With a *large* amount of vegetables a moderate number have no significance; but with a *small* quantity of vegetables an enormous quantity of calcium oxalate crystals indicates an intestinal catarrh, showing that cellulose disintegration has been retarded, with an escape of the crystals from the plant cells. In hyperchlorhydria, an abundance of vegetables will not show many of these crystals, for these are dissolved by the excess of acid in the stomach; consequently there may be an increase of these crystals in the urine. They appear in various forms in feces, as envelope shapes, as typical rosettes, and as rhomboid and acicular varieties (see Fig. 35). They are insoluble in acetic acid and alkalies, but are soluble in mineral acids.

Crystals from Medicaments.—Dark bismuth crystals are found after ingestion of bismuth subnitrate. The use of salicylate of bismuth gives peculiar crystals of this drug; iron, charcoal, and manganese pass as black amorphous granules.

Cholesterin may at times appear as flat superimposed plates, often with re-entrant angles, but as they rarely show typical forms they must be identified chemically. They are easily soluble in hot alcohol, ether, and chloroform. They are insoluble in water, alkalies, and acids. On adding iodine followed by sulphuric acid there is a play of colors, yellow, yellow red, carmine red, violet, green, blue, with melting of the crystals from the edges. Cholesterin appears particularly in children where there is a large amount of mucus passed. It is commonly seen in meconium.

Charcot-Leyden Crystals appear as they do in sputum, as colorless octahedra with sharp margins and generally broken angles. They are commonly seen imbedded in mucus. Leichterstern spoke of them as especially characteristic of helminthiasis. His pupil, Buckler, further emphasized this relationship together with the presence of eosinophilia in the blood, but other authorities disputed this as constant or as sufficiently noteworthy to be of value in diagnosis. Charcot-Leyden crystals are found in abundance, it is true, in cases of helminthiasis, but they are absent in other cases. They have also been found in abundance in other conditions; to wit, in the mucus of enteritis membranacea, by Akerlund and Schmidt. They are no more characteristic of any disease when found in feces than when found in sputum, even though they are present in abundance in cases of bronchial asthma. Neubauer and Staubli[1] called the catarrhal inflammation of the large intestine with the presence of these crystals in large number an "eosinophilous proctitis."

Hematoidin and Hematin.—Hemin crystals are not seen in feces except after ingestion of blood sausage, but hematoidin crystals are common. They occur as reddish yellow rhombic plates, columns, needles, or bundles of needles, at times as amorphous masses. Uffelman reported them in infant feces and Lynch reported them in meconium. Von Jaksch found them in intestinal stagnation hemorrhages or free hemorrhages in adults. They are soluble in ammonia, the solution turning yellow. They are not soluble in potassium or sodium hydrate solutions. Nitric acid turns them blue.

Bilirubin appears like hematoidin as rhombic needle-shaped crystals or golden yellow kernels. They are found more frequently in infantile stools than in adults.

Uric Acid and Uric Acid Salts.—We doubt whether uric acid salts are ever found except as a result of contamination with urine.

Other Crystals.—Schilling[2] reported leucin and tyrosin crystals in feces in cases of pernicious anemia with chronic diarrhea.

Intestinal Parasites.—Parasites are living organisms which, for the purpose of procuring food, take up their residence in the living body. They may be of plant or animal origin; that is to say, phytoparasites or zoöparasites. We are here more especially interested in those parasites which take up their residence in the intestinal canal or structures adjacent thereto, and which may be detected by systematic stool examinations. Parasites might be occasional or permanent. We are here really concerned with the permanent parasites, for helminths, or intestinal worms, belong to this class.

Parasitism is relatively common in this country. It is much more common in tropical countries because of certain customs, failure to cook thoroughly, and also because many foods are ingested in a raw state. With the advent of rapid transport by air, many cases are directly imported into this country and are direct centers for infection of other persons. The spread of World War II into tropical lands resulted in many new cases among our military forces who were sent to these places for duty.

A full description of intestinal parasites may be found in Chapter XII.

Microchemical Reactions

Microchemical reactions are elicited by simply allowing a drop or two of a reagent to run in by capillary attraction between a cover glass and a slide after having made a smear of the feces. If the fecal mass is not fluid, it is impossible to do this, in which case drop the reagent directly on the preparation before placing the cover glass in position.

[1] München. med. Wchnschr., 1906, No. 49.

[2] München. med. Wchnschr., 1900, No. 42.

The following *reagents* are necessary in this work:

0.6% Saline solution
Glycerin
Alcohol, ether, and chloroform
30% Acetic acid
3 to 5% Hydrochloric acid
Concentrated sulphuric acid
15% Potassium hydroxide
Millon's reagent (see page 48)
Modified Lugol solution

Iodine	1 gm.
Potassium iodide	2 gm.
Distilled water	50 c.c.

1% Osmic acid
Sudan III (Herxheimer)
Equal parts of 70% alcohol and acetone saturated with Sudan III.
Sasthoff's Sudan III solution (glacial acetic acid 90 parts, 96% alcohol 10.0, a pinch of Sudan III).
Weak watery solutions of eosin, methylene blue, and safranin
Ziehl carbol-fuchsin
Concentrated watery solution of Nile Blue[1]

Polychrome solution of Friediger[2] made by mixing equal parts (2.0 c.c.) of concentrated alcoholic solution of dimethylamidoazobenzol, absolute alcohol, and 0.5 per cent alcoholic eosin solution, 20 drops mucicarmine, watery concentrated solution, 20 drops.

While it is not necessary to use all these reagents in all cases, one may adopt as a routine the following microchemical procedure in examination of stools.

Preparation of Specimens.—Make three preparations, one of the plain diluted feces, one mixed with acetic acid, and one treated with iodine solution. The first gives a good general picture. In the second, the striation of any muscle fibers is rendered more distinct; connective tissue is swollen up in contrast to elastic tissue which is unchanged; mucus is coagulated and rendered more distinct; cells are cleared and their nuclei appear sharper; albuminous granules are dissolved; some crystals, such as triple phosphate, disappear, while others, such as oxalates, are not affected. In the third preparation, undigested starch granules are colored deep blue; partially digested ones are brown or red.

Most of the material found in feces may be identified microscopically. However, there are certain very minute ingredients representing the breaking down of food remnants which we call "detritus" which cannot be identified.

Meat Fibers.—It is natural to find a certain amount of fibrous residue in the stool. Outside their mere presence, the quantity on certain diets is of great importance in drawing a conclusion as to the status of intestinal digestion. It is difficult to differentiate meat fibers from flesh, fowl, or fish; the coincident finding of scales of fish would suggest the fibers are of fish origin, while the presence of small pieces of feather would suggest fowl origin. The manner of cooking meat plays a part in the finding of meat fibers: well-roasted beef is more likely to remain in the stool than raw meat. Muscle remnants appear as isolated polygonal pieces devoid of sarcolemma. At times they lie together as if bound by the skeleton sarcolemma. They may be stained yellow from bile and thus attract one's attention immediately on looking through the microscope. Long and cross-cut striations are easily identified in the fibers. The size of these fibers varies from minute forms to pieces that entirely fill the field, under which latter circumstances they can be seen with the naked eye. The longer pieces have parallel sides, with cross striations.

---

[1] Arch. f. Verdaumgskrankh. I. 1896, p. 396.

[2] München. med. Wchnschr. 1912, No. 52.

Better digested pieces do not show these sharp contours. The cross striations may be seen with the medium power dry lens. Schmidt states that cross striations in the fibers from fish disappear more rapidly than those from mammalian flesh. The color of fibers is dependent upon admixture of bile, the usual color being yellow or yellowish green. Nuclei can never be detected unless there is an absolute disappearance of pancreatic juice, in which case there is macroscopic evidence of unchanged meat in the stool.

Microchemical Tests.—It is difficult to identify meat fibers by microchemical methods because of the admixture of bile elements and the presence of certain unknown factors. One may attempt to remove bile elements by the use of alcohol; bilirubin-stained meat may be freed of this interfering factor with chloroform. Acetic acid swells the fibers and brings out the cross striations fairly well. The addition of potassium hydroxide causes the fibers to dissolve. If a little copper sulphate is added to the potassium hydroxide and the picture watched under the microscope, a slight violet color (the biuret reaction) may be observed. The addition of concentrated nitric acid with warming of the specimen gives a yellow color of xanthoprotein. Millon's reagent causes a disappearance of structure, with a red coloration. Picric acid and iodine-potassium iodide solution gives a yellow color. Eosin solution causes the appearance of a red color in meat fibers more quickly than in other parts of the stool.

There are are a number of very elaborate methods for exactly determining the amount of meat fibers present in any given stool, together with an estimation of the meat ingested after selected test meals. These methods are of doubtful usefulness. Certain conclusions may be drawn, however, from the presence of a large number of meat fibers in the stool. The process of digestion of meat occurs mainly in the small intestine, due to action of the pancreatic juices. No further digestion of meat occurs beyond the ileocecal valve. Hence the appearance of unchanged or slightly changed fibers in the stool is an indication not of large, but of small gut dysfunction. The disturbance in digestion in the small intestine may be motor, secretory, or resorptive in character. Unduly rapid peristalsis may account for large amounts of meat fibers in the stool, yet this very rapid peristalsis may be based upon a secretory disturbance in the pancreas and the intestinal glandular apparatus. In some cases, whether catarrhal, ulcerative or purely neurotic in origin, all three factors may be deranged. It is, therefore, extremely difficult to say which one of the functions of the intestine is materially deranged when too much meat fiber appears in stools. Summing up all the facts and reports in the literature on this interesting point, we may state that *the undue presence of meat fibers after a test meal indicates a fault in small intestine activity.*

Connective Tissue.—It is very easy to identify connective tissue in the stools with the naked eye, but it is still easier with the microscope. The connective tissue fibers are not found so constantly in feces as are muscle fibers. The finding of connective tissue is dependent upon the manner of cooking. They are found in the stools of infants on a milk diet; their undue presence indicates gastric disturbance. They are not found when cooked milk is ingested.

There are casein clots found under pathologic conditions in stools to which Nothnagel gave the name of ''yellow mucus'' bodies. They consist of casein clumps which resemble short pieces of muscle fibers; but they are not muscular in origin, for they are found three to four weeks after the patient ceases to take meat, as in typhoid convalescent states when no meat has been taken for weeks. They appear as minute yellow round bodies; under the cover glass they give an impression of sandy particles. Microscopically they appear as yellow particles or cells lying close together. There is no differentiation of structure with higher power. They contain no formed elements whatsoever.

They are dissolved by the addition of a mixture of warm water and potassium hydroxide. Acetic acid causes partial precipitation of the clump which is insoluble in an excess of this acid. The addition of potassium ferrocyanide solution causes a white precipitate; Millon's reagent stains them red. They are not found in normal stools. Their presence according to Nothnagel and others indicates a disturbance in small gut activity, usually an inflammatory condition.

Pieces of ingested egg may at times be seen in the stool as small particles of the skin or coagulated material (fried egg remnants). Meconium ''corpuscles,'' so called, are found under the high power magnification. They appear as weakly stained, greenish yellow, homogeneous, round or oval bodies lying near epithelia and cholesterin crystals. Schmidt believed they are shrunken epithelia of vernix caseosa.

Fat.—Fat substances are frequently found in the stool as neutral fat, free fatty acid, or soaps.

(a) *Neutral fat* appears in droplets or in scales of irregular form. The fat scales are usually unstained. The fat droplets appear round. Fat droplets are often stained yellow. In stools of infants fat appears just as it does in a microscopic picture of milk.

Microchemical Reactions.—All neutral fats when heated melt and run together; when cooled, they resume their individual shapes. Fats are insoluble in water, weakly soluble in cold alcohol, soluble in hot alcohol, ether, and chloroform. They are unchanged by the addition of potassium hydroxide. Osmic acid stains fat black, but not necessarily all neutral fats: olein and oleic acid are stained black; palmitin, stearin, and their corresponding acids are not stained except with the addition of alcohol. Fat in the animal body contains all these components. Therefore, osmic acid stains fat black, but with varying shades dependent upon the proportions of the ingredients just set forth. Substances other than fat may be stained black by osmic acid. The addition of a few drops of Sudan III stains fat red. The Friediger reagent stains fat yellow. Concentrated Nile blue reagent produces a rose red color.

(b) *Fatty Acids* appear as drops or scales and are difficult to distinguish from neutral fat, at times showing characteristic crystals. The crystals appear as fine needles with pointed ends, similar forms being seen in sputum. They also appear as lancet-shaped plates, occasionally seen in infantile stools or as needles which resemble soaps.

Microchemical Reactions.—They differ from neutral fats in that they are soluble in potassium hydroxide and cold alcohol. They are not bile stained in the stool nor do they take the stains. They are, however, colored by osmic acid and Sudan III like the neutral fats. They stain intensively with dilute carbol-fuchsin while neutral fats remain unstained. This is the best differential stain.

(c) *Soaps* appear as scales or crystals. They show less luster than neutral fats or fatty acids. They may be unstained or stained slightly yellow by hydrobilirubin or bilirubin. They usually appear as unstained needles. One variety is round with fine radial striations.

Microchemical Reactions.—The basis of these soaps is alkali. They are soluble in hot water and alcohol. They are mainly calcium salt combination. Upon heating the preparation they do not melt as do neutral fats and fatty acids. They are not stained by osmic acid or Sudan III.

Significance of Fat in Stools.—Infantile stools show a great deal of fat, as neutral fats, fatty acids, and soaps. Adult stools show fat, but usually only soaps as scales. They are not found in healthy persons after a test meal. Naked eye appearance of fat means an undue quantity. This fat can be seen as grayish, shining particles of a smeary consistency. Fatty acid crystals are never found in normal stools, but, according to Muller, are always seen in the stools of starving people. Fat as a pathologic entity is seen in stools in connection with disturbances of the biliary function, affections of the neighboring mucosa, or the mesenteric lymph nodes, where there is increased peristalsis without anatomic changes in the mucosa. Gastric and large intestine disease does not seem to have much influence on the undue appearance of fat in stools. Pancreatic disease does not necessarily show fat in the stool.

Fatty stools are sometimes seen in breast-fed infants, a mass of fat droplets with increased fatty acids and soap needles. Biedert called this fatty diarrhea. The addition of acetic acid and heat causes the entire microscopic picture to appear as fat droplets. The appearance of visible neutral fat in the stools of adults, of course, is pathologic except where castor oil has been taken.

Starch.—Unchanged or slightly changed starch granules with concentric or excentric markings seldom appear in the stools of adults. They are never stained by bile pigments; they are of varying size; and are usually changed by the process of digestion so that, except in stools of infants, one does not see starch that has not been subjected to chemical or physical agents. We must accustom ourselves therefore to the changed forms; chemical reactions usually are necessary to identify starch bodies absolutely. The microscope reveals bodies that are of different size from the original starch granule as it was ingested, granules that fail to show the classical markings. Even the ingestion of raw potato gives a starch residue that is not classical, with a corrosion or unevenness of the periphery.

Microchemical Reactions.—Cold water has no effect on starch granules, but warm water produces a slow swelling. Acetic acid has no effect. Iodine produces the well-known blue color on unchanged starch granules. We recommend the use of Lugol's solution for this test (described on page 1404). Rub the solution well into the fecal mass. The cellulose fiber present often hinders penetration of the iodine solution and prevents a reaction. Semidigested starch gives a mahogany red color indicating it has changed to erythrodextrin. In the final stage of digestion starch gives no color at all with iodine. Certain spores of fungi give a blue color with iodine. As stated above, unlike muscle fibers, starch is never stained by bile pigments.

As starch is present in some of the undigested vegetable remnants, care must be taken in the preparation of specimens to prevent these fibers from giving up their starch granules with consequent false interpretations. The presence of starch granules intact in the stools of adults points very definitely to derangement of the activity of the small intestine; hence one must be sure that the granules seen are eliminated as such and are not pressed out of vegetable residue. Starch in vegetable residue is found after the ingestion of peas and beans, especially in dried forms. Pancreatic insufficiency alone does not cause starch granules to appear in the stool. The activity of the intestinal bacteria is responsible for this fact; they evidently digest the starch when the pancreatic juices fail to do so. When, however, there is increased peristalsis with this insufficiency, starch is found in the stool mass. The appearance of starch granules, unchanged or only slightly swollen, therefore, indicates a much more severe grade of insufficiency of small intestinal digestion than does the appearance of muscle fibers.

After the ingestion of oily seeds such as almonds, in place of starch, or with it, are seen granular structures of a rounded or angular form known as ''aleurone'' grains. These are albuminoid in nature and give no blue color with iodine. They are freely soluble in water and pass out of the cell in which they occur in the intestine. As they are insoluble in serum they are seen frequently in stools of serous diarrhea and dysentery.

Cellulose and Vegetable Tissue

Recognition of plant cells and cellulose is important in examination of stools because they may be mistaken for animal remnants and parasites. There is some obscurity as to the exact changes which take place in the process of digestion of vegetable matter. Plant cells are covered or enclosed with cellulose which is commonly supposed to be quite resistant to the action of digestive juices. This is not altogether true, for Moeller has shown that thin cellulose walls are readily broken down in the digestive tract; the pectinlike material which forms the middle lamellae of plant cells is attacked in the intestine, the cells fall apart, and are thus exposed to further digestive activity. Cellulose found in stools is not chemically the same as when ingested, for, instead of the faint *blue* which they give with iodine and sulphuric acid before digestion, they show a faint *purple* coloration. They are also much more freely soluble in copper oxyammonia after digestion than they are before digestion. The nature of the change is probably a hydrolysis brought about by the action of bacteria, the alkaline contents of the intestine, and the intestinal ferments. The ferments from certain molds have the power of breaking down the toughest kind of cellulose; for instance, that of wood. The digestion of cellulose is aided by constipation because the bacteria have a longer period of contact under these circumstances, whereas in diarrheal states with rapid peristalsis, the cellulose is passed almost unchanged. Modifications of cellulose, such as the cutinized peripheral walls of stems and leaves and corky cells, are much more difficult to digest than unaltered material. For this reason they are seen more often in stools. Flat epithelial cells with the intervening stomata of leaves and also plant hairs are characteristic. The plant detritus most often seen is the lignified cells forming the spiral pitted and scariform vessels, and the vast fibers of the fibrovascular bundles. Young green vegetables give only spiral vessels, pitted and reticulated ducts appearing chiefly in old and over-ripe plants. Woody tissue, fruit envelopes of vegetables and fruits, pass through the intestinal canal practically unchanged and appear in stools as such.

Chemical Analysis of Feces

Fresh stools are usually used in chemical researches, but one may use dried stools satisfactorily. Chemical analysis is not commonly performed because of the time necessary for its completion and because not every case requires such an analysis. However, close study of gastroenterologic conditions have convinced us that an occasional chemical analysis gives information to the internist which cannot well be otherwise obtained.

Reaction.—Stools are ordinarily neutral in reaction although we have seen acid and slightly alkaline stools apparently under normal conditions. This acid reaction is due to the presence of lactic or butyric acid and usually is indicative of fermentation in the intestinal canal.

Litmus is the usual indicator. Moisten red and blue litmus paper with distilled water, place on a glass slide and rub on a fragment of feces, observing the change of color from the other side. Or, place a small amount of stool in a test tube, add sufficient water to make a suspension, shake well. Into another small test tube introduce a few cubic centimeters of a watery solution of tincture of litmus, add a few drops of the fecal suspension. Observe the color change. If the cloudiness of the fecal suspension interferes with the reading, centrifuge the suspension first and use only the supernatant fluid. A method published by Bruce[1] follows: Make a one per cent solution of alizarin. Place two small drops of the indicator on a glass slide about one and a half inches apart. Dip a stirring rod into the fluid part of the specimen, or, if the feces are formed, merely puncture the mass. Mix thoroughly in one of the drops using the other drop as a control. An alkaline reaction is indicated by a reddish violet to violet color, neutral no change, and acid, a light yellow. The density of the colors depends upon the amount of acid or alkali present. By placing the slide upon white porcelain, the depth of color may be more easily determined. After a few observations, it is easy to detect any abnormality in the reaction.

Changes in Reaction.—Meat diet gives an alkaline reaction, the more meat ingested, the stronger the alkalinity. Blood, mucus, and pus change the reaction. As putrefaction increases alkalinity and fermentative changes increase acidity, the reaction must be taken soon after passage of the stool. Excess of fat increases acidity from the presence of fatty acids. Catarrh of the upper intestine increases the acidity if peristalsis is rapid. Chronic processes of this kind, however, produce an alkaline state; for instance, in chronic enteritis, whether tuberculous or amebic. If there is a block in the pancreatic juice outflow, there are fatty stools with marked acidity. The presence of much protein may be masked by the ammonia formed, giving an alkaline stool. Block in bile outflow gives an acid stool, if there is associated pancreatic disease; if, however, there is no pancreatic disease, the stools are alkaline. Infectious hepatitis gives alkalinity.

---

[1] Jour. Lab. & Clin. Med. 5: No. 1, 1919.

Reaction of infants' stools is dependent upon the diet. Breast-fed children have faintly acid stools. Bottle-fed children have neutral or slightly alkaline stools. The reaction is dependent upon the proportion of fat and protein present; i. e., when fat predominates the reaction is acid; when protein predominates it is alkaline. Therefore a breast-fed child with persistent alkaline stools shows that the mother's milk is possibly deficient in fats. The persistence of acidity in the stools indicates that there is an abnormal fermentative change.

"Dry" Constituents of Stools.—Normally the stool consists of watery parts, 65 to 85 per cent; dry solids 15 to 35 per cent. This is largely dependent upon diet, a meat diet increasing the solids and a vegetable diet increasing the watery parts. Under pathologic conditions the relative proportions of dry to watery constituents change; i. e., the dry part decreases when there is a block, the watery constituents increase, the most extreme condition occurring in cholera, where, according to the statistics of C. Schmidt, only 1 to 2 per cent of dry substances is found. Increase in watery constituents of stools is due to decreased resorption and increased secretions within the intestines. It might be termed a combination process, with the increase in transudation in the principal role. Schmidt believed that the extreme condition just noted, Asiatic cholera, is an example of blood transudation. An analogous condition obtains when senna or other purgatives are taken. The exact mechanics of these drugs is still in dispute, however.

Search for Bile and Biliary Constituents.—The pigment of feces which gives it its color is *hydrobilirubin* or *stercobilin,* formed from the bilirubin of the bile by reduction processes in the cecum and the upper part of the large intestine. This conversion of bilirubin into hydrobilirubin does not take place in man until bacteria appear in the intestine in early infantile life, usually at the time when the infant begins to take cow's milk.

Schmidt's Sublimate Test for Hydrobilirubin

Place a portion of fresh feces the size of walnut in a mortar and rub up with a small quantity of concentrated solution of bichloride of murcury (bichloride of mercury 25 grams, sodium chloride 2.5 gm., distilled water 500 c.c.). Allow to stand for twenty-four hours in a covered Petri dish. If hydrobilirubin is present, a deep red color develops in a few minutes. If only a trace is present it may take twenty-four hours to develop this color. This reaction may be obtained only if stools are quite fresh. Stools containing much fat must be extracted with ether before applying this test.

Schlesinger's Test

This is substantially the same as that for urobilirubin in urine, although some authorities deny the similarity chemically of hydrobilirubin and urobilirubin.

Shake a sample of feces with ether to remove the fat. Extract the residue with acid alcohol (hydrochloric acid 5 c.c., alcohol 95 c.c.); neutralize the yellow fluid that results with ammonia or sodium hydroxide solution. Mix with an equal quantity of 10 per cent zinc acetate in alcohol. Remove the precipitate, if any forms, by filtration through a dry filter paper. Examine the clear filtrate against a black background for the green fluorescence that indicates hydrobilirubin. Examine the red fluorescent solution with the spectroscope; it will show an absorption band between F and B which moves nearer to F when the fluid is acidified. No bands can be seen if feces contain blood.

These tests are used to prove whether stools are really acholic or not. A negative result with the zinc acetate test shows that no bile is reaching the intestine, and when associated with deep painless jaundice and progressive loss of weight and strength, is strongly suggestive of malignant disease of the head of the pancreas. Jaundice due to obstruction of the common duct permits a little bile to percolate through because there is a soft growth, whereas the hard growths at the head of the pancreas usually cause complete obstruction. Gallstones do not completely block the duct; infectious hepatitis does not completely block off the bile so that in these two conditions there is hydrobilirubin in the feces.

Bilirubin alone or mixed with biliverdin is encountered normally only in the meconium in the first week or two of life.

Gmelin's Test for Bilirubin

Add a few drops of nitric acid containing nitrous acid to a smear of feces on a piece of white porcelain; a play of colors, green, blue, violet, red, and yellow develops. If the stools are already green from the presence of chlorophyl or bacterial pigments, extract with water and test the aqueous extract.

Bilirubin is seen under pathologic conditions in diarrheal states, especially the jejunal diarrhea described by Nothnagel.

Bile acids, glycocholic and taurocholic, are completely reabsorbed from the intestine so that only a very small quantity appears in the lower part of the bowel. There, under the influence of putrefactive bacteria, they are split up into glycocoll, taurine, and cholalic acid. The cholalic acid combines to form cholate of soda which, under normal conditions, is the only representative of bile acids in the stool. If the intestinal contents pass so rapidly that the usual fission processes do not have time to take place within the large intestine, unaltered bile acids may be present.

Test for Biliary Acids

Extract a small quantity of feces with alcohol and filter. Distill the filtrate to drive off the alcohol, take up the residue with water rendered faintly alkaline with sodium hydroxide. Treat the watery solution with a trace of cane sugar, or a few drops of a dilute solution of furfurol, and add concentrated sulphuric acid. In the presence of bile acids a crimson color develops. The sulphuric acid must be added a drop at a time, shaking after each addition. Care must be taken that the temperature does not rise above 70° C., the test tube being cooled in water from time to time.

Watson's Test for Urobilinogen

This is fully discussed on pages 74 ff.

Spectroscopic and Chemical Tests for Occult Blood.—We have already discussed the presence of blood in the gross examination of stools, as well as its presence microscopically. Blood in extremely small amounts can be detected as "occult blood" by chemical or spectroscopic methods. These tests all depend upon the detection of one of the constituents of blood, hemoglobin.

The finding of occult blood in feces is of the greatest importance in the diagnosis of ulceration of the digestive canal. Hemorrhage from the nose, throat, esophagus, and hemorrhoids must be excluded. The finding of occult blood may establish whether an ulcer in the digestive tube is or is not healing. Bleeding from a cancer is *continuous* and bleeding from an ulcer is *intermittent.*

Significance of Occult Blood.—One must be guarded in the interpretation of a positive benzidine test for blood because it is difficult to differentiate exogenous from endogenous blood. The smallest amount of meat in the diet is likely to give a positive benzidine blood reaction. The patient must be kept on a meat-free diet for at least a week before making this test if the results are to mean anything. The physician who interprets this test must make certain that there has been no bleeding from the hemorrhoidal veins. The patient must be cautioned against brushing his teeth to the point of bleeding as the swallowing of even this small quantity of blood may cause a positive reaction in the stools. It is advisable, too, to restrict the amount of fat and chlorophyl-containing vegetables. A positive reaction means bleeding from any portion of the tract. In order to diagnose a case as ulcer of the stomach or pylorus, one must exclude bleeding from the nose, gums, mouth, throat, as well as the bleeding from portal or cardiac obstructions and from polyps and hemorrhoids as already stated. Blood is found in ulcus ventriculi and in malignant disease. During the suckling period blood is encountered in melena vera, hemorrhagic enteritis, from fissures, polyps, rectal papilloma, trauma, the hemorrhagic diathesis, invagination, and typhoid perforation. Duodenal ulcers are common in children and of course may lead to bleeding.

Spectroscopic Test

Snapper's method is the best.

Extract the feces in a mortar with acetone to remove the coloring matter. This leaves a dry mass.

Transfer the dry residue to a clean mortar, and rub up with a mixture of one part of glacial acetic acid and three parts of ether, preferably ethyl acetate.

Filter. Add one-quarter of a volume of pyridine, then a drop of ammonium sulphide solution.

Examine spectroscopically. If blood is present, a hemochromogen band will be found on the boundary between yellow and green.

Chemical Tests

The chemical tests are simpler. There are the guaiac, aloin, benzidine, and others.

Boas-Weber Test

Mix 1 gram of feces with 10 c.c. of 70% chloral hydrate in 95% alcohol.

Add 1 c.c. of glacial acetic acid and filter.

To 1 c.c. of the filtrate, add 1 c.c. of 2% guaiac resin in equal parts of chloral hydrate solution and hydrogen peroxide (3%).

A blue color indicates blood.

Kuttner and Guttmann Modification of the Weber Test

Stir 8 grams of feces with acetone. Let stand and pour off the supernatant fluid.

Treat the residue with 5 c.c. glacial acetic acid in 10 c.c. of 7% sodium chloride solution.

Extract with ether by adding the ether to the mixture, allowing it to settle, then decanting the ether.

Add a few drops of glacial acetic acid to the ether.

(1) Mix 1 c.c. of this with 2% guaiac resin,
(2) Mix 1 c.c. of this with 0.2% guaiac resin,
(3) Mix 1 c.c. of this with 0.02% guaiac resin.

All three are dissolved in equal parts of alcohol and oil of turpentine. The solution becomes **purple** if blood is present. The different concentrations are necessary because one cannot tell how much blood is present before making the tests.

Objection to the test: Less than 10% of blood in feces will not show a reaction.

Aloin Test

The aloin test is the same as above, except that a 2% alcoholic solution of aloin, to which turpentine has been added, is used instead of the guaiac solution.

A **red** color indicates a minimum of 5% of blood.

Pyramidon Test

Stir up a small part of the feces in 3 to 4 c.c. of distilled water. Filter. To the filtrate, add 3 c.c. of 90% solution of Pyramidon and several drops of acetic acid (30%) with hydrogen peroxide.

A **violet blue** is a blood reaction.

Boas Phenolphthalein Test

Reagent.—

Phenolphthalein	1 gram
Potassium hydroxide	25 grams
Distilled water	100 c.c.
Zinc powder	10 grams
Hydrogen peroxide, 3%	5 drops
Alcohol	2 c.c.

Technic.—

Stir 1 gram of feces in a mortar with 5 to 6 drops of glacial acetic acid and 10 c.c. of alcohol.

Filter.

Pour the filtrate on a mixture of 15 drops of Boas phenolphthalein reagent. A red color denotes blood.

Boas Thymolphthalein Test

Reagent.—

Thymolphthalein	10 grams
Potassium hydroxide	1 gram
Distilled water	25 grams
Zinc powder	100 c.c.

Technic.—Stir 1 gram of feces with 10 c.c. of alcohol and 10 drops of glacial acetic acid. Filter. To 30 drops of filtrate, add 30 drops of Boas thymolphthalein reagent and 15 drops of 3% hydrogen peroxide. A blue color denotes blood.

The Benzidine Test*

To make the benzidine reagent, dissolve 6 grams of benzidine base C.P. powder in 100 c.c. of 95% ethyl alcohol, and preferably allow to age 2 or 3 days before using. Collect fecal material in clean containers. Emulsify a small portion of the feces in distilled water, then pass through filter paper (Whatman No. 5 or more retentive paper) into a clean test tube to obtain a clear filtrate. If clouded due to breach in filter paper, refilter. To 3 c.c. of the filtrate add 8 drops of 50% aqueous acetic acid or glacial acetic acid, with mixing. Add 8 drops of hydrogen peroxide (C.P., 3%) to the resulting mixture and shake. Overlay the final mixture with an alcoholic benzidine solution, drop by drop, to obtain a contact ring. Tilt to bring about slight mixing at the ring. A positive reaction is indicated by the appearance of a greenish ring at the area of contact of the benzidine solution and the filtrate mixture, spreading into the benzidine solution either immediately or up to 2 minutes time, the intensity or gradient of color being in relation to the concentration of blood.

---

*This method which is an improvement on other methods described is by M. B. Levin and J. Y. C. Watt: Rev. Gastroenterol. 16: 650-651, 1949.

When testing for blood in vomitus and gastric contents, add water in half the volume of material used, filter, and carry through the test as previously. In urine, when only a few red blood cells are found microscopically, centrifuge or sediment the specimen. Transfer the bottom 0.1 c.c., containing the sediment, to a clean test tube, add 0.4 c.c. of distilled water, and continue as previously described.

This method eliminates most of the substances producing false positive reactions as follows: (a) filtration of the stool suspension eliminates blood-containing particles of meats, oxydase-containing particles of foods, particles of animal charcoal, and insoluble metal salts (of iron, copper, etc.); and (b) the acetic acid destroys soluble oxydases. In the contact layer or ring test the soluble hemoglobin compounds give true positive blood reactions in dilutions up to 1:100,000; meat-free days are unnecessary preceding this test for occult blood.

The Benzidine Dihydrochloride Test.—This is described on page 84.

The Gregersen Benzidine Test

Use a powder consisting of 0.025 gram of benzidine and 0.20 gram of barium peroxide, kept in wax papers. Add the powder to a glass beaker and then add 5 c.c. of 50% solution of acetic acid. This liberates the hydrogen peroxide. As the powders keep indefinitely, and the solution does not, it must be made fresh for each test.

Procure a small portion of feces from the central part of the fecal mass to avoid contamination of blood from the anal region. If the feces have dried, moisten with water.

Spread on a glass slide; add 2 to 4 drops of the benzidine-barium-peroxide-acetic acid mixture. If pathologic blood is present, within one minute a **green** or **green blue** color appears. To be sure of the activity of the benzidine, Gregersen used a blood test paper as a preliminary measure. If when a drop of benzidine solution is placed on this paper, it turns deep blue, it is proof that the benzidine is in good condition.

Positive reactions are divided as follows: If it takes 15 to 60 seconds for a pale green or blue green color to show, it is a weak positive, or a 1 plus. Blood content is less than 1%.

If it takes from 3 to 15 seconds, with deeper color, it is a 2 plus. This is from 1 to 5%.

With an instant color development, it is marked 3 plus, and means 5%.

If benzidine dihyrochloride, 0.025 gram, is substituted for the benzidine base, a much more stable color is produced.

The patient is instructed to eat no meat, fish or certain vegetables, such as French fried potatoes, for at least four days prior to the test. Gregersen denied that chlorophyl-containing vegetables will give a false positive.

Detection of Blood by Formation of Hemin Crystals.—

Teichmann's Method.—Dissolve the suspected stain in a few drops of physiologic saline solution. If the suspected blood is in a liquid, evaporate slowly on a glass slide, and dissolve the residue in a few drops of salt solution.

Allow to dry. Place a cover glass over the dried stain. Run glacial acetic acid under the cover glass.

Heat *very gently* until bubbles begin to form, replacing the acid as it evaporates. Allow to cool slowly. After cooling, replace the acid with water.

Examine for hemin crystals with the high dry and low power objectives. The hemin crystals are dark brown rhombic plates, lying singly or in crosses. (See Fig. 292, page 1204.)

Lime, fine sand, iron rust interfere with the production of the crystals. Too much salt, too great heat, or too rapid cooling interferes with the formation of the crystals.

Protein Substances.—Coagulated albumin is not found in stools under normal conditions. Soluble albumin and albumoses are present only under pathologic conditions. Inasmuch as nucleoprotein is always present, being derived from the nuclei of the mucosa and food remnants, always remove it before testing for albumin.

Detection of Albumin and Albumoses (Schloessmann)

Grind up the feces with water and dilute to a thin fluid consistency. Allow to stand one hour and filter through a double filter. Mix the turbid filtrate with a little pure kieselguhr and filter. Acidify the clear filtrate with 30 per cent acetic acid, avoiding an excess. The precipitated nucleoprotein is removed by filtration once or twice through a double filter. If it filters clear, it is tested for nucleoprotein by adding a few drops of 3 to 5% acetic acid, but if it is turbid or gives reaction for nucleoproteins, add a little kieselguhr and repeat the filtration. The clear nucleoprotein-free fluid is now tested for albumin by adding cold nitric acid, by boiling with acetic acid after the addition of a little sodium chloride, or by the ferrocyanide or potash test. Simon suggested using small pebbles instead of kieselguhr because the latter takes up albumin.

Albumoses are tested for by the acetic acid and brine test. Make the specimen strongly acid with acetic acid and mix with one-sixth of its volume of concentrated sodium chloride solution. If much protein is present, a white precipitate appears, even when cold. If, on warming, the precipitate disappears, albumoses alone are present. If the solution contains both albumin and albumoses, the precipitate will disappear as the solution is further heated, and again show a turbidity when the boiling point is reached. On filtration of this hot fluid, the albumoses form a white cloud in the filtrate as it cools; the albumin will remain on the filter.

Biuret Test for Albumin

Mix the feces with water to a consistency of thin syrup. Test with litmus paper and add to each 10 c.c. a quantity of 10% acetic acid and alcohol, varying with the reaction: if the stool is strongly acid, add 0.15 c.c.; if faintly acid or neutral, 1 c.c.; if slightly alkaline, 1.5 c.c.; if strongly alkaline, 2.0 c.c. to 2.5 c.c. Mix well. Rub 5 c.c. of chloroform into the mixture. Place in a test tube and let stand until the chloroform and the larger particles sink to the bottom. Decant the upper yellow and faintly tinted fluid into another test tube and add a disk of copper sulphate agar. After one hour take out the disk, wash with water, and examine. If the feces contain a large amount of albumin, the disk retains its bright blue color, but if no albumin or only a trace is present, it will be brownish blue. On pouring over it a little diluted solution of potassium hydroxide, the color will change to blue violet if albumin is present.

Copper sulphate agar is made by boiling 2 grams of agar in 100 c.c. distilled water until dissolved, then adding 10 c.c. of a 10% solution of copper sulphate. Pour the hot mixture into a glass tube 0.8 to 1.0 cm. in diameter, 20 to 30 cm. long, closed at one end by a plunger. Close the other end with a rubber cap. To make a test, remove cap, push in the plunger, and cut off a disk about 1 cm. long.

Caution: Hydrobilirubin also gives the reaction. Ury noted that other pigments and the remnants of paranuclein and casein give misleading results.

A simple test will be found on page 62.

Dissolved albumin is found pathologically only with inflammatory conditions. Albumoses are found only under rare conditions and always in association with albumin. They are found more frequently in stools of babies, but here they undoubtedly arise from the food ingested and not from the intestinal wall.

Casein.—No satisfactory test for casein has been devised. It is better to rely upon macroscopic tests than upon chemical analyses.

Nucleins.—Nucleoproteins are combinations of nucleic acid with a protein substance. Nucleins may be broken up into purine bases such as guanine, adenine, xanthine, hypoxanthine, and uric acid. They may arise from remnants of nuclei of food, secretions of the mucosa, juices poured from the alimentary tract by the glands opening into it, and bacteria of the intestinal canal.

Nucleins and purine are tested for as follows: Dilute the entire day's feces with 1 to 2 liters of water acidified with 15 to 20 c.c. of concentrated sulphuric acid, and heat for three hours over a free flame in a flask with a reflux condenser. Make alkaline with sodium hydroxide, acidify with 10 c.c. acetic acid, and heat for a short time on the water-bath. While hot, add 10 grams oxalic acid and an excess of chalk. Cool, make up to 1,500 c.c. with water, and filter. Wash off the residue with hot water, mix with acid solution of sodium acetate, warm, filter, and add the filtrate to the previous filtrate. Place 500 c.c. of filtrate in a flask, make alkaline with sodium hydroxide, mix with 10 c.c. of a solution of sodium bisulphite for each 100 c.c. of fluid, and boil. Add an equal quantity of 10% copper sulphate; boil for a few minutes. Filter, wash the residue on the filter into a flask, make up to 200 c.c. with water and shake well. Boil and add sodium sulphide solution previously treated with 1% sodium hydroxide to free it from sulphuretted hydrogen, until lead acetate paper no longer gives a brown color. Boil, add 10 c.c. acetic acid, heat until the copper sulphide is precipitated. If this does not occur, heat with 5 to 10 c.c. of saturated solution of aluminum acetate. Filter, mix residue with water, boil, filter, and add filtrate to that first obtained. Repeat several times. To the mixed filtrate add 10 c.c. of a 10% solution of hydrochloric acid, evaporate to dryness. Treat residue with 5 c.c. hydrochloric acid, and a little warm water; heat, cool, and filter. Wash the flocculent precipitate with water, test for purine bases with the copper or silver methods (for this method see section on test for uric acid under blood chemical methods).

Mucin.—Mucin is a compound protein radical and a nitrogen-containing carbohydrate, glucosamin. Boiling with acids makes mucin yield a copper-reducing substance like a sugar. Mucin dissolves in weak alkaline solutions and is precipitated by acetic acid. It may be identified by acetic acid, with microscopic study. The mucin becomes cloudy and develops lines. This is a better method than the chemical methods.

Protein Derivatives.—

Amino Acids.—The digestion and putrefaction of protein substances in the intestine yields a number of very interesting amino acids. These are leucine (amino-isobutyl acetic acid), tyrosine (oxyphenyl-amino-proprionic acid), and tryptophan (indol-amino-propionic acid). These undergo further changes, breaking down into phenol, paracresol, indol, and skatol, which appear partly in urine with sulphuric and glycuronic acids, and partly in feces in an unchanged state. Lack of pancreatic action causes leucin and tyrosin to appear in feces.

Gelatin Film Test for Stool Trypsin.—

The gelatin film test estimates roughly the proteolytic activity of stools by determining their ability to liquefy gelatin. Fecal suspensions are placed upon gelatin film (unexposed and unfixed) and the extent of removal of the gelatin film is noted.

In determining the significance of the test, Schwachman, Patterson, and Laguna[1] studied two groups of patients: (1) 500 normal and sick individuals; and (2) 50 patients with pancreatic fibrosis. In group 1, less than 5 per cent of the infant group lacked this proteolytic power. As one advanced into the older age groups, this percentage increased. The administration of a laxative for some older children without tryptic activity resulted in stools possessing tryptic activity.

A total of 220 separate stool specimen was examined from patients in group 2. In 209 specimens, there was no tryptic activity. The remaining 11 specimens from 7 patients showed definite tryptic activity. In this group, 3 patients had minimal tryptic activity in the duodenal fluid.

When oral pancreatin was given to patients with pancreatic fibrosis, the stools became positive for trypsin. When laxatives were given to a few patients with pancreatic fibrosis, the stool trypsin remained negative.

Conclusions and interpretations based on a single examination are hazardous. At least three specimens should be studied to eliminate or to make probable the diagnosis of pancreatic insufficiency, and whenever doubt arises, duodenal intubation is indicated.

There are two procedures, a test tube method, and a gelatin film method. The test tube method is more reliable and reproducible due to the fact that the film substrate in the gelatin film method might change its properties when exposed to different temperatures and if stored for varying periods of time. However, the film method offers the advantage of simplicity and convenience, and can be used as an office test. Photofilm is less reliable than gelatin film.

(1) Test Tube Method.—

Reagents.—

5% Sodium Bicarbonate Solution.—

Dissolve 5 gm. sodium bicarbonate ($NaHCO_3$) in distilled water and dilute to 100 c.c. with distilled water.

7.5% Gelatin Solution.—

Dissolve 7.5 gm. of gelatin in 100 c.c. distilled water heated to about 37° C.

Technic.—

Place 4 c.c. of distilled water in a test tube graduated at 5 c.c.

Add feces to the 5 c.c. mark.

In another test tube graduated at 10 c.c., place 9 c.c. of distilled water.

Add feces to the 10 c.c. mark.

This gives two samples of fecal material diluted, respectively, 1:5 and 1:10 with distilled water. Further dilutions can be made as desired.

Mix the contents of the two tubes thoroughly.

Place 1 c.c. of the 1:5 dilution in one tube and 1 c.c. of the 1:10 dilution of feces in another tube.

Add 1 c.c. of 5% sodium bicarbonate,

and 2 c.c. of 7.5% gelatin solution, previously warmed to 37° C., to each of the two tubes.

Mix well and place the tubes in a 37° C. water bath for 1 hour.

Then transfer both to an ice bath for 30 minutes.

At the same time, prepare a control tube containing all the ingredients except the feces and carry it through the same procedure.

---

[1] Schwachman, H., Patterson, P. R., and Laguna, J.: Pediatrics 4: 222, 1949.

Examine all tubes at the end of the 30-minute period of ice bath incubation.

If the contents remain liquid, record the tryptic activity as 4+.

A rigid gel indicates no activity.

Compare the tests with the control.

(2) Gelatin Film Method.—

Prepare stool dilutions in water as described in method 1.

Place 1 large drop (approximately 0.1 c.c.) of the well-mixed specimen on an unexposed, unfixed gelatin film such as is used in routine hospital practice. The film strip may be clipped to a cardboard to prevent curling.

Incubate the film at 37° C. for 1 hour. Although 37° C. is the recommended temperature, room temperature is satisfactory if the incubation period is prolonged to 1½ to 2 hours.

Wash the film in a stream of cold water with gentle rubbing.

The result is now apparent. A clearing at the site of the drop indicates enzyme activity. A complete clearing is designated as 4+, and a slight clearing only at the periphery of the drop as 1+.

If the drop is small or if the concentration of the specimen is too great, the material will dry and cake.

Proper bacteriologic precautions should be taken when dealing with cases suspected of enteric infections.

Both a 1:5 and a 1:10 dilution of stool are used routinely.

When performing the test for the first time, or when using new gelatin film, adequate controls should be run. Determination of the end point using normal infant stools or a standard trypsin solution is suggested.

Discrepancies between the film and tube methods occur in less than 1% of the tests. The tube method is more sensitive. For example, a specimen showing a 2+ reaction in the 1:10 dilution and a 4+ reaction in the 1:5 dilution on the film will be strongly positive by the test tube procedure using a 1:10 dilution.

Test for Tryptophan

First extract the feces with ether, then with alcohol; filter; evaporate to dryness; dissolve the residue in hot water. The amino acids crystallize out. They appear in characteristic form.

Fischer and Bergell's Test for Amino Acids

Rub up feces with water, then with acetic acid; boil and filter. Concentrate on the water-bath, cool, and shake eight hours with ether in a shaking machine to remove the fat. Decant the ethereal portion and mix the residue with potassium hydroxide, add 25% sulphuric acid and 20% phosphotungstic acid. Filter. Add barium hydroxide to the filtrate, concentrate it on the water-bath, and for every 500 c.c. of the original fluid add 2 c.c. of a 10 per cent solution of naphthalene-sulpho-chloride. Make slightly alkaline and shake for twelve hours in the shaking machine. Every three hours 1 c.c. of the reagent and a little potassium hydroxide are added. Flood the product at the end of the shaking with ether, acidify the supernatant fluid, and allow to stand 24 hours. At the end of that time a crystalline deposit of naphthalene-sulpho-tyrosin is formed. It is readily crystallizable from alcohol, melting at 129° C. The watery portion gives a strong Millon's reaction.

Phenol, Indol, Skatol.—These and other aromatic oxy-acids appear in stools as a result of putrefaction.

Rub feces to a thin mass with water and distill. This distillate contains these products and fatty acids. Neutralize with sodium bicarbonate and distill again. The fatty acids remain behind. To separate the phenol from the others, make distillate alkaline with potassium hydroxide and redistill. This distillate contains the indol and skatol. To obtain the phenol in the residue, make it acid with sulphuric acid and redistill.

Aromatic oxy-acids are detected by taking the residue from the first distillate, adding sulphuric acid, extracting with several portions of ether, evaporating off the ether, dissolving the residue in a little water, and testing with Millon's reagent. A red color on warming results.

Phenol is identified in the distillate by a red color or precipitate with Millon's; amethyst blue on the addition of a few drops of dilute neutral solution of perchloride of iron; and the formation of a turbidity, followed by a precipitate of yellow white needles or a cheesy mass of tribromphenol when bromine water is added.

Indol is tested for in the distillate by treating it with a few drops of nitric acid containing nitrous acid, when a red color and later a precipitate forms, due to the formation of nitroso-indol. On adding a few drops of sodium nitroprusside, and a little sodium hydroxide, a violet color appears which turns blue upon the addition of glacial acetic acid. A pine wood splinter moistened with strong hydrochloric acid turns bright red with an alcoholic solution of indol.

With **skatol** in the distillate, nitric acid containing nitrous acid causes a milky cloudiness to develop; on adding sodium nitroprusside, a yellow color develops, which, on boiling and adding one-half of its bulk of glacial acetic acid, turns violet. Skatol dissolves in hydrochloric acid with the formation of a violet color.

Evidence of intestinal putrefaction is usually sought for in urine rather than in feces; i. e., the test for indican in urine is most commonly used. The evidence of intestinal putrefaction from stool examination must be very carefully interpreted. These products are formed from protein matter, principally from meats. Rapid peristalsis prevents their occurrence. They are present in the largest amounts in constipated individuals on a meat or protein diet. The presence of hydrochloric acid in the stomach has an important bearing on putrefaction. Putrefaction can be increased by lowering the acidity by administering alkalies or atropine, and by giving a diet rich in albumin. As already stated, possible better and quicker results can be obtained by testing for indicanuria.

Cadaverine and Putrescin.—Cadaverine is pentamethylenediamine. Putrescin is tetramethylenediamine. They were first found in feces in 1888 by Udranszky and Baumann.[1] These two substances belong to the class of ptomaines. They were found originally in a case of cystinuria. They are formed from putrefaction of proteins and are related to the diamino acid, lysine, and ornithin. The presence of these two substances is naturally dependent upon protein decomposition. Some maintain they are formed as a result of bacterial activity within the intestinal canal. The tests are intricate and the clinical deductions mean but little. We will, therefore, not devote any space to the test, except to refer to Udransky and Baumann's original article (l.c.). While on this subject of the toxicity of fecal matter, we might refer to the work of Magnus-Alsleben[2] and Rogers and Carneier[3] that the injection of fecal matter from dogs and rabbits intravenously showed strongly toxic characteristics; also to the work of le Play[4] that the same results follow upon the injection of infantile stools.

Fat.—In a consideration of fat in stools we refer actually to the higher insoluble fatty acids. To the casual reader the fat in stools is closely related to the fat ingested and the ability or lack of ability of the normal physiologic processes to handle it. This is true in the main, yet, according to Williams' researches, there may be a general metabolic disorder which throws on the intestine the onus of eliminating some of the fatty acids, calcium salts, etc.; i. e., some of this fat is endogenous and not exogenous. As a rule, we look to the naked eye appearances and to the microscopic examination for a general outline of fat content. The most important conclusion to be drawn from the presence of a large amount of fat in stools is a block in the outflow of bile into the intestinal canal.

According to Biebert, the presence of more than 40 per cent of fat in stools indicates a condition of fat diarrhea. In normal dried stools of infants the fat should not exceed 20 per cent. Increase in fat content to a marked extent is always a biliary or pancreatic affair. Pancreatic juice has for its principal function the digestion of fats, which is markedly increased by the presence of bile and still more by the presence of both bile and hydrochloric acid. Bile of itself can do nothing with fat, but a mixture of bile and pancreatic juice can digest three times as much fat as pancreatic juice alone could do. Wohlgemuth states that the lipase or ferment of the pancreatic fluid exists in an inactive form and that it is activated by the bile. The bile also helps to dissolve the free fatty acids formed by the action of the pancreatic juices lipase on neutral fats, for these acids are insoluble in water but very soluble in bile: bile therefore assists in the absorption of fats.

No data of any value can be obtained from a chemical analysis for fat unless dried feces are used.

Place a required quantity of feces in a shallow porcelain dish of known weight, and carefully weigh. Transfer the dish and contents to a water-bath kept at 50° to 60° C. After most of the water has been driven off, break up the residue with a glass rod. Return the dish to the water-bath and heat for another half hour. Remove the feces from the dish, transfer to a porcelain or glass mortar, grind to a fine powder. Return the powder to the dish and heat for another half hour. Cool the dish and weigh, repeating the process. Two consecutive weighings must give the same results. This figure gives the weight of the dried feces from which to deduce the *water content*. If the stool contains much fat, it is difficult to dry it because the fat forms a film on the surface which interferes with evaporation. To avoid this, lower the boiling point by the addition of alcohol from time to time. Heat on the water-bath for three to four hours in a porcelain casserole. Add 50 c.c. of absolute alcohol, stir with a glass rod and again heat. In one hour add 25 c.c. more alcohol, stirring well, and evaporate as before. Add a third portion of alcohol, stir, and evaporate for another hour. Heat on the water-bath at 108° C. for a short time, thus removing all the water. When a constant weight is obtained there is no more water present.

Another rapid method of drying for fat estimation only: Mix the stool with 10 volumes of silver sand (Merck's purified sea sand) which has been successively washed in hydrochloric acid, water and alcohol and dried. Dry at 100° C.

Test for Total Fat

Neutral fats and free fatty acids are soluble in ether; combined fatty acids or soaps are not. To include both in the analysis, one must break down the latter and set free the fatty acids with a mineral acid. Place 0.5 gram of dry powdered feces in the lower bulb of the Schmidt-Werner milk tube with the use of a funnel. Pour 10 c.c. of diluted 30% hydrochloric acid into the tube to carry down the particles that may adhere to the sides. Heat in a boiling water-bath for 15 minutes, rotating occasionally to mix contents. Cool, fill to the 50 c.c. mark with ether, securely cork, invert forty or fifty times, rotate between hands to get rid of air bubbles, fix in upright position, allow to stand a half hour to give time for all the solid particles to sink to the bottom of the tube. Rotation of the tube occasionally hastens this process. Pipette off 20 c.c. of the clear supernatant fluid and place in small weighed beaker. Evaporate the ether, dry the residue on a water-bath, cool, and weigh. The difference in weights is the weight of the fat contained in 20 c.c. of the ether. Read off the height of the liquid in the tube after the 20 c.c. have been withdrawn.

Calculate the percentage of fat as follows:

If $w =$ the weight of the feces taken
$x =$ the weight of fat found in 20 c.c. of ether
$y =$ the number of c.c. left in the tube

then $(y - 10)$ will be the amount of ether left in the tube, for 10 c.c. were dilute hydrochloric acid, and $20 + (y - 10) = (y + 10)$ will be the total bulk of the ether in which the fat from "w" grams of feces was dissolved.

$$\frac{x\ (y + 10) \times 100}{20 \times w} = \text{the percentage of fat in the stool.}$$

Besides the total fat, the ether extract of the feces contains the lower fatty acids, cholesterin, lecithin, cholalic acid, pigments, etc. These exist in quantities so small that they are negligible.

Tests for Neutral Fat, Free Fatty Acids, and Soaps

Neutral Fat and Free Fatty Acids are soluble in ether, whereas the combined fatty acids or soaps are not, and must be broken down by the addition of a mineral acid to make them soluble.

Test for **neutral fats** in the following manner: Place 0.5 gm. of dried feces in the lower bulb of the Schmidt-Werner tube; add 10 c.c. of distilled water; heat the tube for fifteen minutes in a boiling water-bath, rotating the tube occasionally to get a good mixture. Cool; fill to the 50 c.c. mark with ether; carry on the remainder of the test of the feces for the total fat and the fatty acids and neutral fats side by side, labeling the tube "A" which has been treated with acid,* and the tube "B" which has been treated with water. The ether extract of tube B gives the sum of the neutral fats and the fatty acids (free). The contents of tube B gives the unsaponified or, as Cammidge speaks of it, the "unsoaped fats," while the difference between the two gives the combined fatty acids or soaps. To determine the relations between the neutral fats and free fatty acids, dissolve the ether extract from tube B in an excess of ether (about 20 c.c.), add a few drops of an alcoholic solution of phenolphthalein; then titrate with a decinormal sodium hydroxide in alcohol. The number of cubic centimeters used to neutralize the solution, multiplied by 0.0284, gives the weight of the free fatty acids contained in the quantity of feces originally used. The difference between this and the weight of the ether extract gives the quantity of neutral fat (and lipoids).

There are a number of other tests for fat which are sufficiently important to be carried out in certain cases.

The **acid test** is the number of milligrams of potassium hydroxide necessary to neutralize a gram of fat; this is a measure of the degree to which the fat has been hydrolyzed. Weigh a small amount of the fat, dissolve in neutral alcohol or alcohol-ether; add a few drops of 1% alcoholic phenolphthalein, or if the fat is dark in color, a 2% solution of alkali blue 6 B; titrate with tenth or half normal aqueous potassium hydroxide.

The **saponification value** is obtained by determining the number of milligrams of potassium hydroxide necessary to neutralize the fatty acids split off from one gram of fat on saponification. Boil a weighed quantity of fat with alcoholic potassium hydroxide on a waterbath for half an hour. Titrate the alkali in the flask with half normal hydrochloric acid, using phenolphthalein as an indicator. Compare the result with that given by a control experiment in which the alcoholic potassium hydroxide only was used. The difference gives the amount of alkali neutralized by the fatty acids liberated from the weighed quantity of fat, and from this the saponification value can be calculated. As the soaps formed are hydrolyzed by water, and, therefore, react alkaline, it is necessary to add neutral alcohol from time to time in sufficient amount to keep it at over 40% since hydrolysis of soaps does not occur in this strength of alcohol. The saponification value is a measure of the mean molecular weight of the fatty acids entering into the composition of the fats. By means of it the nature of the fat present is suggested. Fats such as tallow or lard give a saponification value of about 195, butter 220 to 233, cocoanut oil 250, and cod liver oil about 171 to 189.

---

*Test for total fat.

The **ester value** is the difference between the saponification and the acid values of the fat, and is therefore the number of milligrams of potassium hydroxide necessary to neutralize the fatty acids present in the form of neutral esters.

The **iodine value** of a fat is the amount of halogen, reckoned as iodine, that the unsaturated fatty acids of this fat will absorb, expressed as a percentage of the weight of the fat. The iodine value of a fat or a mixture of fats is, therefore, an index of the proportion of unsaturated or saturated fats present, for the latter do not absorb iodine. In feces, oleic acid, with an iodine value of 90.1, is the most important unsaturated fatty acid. Feces of children fed on cow's milk have a lower iodine value and a higher melting point than of those fed on mother's milk. The first stools of the latter after the meconium has been voided are particularly rich in this substance. They have an iodine value of 48% and a melting point of 40° C. At the end of the first week the proportion of oleic acid sinks, and the melting point and iodine value approximate those of older children; namely, 47° C. for the former and 20% for the latter. In cases of dyspepsia, the iodine value rises and the melting point sinks.

Method: A titrated solution of iodine monochloride, obtained by mixing solutions of iodine trichloride and iodine in glacial acetic acid, is added to a solution of the fat in carbon tetrachloride. This, after standing in the dark for one to two hours, is mixed with a 10% solution of potassium iodide, and is then titrated with a standard solution of sodium thiosulphate. From the amount of iodine absorbed by the known weight of fat taken the iodine value can then be calculated.

Hehner's value is the percentage of fatty acids insoluble in water given on saponification of the fat. For triolein, the Hehner value is 95.7, for lard and most fats and oils 95, for butter between 86 and 88, and for cocoanut oil, still lower.

Saponify a weighed quantity of fat with alcoholic potassium hydroxide, evaporate the alcohol, dissolve the soap in hot water, and make the solution acid with hydrochloric acid. Heat until the aqueous layer is clear, and filter. Wash the fatty acid with boiling water as long as any acid reaction can be detected, then dry and weigh.

The **Reichert-Meissel value** is the number of cubic centimeters of decinormal potassium hydroxide necessary to neutralize the volatile acids produced by the saponification of 5 grams of the fat, and is a measure of the amount of lower fatty acids (which volatilize in a current of steam) that enter into the composition of the fat. To obtain comparative values, the experiment must be carried out under certain prescribed conditions, which vary somewhat in different countries.

The **acetyl value** gives the number of milligrams of potassium hydroxide necessary to neutralize the acetic acid liberated when one gram of acetylated fat or fatty acids, formed by heating the fat with twice its weight of acetic anhydride, is saponified. Animal fats do not give an acetyl value unless they are mixed with cholesterol or some alcohol soluble in water, but certain vegetable oils have high acetyl values; thus, for castor oil, it lies between 153 and 156.

Total Nitrogen.—

Use the Kjeldahl method. The ammonia nitrogen and protein nitrogen are converted into ammonium sulphate by heating with sulphuric acid. The ammonia is set free with an alkali and the distillate is titrated with a standard acid. To destroy the organic matter, mercury is added to the sulphuric acid mixture. Use dry stool or about twice the weight of fresh stool.

Weigh two grams of dried feces and place in the bottom of a Kjeldahl flask.

Add 800 c.c. of pure sulphuric acid, 200 c.c. of fuming sulphuric acid, and 100 grams of anhydrous phosphoric acid free from nitrogen. Add about 0.1 c.c. mercury from a pipette; place flask aside for twelve hours after shaking it, as it will foam too much if heated at once. Heat in the usual inclined position on a sand bath or asbestos mat with a small flame, later with a full flame, until the fluid is clear. This takes three to four hours. Shake down any particle that comes up on the neck of the flask. Cool and wash the contents into a 500 c.c. distillation flask with 50 c.c. water. Wash the residue into this flask with fresh portions of water, keeping the total contents below 200 c.c. Cool the flask, add 50 c.c. of 10% sodium hydroxide solution, 40 c.c. of 4% potassium sulphate solution, and a spoonful of talc or a few zinc filings. Add 60 c.c. of the sodium hydroxide solution, connect quickly with the condenser. The delivery end of the condenser dips into a small flask containing 50 c.c. of fifth normal sulphuric acid. Heat and distill. Disconnect and stop the heating in 20 minutes. Wash the delivery tube with a little distilled water into the receiving flask, adding a litle cochineal or methyl orange solution. Titrate with N/5 sodium hydroxide. The number of milligrams of nitrogen in the dried stool is obtained by multiplying the number of c.c. of N/5 sulphuric acid bound by the distilled ammonia by 2.8.

The interpretation of the amount of total nitrogen found is difficult: The nitrogen comes from the proteins of food, from the secretions and metabolism of the gastrointestinal tract, and from bacteria. Schmidt and Strassburger consider that on a diet yielding only a small amount of residue, bacteria furnish no less than a quarter, or even half, of the total nitrogen of stools. In general very little help is obtained in the diagnosis of pathologic conditions from total nitrogen determinations.

Carbohydrates.—

Sugars do not ordinarily appear in stools of adults. Interference with absorption may cause them to appear in stools of children. Sugars can be determined by the usual reduction processes. It is more important to determine, however, whether the normal process of fission has taken place. Orban proved the absence of lactose in the acute stages of several intestinal affections of children, and Pfaundler found that the inversion of milk sugar does not take place in marasmic children, thus accounting for the lactosuria that has been reported in such cases.

Extract the dried stool with water; filter; test the filtrate with or without evaporation, with Fehling's, Trommer's test, Nylander's, phenylhydrazin, or Benedict's test. Albumoses and peptones are interfering substances; therefore, it is preferable to extract with alcohol, filter, and evaporate the alcohol, dissolve residue in water, and apply the reduction tests.

Starch may best be determined by the microscope or the microchemical methods already described.

Of pure chemical methods we shall describe the well-known Schmidt fermentation test. This test depends upon the fact that the dissolved carbohydrates, as well as those starches which lie free and are easily acted upon, are inverted by the diastase which is always present in the feces, and are then fermented by the intestinal bacteria, with the formation of gas.

Technic.—

Place 5 grams of stool, well mixed with water, in the receptacle of the Schmidt apparatus, close with a rubber stopper, excluding air bubbles. Connect the outlet tube with a closed graduated tube filled with water, in which the gas that is formed collects. Join this in turn to a tube where the displaced water passes. Fill and set up and place in the incubator at 37° C. for 24 hours. If gas has collected in the tube, cool the apparatus to the temperature of the room and measure the gas. Test the reaction of the fecal mixture with litmus. An acid reaction plus gas indicates the presence of fermentable carbohydrates. Only a positive result is of value.

Schmidt claims that a patient should take a test diet for several days and if the gas fills one-fourth of the tube, intestinal dyspepsia can be proved. Rice, cellulose, and fat should be excluded from the diet.

Concretions.—Our interest in the various kinds of concretions found in stools lies mainly in distinguishing coproliths from real concretions such as gallstones, pancreatic calculi, and intestinal sand. It is comparatively simple to distinguish between a stone made up of organic from one of inorganic structure; heat on a platinum dish causes the organic material to carbonize and crumble away, while the inorganic substance remains unchanged or blackens a trifle. Furthermore, organic pancreatic stones, according to Minnich, on heating give off an aromatic odor and are easily soluble in chloroform.

Gallstones consist of a mixture of the constituents of the fluid in which they are produced. They are always "mixed"; that is, they have more than one constituent. Cholesterin is found in all stones. Calcium salts of the bile pigments are commonly present; sometimes they form the chief part of the stone. Naunyn divided them into the following classes:

(a) *Pure cholesterin stones,* smooth surface, white to yellow, rarely green or brown on the surface, crystalline, oval or spherical, seldom faceted.

(b) *Laminated cholesterin stones* contain calcium salts of the bile pigments, found in yellow, brown, or green layers, alternating with the white layers of cholesterin. Cholesterin forms 75 per cent of the stone. They are often faceted.

(c) *Common gall bladder stones:* Chemically like the former; physically they show an external firm laminated crystalline crust which surrounds a softer pigmented nucleus, frequently containing a cavity filled with a yellow alkaline fluid. They are seldom larger than a cherry. Surface is yellow, sometimes white or brown. They are usually faceted.

(d) *Mixed bilirubin-calcium calculi:* Calcium bilirubin is the chief constituent, but there is also found biliverdin, calcium bilifuscin, oxidized bilirubin, always some cholesterin. These stones are small and occur in two forms, one of waxlike consistency, with round irregular surface; the other hard and brittle, steel gray in color, with a metallic luster.

(e) *Rare forms* are found, to wit, amorphous and incompletely crystalline cholesterin gravel with a nucleus of calcium bilirubin, surrounded by cholesterin, varying in size from a grain of sand to a pea; calcareous stones consisting of calcium carbonate with bilirubin calcium, rare in man, but common in cattle and herbivorous animals; concretions with included foreign bodies such as ligatures, needles, plum stones, around which gallstones are formed.

Test for Stones

We have already noted the test in a platinum dish. Boil two grams of the powdered stone in a flask with distilled water to remove the bile acids and other water-soluble substances. Divide the filtered extract into two parts. (a) Evaporate one to dryness and weigh, giving the weight of the water-soluble material in the amount of dry material used. Incinerate and again weigh, this weight being the quantity of water-soluble ash. Evaporate the other half (b) to dryness, and extract the sodium glycocholate with a mixture of alcohol and ether from the dry residue.

Dry the residue from the water extract and extract with warm alcohol, thus separating the fats along with a small proportion of the cholesterin. Extract the residue from this ether, which dissolves the cholesterin. Evaporate the ether, weigh the cholesterin, and examine for crystals of cholesterin, which are best seen by re-crystallizing from warm alcohol; also try the chemical reactions for cholesterin. Crystals treated with sulphuric acid (5 parts of concentrated sulphuric acid with one part of water) melt at the edges and turn crimson. Add a small quantity of iodine and note a play of colors: violet, blue, green, and red. Evaporate a small quantity on the edge of a porcelain crucible with hydrochloric acid and add a trace of ferric chloride; this gives a blue color. Dry cholesterin dissolved in chloroform and mixed with an equal volume of concentrated sulphuric acid gives, on shaking, a blood red upper layer of chloroform which changes to cherry red and finally to purple, and a lower green fluorescent layer of sulphuric acid. With dilute solutions, the chloroform solution is yellow to rose red, while the sulphuric acid is yellow with a greenish fluorescence. A small quantity of cholesterin, mixed with acetic anhydride, gives a rose color changing to blue and then to blue green on adding concentrated sulphuric acid drop by drop (Liebermann-Buchard reaction). A specimen, purified by repeated crystallization from hot absolute alcohol and dried, melts at 145° C.

After treatment with ether, extract the residue with dilute hydrochloric acid (1 to 3) and filter. (Calcium, if present, is shown by making a portion of the solution alkaline with ammonia and adding acetic acid and ammonium oxalate solution. Copper may be detected by adding a few drops of potassium ferrocyanide, when a brown color develops.) Wash the residue on the filter with water until free from hydrochloric acid. Dry the filter, cut into pieces, and warm in a dry flask with chloroform. Filter and examine for bilirubin, evaporate a small portion spontaneously on a watch glass, showing microscopically small, ill-defined rhombic plates, or indistinct crystalline grains which on being moistened with nitric acid give the colors of Gmelin's reaction (page 1289). Again, shake the chloroform mixture with dilute sodium hydroxide; the pigment goes into alkaline solution, while the chloroform remains decolorized. The separated alkaline solution left to stand in the air turns green from the formation of biliverdin. Detect the presence of hydrobilirubin by the spectroscope.

Examine the stools carefully for stones, especially after washing in a sieve arrangement already described. Many of the objects commonly called gallstones are not real stones; they are intestinal sand coproliths. Chemical and microscopic study of all stones must be made to verify the diagnosis. With the aid of the roentgen ray, too, much information about the gall bladder region is obtainable which will substantiate the stool findings. An artefact is sometimes seen after the administration of large quantities of olive oil in suspected cholelithiasis. It is a concretion composed of fatty acids, fats, and soaps; it is soft, greasy, and transparent. Microscopic and chemical examinations will reveal its true nature.

Pancreatic Calculi are rarely found, less than a hundred cases having been reported. They are small, gray white, with no facets on the surface. Heated on a platinum dish they yield a large amount of white ash and give off an aromatic odor, as above stated. They are soluble in chloroform. Chemically they consist of 50% lime, as carbonates, phosphates, or even oxalates. Pigments and cholesterin in a very small amount are found in the external layers. Cammidge (l. c.) presents a very good illustration of these stones.

Intestinal Sand has been described above.

BACTERIOLOGY OF THE STOOLS

When we apply bacteriologic methods to a study of stools, we are apparently entering upon a task that has no ending. The variety and number of bacteria normally found in stools are so great that ordinarily, unless there is some special reason, we do not make a thorough bacteriologic test. There are certain occasions, however, when a bacteriologic study must be made. Some mathematically inclined bacteriologist has shown that a normal individual passes out via the stool every day some *one hundred and twenty-six billion bacteria,* of many varieties and kinds. What would it avail one, therefore, to conduct routine bacteriologic analyses?

Detailed methods for bacteriologic examination of the feces are found in Chapter X, pages 1629 ff.

In searching for bacteria, feces should be examined as soon after passage as possible. They should be passed in a sterile vessel, placed on ice, and rapidly smeared, stained, plated, and inoculated on special media or placed at once in a preserving medium. Refer to the chapter on Bacteriology. The investigation of the stools of babies is preferably carried out by procuring the stool by means of a specially devised and sterilized glass tube. That suggested by P. Cohnheim is very serviceable. (See Fig. 311, page 1265.)

CHAPTER IX

SPECIAL TESTS

C-REACTIVE PROTEIN*

C-reactive protein is an abnormal protein which appears in blood in the acute stages of various inflammatory disorders and which is undetectable in the bloods of healthy persons. The name of the protein is derived from the fact that it forms a precipitate with the nontype-specific somatic C polysaccharide of the pneumococcus. It is an alpha-globulin and its production is stimulated by bacterial infections, various pyogenic agents (typhoid vaccine), or the products of injured tissue (as in myocardial infarction).

The C-reactive protein was isolated and purified by MacLeod and Avery in 1941.[1] By injecting the purified protein into rabbits, an antiserum is obtained (C-reactive protein antiserum, CRPA). This antiserum is used for the demonstration of C-reactive protein in human serum by the employment of a simple precipitation test.[2]

C-reactive protein is invariably present in the sera of patients with frank rheumatic activity as well as in the sera of patients with low-grade rheumatic activity. The presence of CRP in the serum of a rheumatic patient is an "extremely reliable and sensitive indicator of rheumatic activity." The test is not specific (since CRP appears in blood as a response to other inflammatory conditions also); however, in the case of questionable rheumatic fever, with minimal or no clinical signs, the presence of CRP may be of diagnostic value. The absence of CRP rules out rheumatic activity.

In following the course of treatment in rheumatic fever, the disappearance of CRP from the patient's serum is a true reflection of inflammatory activity as a result of therapy or spontaneous remission.

The advantages of the CRP test over the erythrocyte sedimentation rate are: the sedimentation rate may be elevated without inflammation, as in anemia, pregnancy, convalescent stage of infectious disease, nephrotic syndrome, and hyperglobulinemia; it may be normal in cases with frank rheumatic activity in the presence of congestive heart failure. In such cases, CRP, which is present *only* in inflammatory conditions, is a valuable adjunct or substitute for the sedimentation test.

In rheumatic patients treated with ACTH and cortisone, C-reactive protein reappears upon discontinuing treatment. This is due in most cases to the so-called "rebound phenomenon" which disappears within days. When CRP is present in such cases for a period longer than two weeks, treatment is renewed, since the persistence of CRP is considered evidence of the persistence of rheumatic activity.

---

*This section contributed by Alex C. Sonnenwirth, M.S., St. Louis, Mo.

[1] J. Exper. Med. 73: 183, 1941.

[2] Anderson, H. C., and McCarty, M.: Am. J. Med. 8: 45, 1950.

In Sydenham's chorea the CRP test is negative, a positive test being indicative of associated carditis. In cases of coronary insufficiency *without myocardial necrosis,* the CRP test is negative. In cases of myocardial infarction and coronary occlusion and of myocardial infarction with coronary insufficiency, the test is positive.

It is to be expected that studies of CRP in various other inflammatory conditions may increase the value and usage of this test. There are preliminary reports (1955) indicating areas in which the CRP test may be useful (differentiation of widespread malignant disease from primary carcinoma, viral hepatitis, tuberculosis). However, it would be premature at this time to draw general conclusions from these reports, since they have not yet been adequately evaluated.

At the present time the CRP test is accepted as a valuable aid in the diagnosis of low-grade, questionable rheumatic fever, in following the course of this disease during treatment, and in the differential diagnosis of coronary insufficiency, particularly as to the presence or absence of myocardial infarction and cessation of inflammation.

Regular Technic.—

Draw up the CRPA* to one-third of a 90 mm. long, 0.4 mm. inside diameter capillary tube length. Place the finger over the tube. Wipe the tube clean.

Draw an equal amount of the patient's serum into capillary.

Invert the tube several times, slowly, to insure proper mixture of CRPA and serum. Do not let an air pocket form between CRPA and serum.

Insert the capillary tube in the capillary tube rack, making sure that the bottom meniscus of the fluid column in the capillary tube is several mm. (5 to 10) above the clay. Wipe the capillary tube clean to facilitate subsequent reading.

Place the rack in an incubator set at 37° C. for 2 hours. At the end of this time preliminary reading can be made to determine whether the reaction is positive or negative; presence of precipitate indicates a positive reaction.

Remove the rack from the incubator and place in a refrigerator at 40° C. overnight. At the end of this time, a final reading may be made as to the relative quantitative aspect of the reaction. It must be borne in mind that packing may not have occurred. In such cases, where the precipitate is dispersed throughout the fluid column, the reading may be obtained from the summation of the total dispersal precipitate. Semiquantitative as well as definite qualitative readings are best made against a dark background, using oblique illumination.

The readings may be evaluated as follows:

No visible reaction	0
Definite but slight reaction 1 mm. column of precipitate	1+
Moderately strong (2 mm.)	2+
Strong reaction (3 mm.)	3+
Very strong reaction (4 mm.)	4+

Finger-tip Technic.—

A modification of this method has been worked out by Goldin and Kaplan, which is known as the "finger-tip method," which can be used for children and debilitated adults.

---

*C-reactive protein antiserum available from Schieffelin & Co., 18 Cooper Square, New York 3, N. Y.

Draw the blood into capillary tubes, larger than those used for the CRP test, preferably blood-collecting tubes.

Seal the tip of the tube with paraffin or in a flame.

After the blood has clotted it may be centrifuged or allowed to stand overnight at room temperature.

The inside diameter of these special tubes should be large enough to allow transfer of the serum directly to the capillaries in which the CRP is being run.

The evaluation of the test is as stated in the regular technic.

DISCUSSION OF HORMONE ASSAYS*

Gonadotropins

Gonadotropins fall into two categories: those of pituitary origin and the chorionic gonadotropin. The biologic characteristics of these substances suggest that they are different chemically. The action of chorionic gonadotropin in human pregnancy urine (PU) simulates that of LH (luteinizing hormone) in the male and FSH (follicle-stimulating hormone) plus LH in the intact female rodent.

The actions of gonadotropins are usually measured by one or more of the following observations in rats or mice: (a) increase in ovarian weight, (b) increase in uterine weight, (c) proportional incidence of vaginal cornification, (d) premature opening of vagina, (e) formation of corpora lutea, (f) changes in the histology of the ovaries, vagina, and uterus, and (g) increase in the weight of the seminal vesicles and prostate.

In interpreting the assays of gonadotropins it is important to take into account that the proportion of FSH and LH affects the qualitative and quantitative responses. These hormones act synergistically and when one of them is present in much larger amounts than the other the characteristic effects of the other may be masked. This is particularly true if a large amount of FSH is present in an extract with a small amount of LH. It is possible for a dosage of an extract containing much LH and little FSH to produce the same size ovaries as a dosage of another extract containing much FSH and little LH. Therefore, a quantitative assay gives little information concerning the amount of each substance present unless it is also accompanied by a careful qualitative analysis.

To determine the approximate amount of the two factors in any given specimen, it is necessary to compare their relative activities by the ovarian and seminal vesicle response. The enlargement of the ovaries is governed chiefly by FSH and seminal vesicle largely by LH, although in each instance the response is increased by the presence of the other factor.

The finding of mature unruptured follicles in immature mice or rats indicates the presence of FSH; hemorrhagic follicles or mature corpora lutea alone or in combination signify LH.

In clinical studies of gonadotropin secretion the effect of a mixture of these hormones is usually determined (gonadotropins, total activity). The gonadotropins are extracted either by precipitation with alcohol or by ultrafiltration. Gorbman[1] described a convenient method for the ultrafiltration of urine through a collodion membrane under pressure. Immature mice are used most frequently for the bio-assay because they are approximately five times as sensitive as rats. It is advisable to use both uterine and ovarian weights as assay end points. With small doses uterine weight increase occurs without ovarian weight increase. At higher dose levels, increase in ovarian weight and maximal increase in uterine weight are observed.

---

*Contributed by V. Allen, Director, Biochemical Procedures, Inc., Los Angeles, Calif.

[1] Gorbman, A.: Endocrinology 37: 177, 1945.

Normal male urine so processed and assayed for gonadotropin (in 21- to 24-day-old female mice weighing from 6 to 8 grams) gave values of 5 to 15 mouse uterine units per 24-hour urine sample, a unit being the amount of hormone necessary to produce a 100 per cent increase in uterine weight in immature mice.

Using alcohol precipitation or dialysis extraction technics and the mouse uterine weight, Klinefelter and associates[3] found that normal postpuberal males usually excreted 6.6 mouse uterine units or more per 24 hours; none excreted as much as 105 units. Regularly menstruating females excreted from 6 to 50 mouse uterine units per 24 hours. This laboratory utilizes the alcohol precipitation method with ether and methanol wash, and reports the result in mouse uterine units per 24 hours of pituitary gonadotropin.

Chorionic Gonadotropin.—

Although pregnancy urine of itself increases ovarian weight to a slight extent, studies in hypophysectomized animals show that it does not produce follicular growth and maturation unless some FSH is present. The increased ovarian weight resulting from the two substances is far in excess of their additive effects. The production of luteinization by urinary extracts without doubling the weight of the ovary is an indication of PU (pregnancy urine).

In this country Weisman and co-workers[4a] introduced the use of the South African frog *(Xenopus laevis)*. The mature female Xenopus extrudes eggs within a few hours after the injection of human chorionic gonadotropins. The accuracy of the test in the diagnosis of pregnancy exceeds 99 per cent. This also applies to the use of the North American frog, *Rana pipiens,* which extrudes spermatozoa upon introduction of human chorionic gonadotropin.

There usually is an abnormally large amount of gonadotropins in the blood of toxemic patients; in individuals with hydatid mole or chorioepithelioma it greatly exceeds that of normal pregnancy. If several weeks after a mole is delivered chorionic gonadotropin is present, chorioepithelioma should be seriously considered as one possibility. In males, values under 1,000 mouse units are associated with relatively benign tumors of the testis; 10,000 mouse units or more are found with chorioepithelioma.

Unfortunately, the only scientifically acceptable assay for gonadotropins at present is a biological assay. Chemical or physical (polarographic) methods for the determination of gonadotropins are, to our knowledge and experience, without merit. Therefore, it is our opinion that the accuracy and flexibility of these assays are limited.

Estrogens[5, 6]

Chemical Methods.—

The most obvious and ultimately the definitive method of chemical measurement of presumed estrogens is the weighing of the isolated crystalline compounds and their identification by melting points, melting points of derivatives, and other physical characteristics. The gravimetric determination of estriol in late human pregnancy urine is practical in view of the relatively large amounts obtainable and the possibility of separating this compound out almost quantitatively by fairly simple fractionation and subsequent chromatography. In all other instances in which analysis of human estrogens has been sought, isolation is not practical unless extremely large quantities of starting material are used and ordinarily rather complex extraction procedures employed. In clinical analysis the most common micromethod employed is an estrogen color reaction or fluorometric measurement.

When a solution of a steroidal estrogen is heated in a mixture of phenol and sulphuric acid, cooled, diluted with water, and reheated, a pink color having an absorption maximum at 520 millimicrons develops. Kober, Cohen and Marrian, Venning and associates, and Bachman, among others, have introduced modifications of this procedure with a view to making the reaction more specific and less affected by extraneous chromogens. When solutions of pure compounds are used, the reaction displays a remarkable specificity for the steroidal estrogens. However, in urinary extracts a brown pigment is formed which obscures the pink Kober color. This interference is most marked in urines containing small amounts of estrogens.

The problem of extraneous interfering chromogens in nonpregnancy urine has been attacked in three ways: (1) the quantitative measurement of the material and the application of an appropriate correction, (2) the destruction of the estrogen color, and (3) the purification of the urinary extract by utilization of solubility in various solvents with a view to the elimination of the interfering material.

The observation that phenolic and naphtholic steroids are converted to fluorescent substances by treatment with strong sulphuric acid was made many years ago, but it was only recently that attempts have been made to apply this reaction to the quantitative estimation of urinary estrogens.

Finkelstein and co-workers,[7] Bates and Cohen,[8] and Jailer[9] published photofluorimetric methods for the estimation of estrogens. Finkelstein and associates convert the estrogens to the fluorescent substances by heating with phosphoric acid while the other two groups use sulphuric acid for this pur-

pose. The photofluorimetric methods have the advantage that there is relative to the Kober reaction less interference due to contaminating pigments and fluorophors. This method has been found useful for following estrogen excretion in patients and gives values consistent with bio-assay findings. Its speed, simplicity, and the small volumes of urine required recommend its use as the best and most feasible of the various methods of estrogen determination in the clinical laboratory.

17-Ketosteroids[10-14]

Accumulated evidence indicates that the adrenal cortices and the interstitial cells of the testes secrete steroids which are excreted in part in the urine as 17-ketosteroids. To a limited extent adrenocortical function can be distinguished from gonadal by simple procedures, i.e., the relative proportion of cis (beta) and trans (alpha) stero-isomerism with respect to the hydroxyl at position number 3. The cis (beta) fraction is believed to be derived primarily from the adrenal cortex, while the trans (alpha) fraction is believed to result from hormones elaborated by the gonads. This laboratory uses the method which employs ether extraction accompanied by thorough alkali washing and then followed with the color development with alcoholic potassium hydroxide and meta dinitrobenzene. The fractionation is completed with the use of alcoholic digitonin for precipitation of the beta fraction.

Biological and polarographic assays are also utilized in these determinations.[15, 16]

Corticosteroids[17-20]

The term urinary corticoid or corticosteroids refers to substances of adrenal cortical origin. This laboratory utilizes the method which entails n-butyl alcohol extraction at a pH of 1.0 and consequent purification of extract with color development by way of phenylhydrazine hydrochloride and sulphuric acid. Corrections must be made for reagent color and urinary chromogens and also char development.

Pregnandiol[21-24]

Pregnandiol is the chief urinary transformation product of progesterone in human urine and provides a measure of both luteal and adrenocortical function. Some pregnandiol is also derived from desoxycorticosterone. This

laboratory uses the toluene extraction followed by sodium hydroxide methanol precipitation. Fritted glass filtration and purification by relative solubility then gives a residue which can be developed with sulphuric acid.

LABORATORY TESTS FOR PREGNANCY

Attempts have been made for a number of years to work out a satisfactory test for pregnancy. The need for such a test is sometimes very great; for instance, to determine the presence or absence of ectopic pregnancy, on which the performance of an emergency surgical operation depends. Early pregnancy, too, has been confused with cysts of the ovary and uterine fibroids. Ectopic pregnancy has been confused with pelvic inflammation. The following conditions associated with amenorrhea often mimic early pregnancy.*

1. Lactation and the onset of the menopause.
2. Endocrine dysfunctions, such as ovarian, anterior pituitary, thyroid, and adrenal.
3. Metabolic disturbances frequently associated with obesity.
4. Ovarian cysts and uterine fibroids.
5. Primary and severe secondary anemias.
6. Debilitating diseases, such as tuberculosis and acute infections.
7. Chronic intoxications: lead and alcohol.
8. Psychic amenorrhea due to fear of pregnancy, especially in the unmarried, and the anxiety to bear a child.

After struggling through many different methods of making this diagnosis by laboratory methods, we have finally come to accept the Aschheim-Zondek test or modifications as just the test that is needed for this purpose. These tests depend on the demonstration of a gonadotropic hormone derived from the placenta, similar to the pituitary hormone, in the urine in pregnancy. The test was worked out after it had been previously determined that the anterior pituitary hormone was easily demonstrable in the urine of pregnant women. It is naturally eliminated in the urine of gravid women due to the increased permeability and the low renal threshold observed in pregnancy.

The original technic of Aschheim-Zondek is as follows:

Mouse Method

Aschheim-Zondek Technic

The test is carried out on infantile, three-week-old white female mice that do not weigh more than six to eight grams. Five of these infantile mice are used in the test. Some of the mice are likely to die from the toxic properties of the urine. It is to be noted that the reaction may be positive on the right ovary and negative on the left ovary. The pregnancy is considered positive even though the reaction is present in only one ovary.

It is preferable to obtain the urine by catheter, although this is not essential because these young mice are rather resistant to infection. The urine must be collected in a clean vessel. If it is to be sent from a distance, add to each 25 c.c. one drop of pure tricresol. Shake the urine so that the tricresol is thoroughly mixed. Thirty c.c. of urine are sufficient for the test.

---

*Wohl: Bedside Interpretation of Laboratory Findings, The C. V. Mosby Co., St. Louis, Mo.

Before making the test, take the reaction of the urine. If it is alkaline or neutral, add a few drops of acetic acid until the urine reacts acid to litmus paper. If the urine is cloudy, it should be filtered.

The urine is injected in six portions, divided over a period of twenty-four hours. It is preferable to begin the tests on Monday or Tuesday so that they can be completed by the end of the week. The schedule of injection of urine into mice is as follows:

1. Monday morning, between 11 and 12.
   Monday afternoon, 5 P.M.
2. Tuesday morning, 10 A.M.
   Tuesday afternoon, 1 P.M.
   Tuesday afternoon, 5 P.M.
3. Wednesday morning, 10 A.M.

The urine is injected in the following amounts subcutaneously:

Mouse No. 1—six times, 0.2 c.c.
Mouse No. 2—six times, 0.25 c.c.
Mouse No. 3—six times, 0.3 c.c.
Mouse No. 4—six times, 0.35 c.c.
Mouse No. 5—six times, 0.4 c.c.

If this test is started on Monday, the animals are sacrificed on Friday; if started on Tuesday, they are sacrificed on Saturday.

They are sacrificed with illuminating gas or ether and pinned to a cork board. The abdomen is opened and the sexual organs are examined. In most cases, the diagnosis can be made by macroscopic view of the ovaries. In positive cases, the ovaries are large, hyperemic and show the so-called ''blood spots'' or hemorrhagic spots.

Microscopic sections are then made. When positive, note graafian follicles, hemorrhage into the follicles, and corpora lutea.

It is preferable in making the sections to fix the specimens in Zenker solution rather than Formalin, since Formalin tends to shrink the cells and make the diagnosis difficult.

At times, there is a demand for a quicker method than the original method, so that Zondek has devised a more rapid method. This is particularly important in cases in which operation for extrauterine pregnancy may be needed. Zondek has attempted to concentrate the hormone as follows:

Treat 66 c.c. of urine with a small amount of 10% acetic acid until a weakly acid reaction occurs with litmus, filter, and add 40 c.c. of 96% alcohol.

Shake 5 minutes until a flocculent white-yellow precipitate forms. Let this stand one-half hour and then centrifuge.

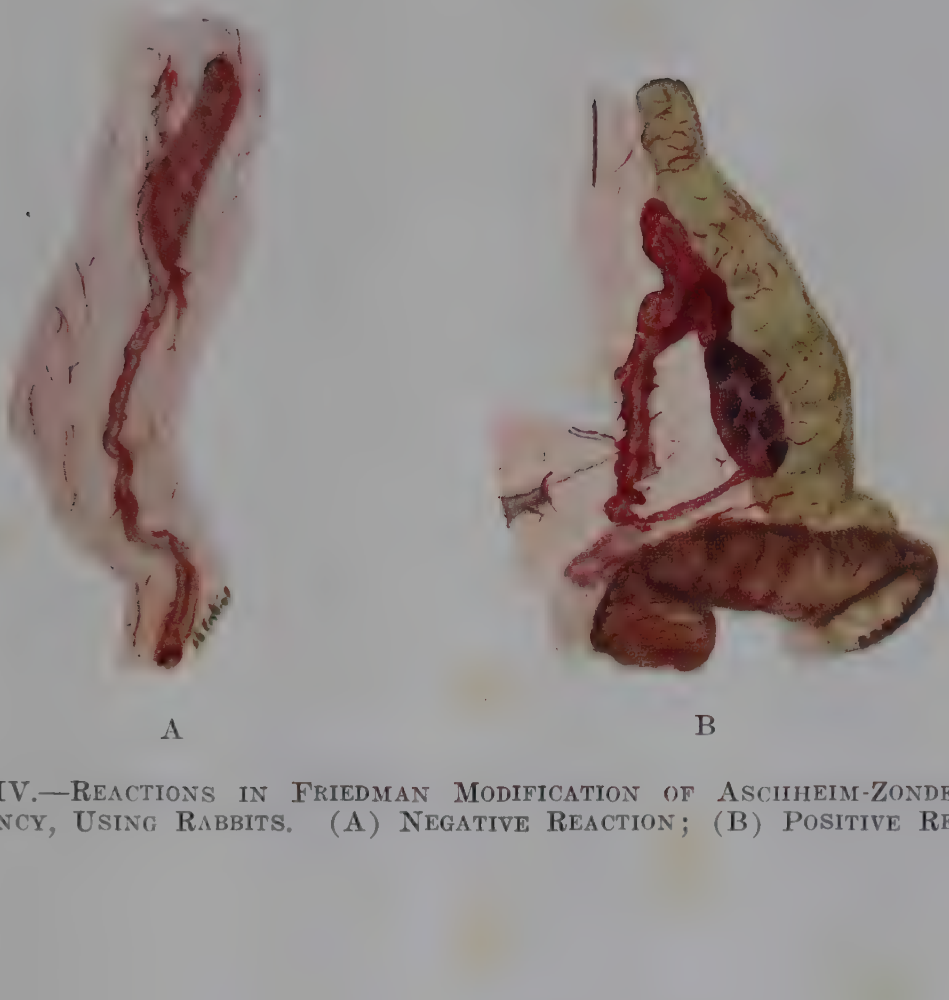
The hormone is in the sediment. Treat this sediment with 30 to 40 c.c. of ether for 3 minutes, shake, pour the ether off, and take up the sediment with 11 c.c. of distilled water, shake 5 minutes, and centrifuge.

The hormone is now dissolved in the water. Throw away the sediment. The solution is yellowish and often becomes cloudy. The whole process takes about 1 hour.

These 11 c.c. of water represent the amount of hormone in 66 c.c. of urine, therefore it is a six-times concentration. Four 6- to 8-gram infantile female mice are each injected every eight hours with 0.4 c.c. of urine six times each, thereby receiving 2.4 c.c. which is equivalent to 14.4 c.c. of the original urine.

After fifty-one and fifty-seven hours, the blood points in the ovary are usually seen so that the diagnosis can be made in the fifty-first or fifty-seventh hour.

Zondek states, however, that the concentrated quick method does not compare in exactitude with the original method, and it is to be used only in



A B

Plate XXXIV.—Reactions in Friedman Modification of Aschheim-Zondek Test for Pregnancy, Using Rabbits. (A) Negative Reaction; (B) Positive Reaction.

emergency cases where it is necessary to make an early diagnosis of extra-uterine pregnancy.

Rabbit Method

Owing to the fact that it is not always possible to have on hand or to secure young female white mice for this test, the use of a young female white rabbit was suggested. We have found rabbits preferable to mice: first, because they are sturdier animals; second, because they are easier to obtain from dealers; and third, because the presence or absence of the blood spots on the ovaries is more easily determined.

The Friedman Modification of the Aschheim-Zondek Test for Pregnancy

The Friedman modification of the Aschheim-Zondek test uses rabbits as ideal test animals for hormone reactions for pregnancy. Although ova continually mature and graafian follicles ripen in the ovaries of rabbits, ovulation does not take place until after copulation. Thus in properly caged female rabbits it is possible to study the effect of urine on ovaries previously free of corpora hemorrhagica. Another reason that rabbits are ideal animals is that after reaching maturity they are always ready for use in the test. One need be assured only that the rabbit has not recently copulated, is not pregnant, or has not been used as a test animal in the previous six weeks or two months.

Technic.—

Method Using Urine.—

The animals to be used are healthy female rabbits seventeen weeks old. On the average, female rabbits attain sexual maturity in five months. If the animal is purchased from an outside source it is caged separately for two weeks before use. Since the period of gestation in the rabbit is only 21 days, pregnancy in an animal will be easily detected by palpation and eliminated at the end of two weeks, or if ovulation without conception has resulted from excitation by a male rabbit, the corpora hemorrhagica will have entirely disappeared by this time.

The urine specimens preferred are the first voided on rising, because the hormone as well as other constituents will be more concentrated in the high-specific-gravity urine voided at this time. The specimen should not be more than four hours old, although evidence is accumulating that the hormone is not so labile as it was formerly believed. It should be received under all circumstances into a sterile bottle. It is preferable, if possible, to withdraw it with a sterile catheter to prevent bacterial contamination. This is especially true for specimens from a distance.

The first injection of 10 c.c. of urine is made into one of the marginal ear veins of a rabbit. The second injection of 5 c.c. is made 24 hours after the first injection, in the same manner. Rabbit should be labeled and kept in separate cage after injections. The ovaries of the rabbit are examined by laparotomy or by anesthetizing the rabbit to death 24 hours after the second injection. There is no difficulty in finding the ovaries of the rabbit or in recognizing a positive reaction.

The reading of the test is not difficult. The negative test shows a white or light pink ovary which is usually studded with clear mature graafian follicles. The uterus is usually not injected. Congestion and injection of the uterus, however, are thought to be produced by the ovarian hormone independent of the anterior pituitary and thus have no significance in the reading of the test.

Positive reactions are seen as follows: ovaries studded with from 1 or 2 to half a dozen or more corpora hemorrhagica and a coiled hyperemic uterus. The small rosy spots that may appear in large clear follicles are suggestive but not positive and another test should be made.

Positive reactions occur in cases in which embryonal tissue is in biological contact with maternal or host tissue. Conditions other than pregnancy in which positive reactions occur are hydatidiform mole, chorioepithelioma, and certain embryonal malignant tumors of the testis. Tubal pregnancy in which the fetus is dead but the placental tissue is still viable, and incomplete abortion with retention of viable placental tissue also give positive reactions.

False negative reactions occur with pregnancies in which all placental tissue is dead, missed abortions, and ectopic pregnancies. They may also be occasioned by the use of an immature animal which is incapable of reacting or by accidental confusion or willful substitution of specimens by persons interested in inducing the physician to curette the uterus in the patient being studied.

Increase in gonadotropic factors reaches the peak between the 30th and 50th days in normal pregnancy. In hydatidiform mole and chorioepithelioma these gonadotropic factors are elevated above the level reached in normal pregnancy. A quantitative test is of importance in the diagnosis of hydatidiform mole because as many as 300,000 mouse units per liter may be present. In chorioepithelioma the hormone amounts vary around 100,000 mouse units per liter. In using this test in chorioepithelioma excluding an early pregnancy, repetition of the quantitative test must be made. The test is useful, too, after operations for chorioepithelioma, to detect metastases.

Method Using Blood Serum.—Female rabbits, ten weeks to three months old, are used. No rabbit is used if it is older than three months. Obtain serum in the usual manner. Inject 2.5 c.c. of the serum intravenously into the marginal ear vein of a rabbit (page 2038). After twenty-four hours, sacrifice the rabbit with chloroform anesthesia, autopsy, and examine as above for corpora hemorrhagica. Refer to the test, using male frogs, page 1317.

Tests for Pregnandiol

Progesterone, which is elaborated by the corpus luteum and placenta, is excreted in the urine as a pregnandiol-glucuronic acid conjugate. Guterman[1] reported a modification of the Astwood and Jones[2] procedure by adding the color reaction of concentrated sulphuric acid on pregnandiol originally described by Kober.[3] Guterman's method shortened the Astwood and Jones procedure to three hours by making only one extraction with toluene and one precipitation of pregnandiol from acetone. Parks and Mack[4] have modified the Guterman procedure so that the test can now be completed in from one to one and one-half hours with an accuracy which they claim surpasses that of the complete Guterman technic.

Guterman Technic.[1]—

A. Hydrolysis and Extraction of Pregnandiol.—

1. Place 100 c.c. urine, first morning specimen,
   50 c.c. toluene, c.p.,
   10 c.c. concentrated hydrochloric acid,

---

[1] Guterman, H. S.: J. Clin. Endocrinol. **4**: 262-267, June, 1944.
[2] Astwood, E. B., and Jones, G. E. S.: J. Biol. Chem. **137**: 397-407, Jan., 1941.
[3] Kober, S.: Biochem. Ztschr. **239**: 209-212, 1931.
[4] Parks, A. E., and Mack, H. C.: Harper Hosp. Bull. **4**: 167-168, Sept., 1946.

and 2 glass beads
in a 500 c.c. flat-bottomed Florence flask.

2. Connect the flask via a one-holed cork stopper to a vertical, water-cooled, 400 to 500 cm. jacket-length Liebig condenser.

Boil vigorously over an electric hot plate for 15 minutes.

3. Cool to room temperature under running tap water.

4. Transfer to a 500 c.c. separatory funnel and draw off the lower (urine) layer.

5. Wash the toluene layer and the toluene-water emulsion with 15 c.c. portions of N/10 sodium hydroxide, then twice with 15 c.c. of distilled water.

B. Precipitation of Impurities.—

1. Transfer the washed toluene and toluene-water emulsion to a 125 c.c. Erlenmeyer flask with 2 glass beads.

2. Boil over an electric hot plate (under the hood).

3. When the water has evaporated and the toluene mixture is boiling smoothly, add 10 c.c. of 2% sodium hydroxide in absolute methanol.

4. Evaporate to one-half the original volume of toluene.

5. Filter the toluene mixture while hot through a fritted glass filter (medium porosity, Pyrex) using mild suction. If the filtrate has an orange, pink, or brown tint, steps 3, 4, and 5 must be repeated until the filtrate is yellow or yellow green.

6. Wash the precipitate with 15 c.c. of hot toluene, and combine this washing with the filtrate obtained in the previous step.

7. Evaporate to dryness over the hot plate, in the hood, using a gentle air stream to drive off the last traces of toluene. This prevents charring of the residue.

C. Precipitation of Pregnandiol.—

1. Add 5 c.c. of acetone to the residue (in the previous section) and warm the mixture over a hot plate until solution is complete.

2. Add 20 c.c. of N/10 sodium hydroxide slowly while the mixture is still on the hot plate.

3. Place the flask in an ice-water bath for 30 minutes or in a refrigerator at 5° C. for one hour.

D. Isolation of Pregnandiol.—

1. Use the mixture obtained in section "C-3" and filter through a fritted glass filter of medium porosity, Pyrex, using mild suction.

2. Wash the precipitate with 15 c.c. distilled water.

3. Change the receiving flask and pass 10 c.c. of hot absolute alcohol through the fritted glass filter to dissolve the precipitate.

4. Evaporate the alcohol filtrate to dryness over an electric hot plate in the hood.

E. Color Development.—

Add 10 c.c. concentrated sulphuric acid to the residue and observe the color in a test tube when solution is complete. Colorless to light yellow solution is negative. Orange to deep orange-brown is positive.

Pregnandiol Precipitation Test

Method of Mack and Parks[1]

Repeated attempts have been made to perfect a chemical test for the early diagnosis of pregnancy through identification of pregnandiol in the urine of amenorrheic women. Various methods have been tried, all of which present many technical difficulties. A greatly simplified technic has been developed by Mack and Parks.

---

[1] Mack, H. C., and Parks, A. E.: J. Clin. Endocrin. 2: 351, 1947.

Reagents.—

Toluene.—Reagent quality.

Hydrochloric Acid.—Concentrated.

Glass Beads.—

0.1N Sodium Hydroxide.—See pages 25 ff.

2% Sodium Hydroxide in Methyl Alcohol.—

Dissolve 2 gm. of sodium hydroxide, c.p., in absolute methanol and dilute to 100 c.c. with absolute methanol.

Acetone.—

Technic.—

(A) **Hydrolysis and Extraction of Pregnandiol.**—

Secure a first morning urine specimen and record the specific gravity.

Measure 100 c.c. of urine and pour it into a 500 c.c. Erlenmeyer flask.

Add 50 c.c. of toluene
and 10 c.c. of concentrated hydrochloric acid
and 2 glass beads to the flask.

Connect the flask to a vertical Liebig condenser and allow the sample to reflux on a hot plate for 15 minutes.

Remove the flask and cool rapidly to room temperature under a water tap. Avoid agitation of the sample while cooling to prevent formation of an emulsion.

Transfer the sample to a 500 c.c. separatory funnel.

Draw off and discard the lower layer (urine).

Small amounts of emulsion present at this point can be disregarded. If large amounts are present, transfer the sample to a 100 c.c. tube and centrifuge for 5 minutes. The toluene and associated urine are then poured into the separatory funnel, leaving the emulsion in the tube.

Add 15 c.c. of N/10 sodium hydroxide to the separatory funnel and wash by inverting twice and swirling the sample gently.

Discard the sodium hydroxide which settles to the bottom of the funnel.

Repeat by adding 15 c.c. of N/10 sodium hydroxide; then proceed as above, following the same procedure with two 15 c.c. portions of water.

After the last washing with water, make a very careful separation and transfer only the toluene layer to a dry 125 c.c. Erlenmeyer flask.

(B) **Precipitation of Impurities.**—

Add 2 glass beads and bring the sample to boiling on a hot plate.

When the vapors reach the mouth of the flask, slowly add 10 c.c. of 2% sodium hydroxide in absolute methanol while the flask remains on the hot plate.

Boil until the methanol has evaporated and the toluene is reduced to about one-half its original volume.

Filter, while hot, through a fritted glass filter, Pyrex, medium porosity, using suction.

Collect the filtrate in a large test tube.

Add 15 c.c. of toluene to the flask as a rinse, heat to boiling, and use it to wash the precipitate remaining on the filter.

Pour the filtrate from the test tube into a dry 125 c.c. Erlenmeyer flask and evaporate to dryness on a hot plate. Use a gentle air stream to remove the last traces of toluene.

(C) **Precipitation of Pregnandiol.**—

Add 5 c.c. of acetone to the residue in the flask.

Place the flask containing the acetone on a hot plate. When it begins to boil, add 25 c.c. of boiling N/10 sodium hydroxide slowly, 3 to 4 c.c. at a time.

Remove the sample from the hot plate and read.

(D) **Reading of Result.—**

Swirl the sample and observe the side of the flask above the level of the liquid, standing in front of a window or a good source of light. In samples containing 0.75 mg. or more of pregnandiol, a precipitate is evident immediately. Due to surface tension of the liquid and the lightness of the precipitate, it is carried up the side of the flask and becomes evident as tiny, white particles.

If no precipitate is immediately evident, place the sample in an ice-water bath for 10 minutes.

Remove from the ice bath and allow it to stand for 30 minutes at room temperature.

Again observe as above.

As a method of checking the amount and character of the precipitate, follow the procedure for reading and grading Kahn tests.

Place 1 c.c. of the sample in a standard Kahn tube and view it in a fluorescent light box. The reaction can thus be graded as 0, +, ++, +++, or ++++.

(E) **Description of the Precipitate.—**

The substance which is precipitated under the conditions listed above is manifestly impure pregnandiol, contaminated by cholesterol and other steroids. The precipitate is birefringent and does not form clearly defined crystals.

In examination of urine in 94 pregnant and nonpregnant controls and in 121 unknown urine samples, all known pregnancy control urines gave positive tests. Negative pregnandiol tests were obtained in all nonpregnant controls except for determinations made during the luteal phase of the normal menstrual cycle. It may be concluded that false positive pregnandiol tests for pregnancy may be obtained during delayed luteal phases of prolonged cycles where late ovulation has occurred. This limits the accuracy of the pregnandiol test which is most reliable in amenorrhea of otherwise normally and regularly menstruating women.

The test has been applied in serial determinations in 14 instances of threatened abortions. The clinical outcome coincided with laboratory findings in 13 cases. Consistently negative pregnandiol tests foreshadowed abortion in 7 cases; consistently positive pregnandiol excretion or negative tests which became positive coincided with retention of the pregnancy in 6 cases. In 1 instance of abortion at five and one-half months, strongly positive qualitative tests were obtained.

This test suggests its practical usefulness as a rapid means of diagnosis of pregnancy and as an adjuvant to the management of threatened abortion.

The Male Frog Test (Rana Pipiens) for Pregnancy

The gametokinetic response of the male Batrachia to gonadotropic substances was described by Rugh in 1937.[1] The clinical application of this observation to the laboratory diagnosis of pregnancy was reported by Galli-Mainini.[2] Impetus was lent to the popularization of the male frog test for pregnancy in this country by Robbins and Parker.[3] This has been accepted therefore as a rapid, economical, and accurate procedure in the diagnosis of pregnancy. Blood serum was substituted as a test material and has been used by Haskins and Sherman[1] exclusively in routine pregnancy testing. Their opinion and that of others suffice to recommend this male frog test as the best method of blood serum testing for pregnancy, especially in view of the fact that concentration of chorionic gonadotropin is greater in serum than in urine. This method obviates the annoyance and expense of repeating tests because of the premature death of the test animal from toxic substances in urine.

Technic.—

Use male *Rana pipiens* obtained from a single laboratory supply house. Sexing of the frogs can be determined by examination of the thenar eminences, which in the male are hypertrophied.

Keep the frogs refrigerated at 6° C. prior to their use; this allows prolonged storage at low metabolic level and obviates the need for feeding them. In other words, purchase a supply of frogs and keep in a refrigerator at 6° C. until time to use them. Refrigeration also reduces the stimulation of the frogs to gametokinesis by amplexus.

Prior to injecting the test animal, examine its urine for sperm. Discard for injection purposes those rare animals in which urinary sperm is found.

Administer 3 c.c. of serum to each of 2 frogs in routine testing, or, better, use 1 c.c. of serum to each 10 gm. of frog weight.

After injection, place each frog in a separate container for the remainder of the test.

Inject the serum intraperitoneally.

Obtain urine from the cloaca by a small pipette, each 30 minutes, until a positive response is obtained, or until 2 hours have elapsed.

Report a test positive when urinary sperm is found in either or both frogs.

This method of testing for pregnancy is especially recommended. In 800 frog tests performed by Haskins and Sherman, accuray in the test was 97 per cent.*

The "Frog" Test (Xenopus Laevis) for Pregnancy†

Weisman, Snyder, and Coates[2] have given ample evidence of the usefulness of the frog test in the rapid diagnosis of pregnancy. This test uses the South African clawed frog, *Xenopus laevis.* The advantages of this test are its high degree of accuracy and the rapidity of reaction, i.e., four to eighteen hours. Weisman and associates report their findings in 53 clinical cases of suspected pregnancy.

This frog test is based on the peculiar biologic function of the mature female Xenopus in that she carries eggs throughout the year, extruding them only at mating or after the injection of hormones peculiar to pregnancy. Since the test animals are kept isolated from the males, the extrusion of any ova following the injection of suspected urine becomes definitive for pregnancy. Parallel tests on segregated rabbits were used by Weisman and associates[3] on the

---

**Rana pipiens* may be secured from E. G. Steinhilber & Co., Oshkosh, Wis. This company ships frogs every day. If an order is received in the late afternoon, they are shipped the following morning, Monday through Thursday. Saturday and Sunday deliveries are avoided. Most shipments are made by air parcel post or surface parcel post, rather than by express, to save transportation costs and speed delivery. Shipments for Monday delivery are made ordinarily on Saturday by air parcel post. To be sure of fresh stock, order often during the summer months. To be sure of a steady supply, the supplier recommends placing a standing order for a specified number to be shipped or delivered at a certain time each week. One's requirements thus are scheduled regularly, and deliveries are made without having to reorder each time. In ordering, specify "special males."

†*Xenopus laevis* frogs may be procured from Jay E. Cook, Cockeysville, Md. See also Weisman and Coates' bulletin entitled "The South African Frog (Xenopus Laevis) in Pregnancy Diagnosis," publisher, New York Biologic Research Foundation, 1944.

same specimens of urine as they used on the frogs. In one case of disagreement, where the frog test was positive and the rabbit test was negative, the patient was operated upon with a preoperative diagnosis of ectopic pregnancy. Upon laparotomy, an unruptured tubal pregnancy was discovered in the pelvis, the diagnosis of which was later confirmed in the pathologic laboratory. In this instance, the frog test was proved to be correct and the rabbit test false. These investigators believe that the frog test is a more sensitive indication of early pregnancy than the rabbit test. Table 134 of Weisman and associates shows the advantages of this frog test.

8	Special precautions	None	Age and weight	Isolation
9	End reaction	Simple observation of eggs in water	Search for ovaries in five animals	Search for ovaries

*Frogs are used over and over again.

Technic.—

The basic method of keeping the frogs entails the use of three twelve-gallon aquaria for each group of eight frogs. Tank *A* is used as a "rest" tank in which the animals recuperate for four weeks after having extruded ova in a positive reaction. Tank *B* is the "negative reaction" tank in which those frogs not reacting to injections of urine (negative test) are rested for a week. Tank *C* is the "active" tank from which animals ready for use are taken. It is apparent that both *B* and *A* become "active" tanks when the rest periods are completed.

Water in the tanks is kept at ordinary room temperature, 70° F., and is maintained at a level of about three inches from the bottom. The frogs are fed small strips of beef heart, calf liver, and garden worms (if available) twice each week. Tank water should be replaced by fresh water of the same temperature prior to each feeding and 24 hours after each feeding. The animals should not be fed for at least 24 hours prior to testing since the injection causes regurgitation of partially digested food which may interfere with the visualization of the eggs and the correct reading of the test.

For the actual tests, standard two-gallon fish tanks are used. These are stacked one above the other if a number of tests are to be made simultaneously. Half-inch wire mesh should be bent to form a platform about one inch from the bottom of each test tank to prevent the frog from devouring its own extruded eggs. A set-up test tank should contain about three inches of water and should be kept covered with a glass plate, slightly elevated above the frame of the tank to allow passage of air. The glass should be taped or weighted down to the tank so the frogs cannot climb out. The water in all the tanks should be of the same temperature and the room for housing and testing should be bright and airy with little variation in temperature. After each test it is advisable to burn off any contaminating eggs from the wire platform with a Bunsen burner.

HORMONE

CHORIONIC GONADOTROPIN	PITUITARY GONADOTROPIN	17-KETOSTEROIDS
NORMALS: **Normal Female:** Trace amounts **Pregnant Female:** Increases within first two months to peak of 100,000 and more mouse uterine units/24 hr., decreasing after 8th-12th wk. to 2,000-10,000 mouse uterine units/24 hr.	**NORMALS:** **Male and Female:** 6-50 mouse uterine units/24 hr. **Male Children:** Under 11 yr.: 0 **Female Children:** Detectable in small amounts one year prior to menstruation	**NORMALS:** **Female:** 6-18 mg./24 hr. **Male:** 10-22 mg./24 hr. **Children under 6 yr.:** Less than 1 mg./24 hr. increasing gradually to age 18; normal adult range may be encountered after age 12 **After 60 yr. of age:** Male: 2-9 mg./24 hr.; female: 1-8 mg./24 hr. **Normal Beta/Alpha Ratio:** Approximately 1/10-1/9
PATHOLOGIC FINDINGS: **Increased in:** Testicular tumors (mixed epithelioma type) Hydatidiform mole Chorioepithelioma	**PATHOLOGIC FINDINGS:** **Increased in:** Cushing's syndrome Hyperpituitary activity Menopause Seminiferous tubule failure Male climacteric **Decreased in:** Simmonds' disease Panhypopituitarism Administration of excessive amounts of testosterone and estrogens	**PATHOLOGIC FINDINGS:** **Increased in:** Testicular tumors (interstitial cell)—very high Adrenal hyperfunction Following endocrine therapy (ACTH, testosterone, chorionic gonadotropin) Severe stress Human pregnancy (third trimester) Ankylosing spondylarthritis Cushing's syndrome Simple hirsutism **Decreased in:** Female hypogonadism, moderately low if associated with various metabolic disorders. Normal in majority of patients with primary ovarian failure, male hypogonadism, pituitary tumors, thyrotoxicosis, hypertension, diabetes mellitus, Addison's disease, hypothyroidism, nephrosis, gout, chronic illnesses. Acute illnesses: common cold, malnutrition, anemias, anorexia nervosa, hepatic disease, physical fatigue **Male:** Two-thirds of the total 17-ketosteroids are from the adrenal cortex and one-third from the testes **Female:** Traces from the ovary and the rest from the adrenal cortex **Ratio of Beta/Alpha:** 1/1 is usually evidence of tumor

Concentration of Urine.—

The present method recommended by Weisman et al. means that a simple concentration can be made in half an hour or less. Four ounces of morning urine are required, of which 80 c.c. are used. To 80 c.c. of urine, add twice the volume of acetone. Thoroughly stir the mixture and allow to stand for 15 minutes or thereabouts when the precipitated proteins and hormones will have settled to the bottom. Decant the supernatant fluid and save for redistillation. Allow the precipitate to dry. This may be hastened by a current of air induced by a suction apparatus or an electric fan. Add 2 c.c. of distilled water to the dry precipitate and stir thoroughly then pour the mixture into a small centrifuge tube. Centrifuging brings down the insoluble proteins and other material while the gonadotropic hormone remains soluble in the water. Immediately prior to injection, decant the supernatant fluid and adjust with ten per cent sulphosalicylic acid to pH 5.5, using nitrazine paper, Squibb. Use 1 c.c. of the concentrate for each injection, the remaining cubic centimeter being reserved for use in case recheck is necessary; or a second frog may be injected immediately. If you have plenty of frogs, it is better to use two frogs for each test. Each c.c. of the final concentrate is equivalent to 40 c.c. of whole urine.

The Test Animal.*—Only mature, female, healthy and well-nourished animals can be used. Standardized animals—those which have reacted previously by egg extrusion after injection of gonadotropic substance—must be used to attain the greatest possible degree of accuracy.

Mode of Injection.—Select the dorsum of the animal as the site of injection since it is the largest lymph space. Care as well as experience is required when injecting the frog. Puncturing the lung usually means death of the animal. The frog is injected subcutaneously by means of a short insulin-type needle. The lymph space is reached by thrusting the needle superficially into the left thigh muscle, directing the point medially to the midline of the dorsum approximately one-half inch above the upper cloacal fold. Throughout its course, the needle should be seen clearly just beneath the skin. A firm gentle thrust carries it through connective tissue into the lymph space. Do not permit the point of the needle to advance cephalad toward the lungs. If the needle is anywhere near the lung, a sudden effort by the animal may cause lung puncture.

Reading the Test.—After the animals are injected with the urine concentrate, place them in separate waiting "test tanks" and observe at intervals after the first four hours. Positive extrusion of eggs may be seen as early as four hours after injection, but ordinarily the reaction occurs between six and twelve hours. If after 18 hours no eggs are visible in the tank, the test may be considered negative and the animal is placed in tank *B* for a rest of one week.

Six-Hour Pregnancy Test

(Salmon, Geist, Salmon, and Frank)

A 6-hour pregnancy test, using immature white rats, has been originated by Salmon, Geist, Salmon, and Frank.[1]

For the performance of the test, three white rats (35 to 45 gm., ages 22 to 25 days) are injected subcutaneously with 2 c.c. of the first morning specimen and autopsied at the end of six hours.

Ovarian Reaction.—The ovaries are enlarged and bright red in appearance in sharp contrast to the small, white or faintly pink ovaries of the control animals. The administration of human pregnancy urine to immature female rats results in marked hyperemia of the ovaries. That this vascular reaction is due to the gonadotropic factor present in pregnancy urine was shown by the production of a similar vascular reaction with chorionic gonadotropin and by the failure to induce the reaction with pregnancy urine, in which the gonadotropin had been inactivated by boiling. The work of these authors reveals further that urine of pregnant women contains estrogens in such high concentration that administration of 2 c.c. of urine to an immature rat causes proliferation of the epithelial and muscular coats of the vagina, which is detectable microscopically and grossly 24 hours after the injection. The proliferative changes in the vaginal mucosa are identical to those induced by estrogens.

---

*Frogs are obtainable from Jay E. Cook. Cockeysville, Md.

[1] Salmon, Udall J., Geist, Samuel H., Salmon, A. Austin, and Frank, Irving L.: J. Clin. Endocrinol. 2: 167-170, 1942.

If, for any reason, it is inconvenient to examine the ovaries at 6 hours, the animals may be autopsied at any time during the following 24 hours, but the ovaries must be examined immediately after death in order to detect the hyperemia of the ovaries. The method used by the authors is to asphyxiate the animals with illuminating gas. In performing the autopsy, it is important to avoid injuring vessels in the abdominal wall, since blood in the abdomen makes it difficult to detect the ovarian hyperemia.

This 6-hour test has the advantage of being more rapid and less costly than the Aschheim-Zondek test performed on five mice, which takes 96 hours, and the Friedman test, which requires 48 hours.

Explanation of This Reaction.—The failure of the pregnant woman to react is explained on the assumption that early in pregnancy the production and absorption of the active substance from the breast leads to an immune state which prevents the local reaction at the site of injection, except the weak reaction seen in 80 per cent of the cases in the first six and the last three weeks of pregnancy, during labor, and in the early days of the puerperium.

URINARY 17-KETOSTEROIDS*

Human urine contains a variety of steroid compounds, acidic, phenolic, or neutral. The acidic steroids represent the bile acids; the phenolic include the estrogens; and the neutral represent principally metabolites from the testes or ovaries and from the adrenals. The term ''17-ketosteroids'' is used with reference to the neutral urinary steroids, which are characterized by a carbonyl linkage at carbon 17. The 17-ketosteroids represent excretion products of hormones coming from the testes of the male and the adrenal cortices of both sexes. Determination of the 17-ketosteroids is made to consider the combined activity of the adrenal cortex and the testes in the male, and of the adrenal cortex alone in the female. Since both the adrenal cortex and the testes are under control of the pituitary, the test may also be considered an indirect measure of the function of that gland.

The principal members of the 17-ketosteroid group are androsterone, isoandrosterone, dehydroisoandrosterone, and etiocholanolone. The 17-ketosteroids are further subdivided into alpha and beta fractions. The beta-17-ketosteroids are precipitated by digitonin and the alphas are not. The alpha-17-ketosteroids normally comprise about 85 to 95 per cent of the total, making the beta : alpha ratio about 1 : 9.

The test, a chemical one with measurable colorimetric end point as a result of the Zimmermann reaction, is considerd as an index of androgenic function. Results parallel the androgen excretion as measured biologically by the effect on the size of the comb of a capon.

The method is that of Holtorff-Koch, a modification of the Zimmermann technic. The normal by this method is 8 to 14 mg.[1]

---

*Much of this section is from Roberto F. Escamilla, "Laboratory Aids in Endocrine Diagnosis," Springfield, Ill., 1954, Charles C Thomas. By permission of the author and the publisher. Sections are from Bull. Lab. Med. 1: 8, 1952.

[1] Drekter, I. J.: J. Clin. Endocrinol. 7: 795, 1947.

Modified Method of Holtorff and Koch[2]

Reagents.—

Concentrated Hydrochloric Acid.—

50% Sulphuric Acid.—

Carefully add 50 c.c. of concentrated sulphuric acid, c.p., to 50 c.c. distilled water. When cool, dilute to 100 c.c. with distilled water.

2% Thymol in Glacial Acetic Acid.—

Use 2 gm. thymol per 100 c.c. of glacial acetic acid.

Ether.—

Detergent.—

Use a detergent such as Vel or Dreft.

Sodium Hydroxide-Sodium Hydrosulphite Solution.—

This must be freshly made.

Add 10 gm. of sodium hydrosulphite powder to 100 c.c. of 10% sodium hydroxide solution.

Absolute Alcohol.—

80% Alcohol.—

Metadinitrobenzene Solution.—

This must be prepared fresh for the test.

Dissolve 34.5 mg. of purified metadinitrobenzene crystals[3]
in 3 c.c. of absolute alcohol.

5N Aqueous Potassium Hydroxide Solution.—

Dehydroisoandrosterone Solution.—

Dissolve 25 mg. of dehydroisoandrosterone
in 100 c.c. of absolute alcohol.

This solution keeps fairly well if kept in a refrigerator.

Technic.—

Collect a 24-hour urine sample in a jug containing 15 c.c. of concentrated hydrochloric acid or 5 c.c. of 50% sulphuric acid as a preservative; or 5 c.c. of 2% thymol in acetic acid may be used, and if the specimen is kept refrigerated, not only the 17-ketosteroids, but also the compound E and compound F content can be run from the same urine.

Measure the total volume and record.

Use a 50 c.c. aliquot for the test.

Carry out hydrolysis by acidifying the sample with 10 c.c. of concentrated hydrochloric acid in a 125 c.c. Erlenmeyer flask with a ground glass stopper.

Place in a constant temperature water bath at 80° C. for 15 minutes, then cool. After cooling, the sample can be kept in a refrigerator for as long as 24 hours.

Pour the cooled sample into a 250 c.c. separatory funnel and mix twice with 20 c.c. portions of ether and once with a 10 c.c. portion, shaking 1½ minutes each time. A pinch of a detergent may aid the separation of ether layers.

Wash by combining the 3 ether extracts in a 250 c.c. separatory funnel, adding 10 c.c. portions of a freshly made sodium hydroxide-sodium hydrosulphite solution.

Wash 3 times, shaking 1 minute each time. This removes the phenolic fraction which contains estrone.

Wash the extract 3 times with distilled water, or until the washing is neutral.

Evaporate as follows:

Transfer the ether extract to a 50 c.c. Erlenmeyer flask and evaporate to dryness over a hot plate, using grooved corks. Reduced pressure for this may be obtained by using a water pump. Any remaining water can be evaporated slowly at relatively low temperatures. The cooled flask may be placed in a desiccator overnight and the dried extract can be stored indefinitely.

---

[2] Holtorff, A. F., and Koch, F. C.: J. Biol. Chem. 135: 377, 1940.

[3] Callow, N. H., Callow, R. K., and Emmens, C. W.: J. Endocrinol. 2: 88, 1940.

Zimmermann Reaction:

Dissolve the dried extract in 2 c.c. of absolute alcohol.
Heat in a pan of hot water at 50° C. to aid solution, if necessary.
Use 0.2 c.c. of this extract for the reaction.

Prepare Klett tubes.

(a) **Unknown.—**
0.2 c.c. of urine extract
0.2 c.c. metadinitrobenzene solution
0.2 c.c. 5N aqueous potassium hydroxide.

(b) **Pigment Blank.—**
0.2 c.c. absolute alcohol
0.2 c.c. alcoholic extract of urine
0.2 c.c. 5N potassium hydroxide.

(c) **Standard.—**
0.2 c.c. dehydroisoandrosterone solution
0.2 c.c. metadinitrobenzene solution
0.2 c.c. 5N potassium hydroxide.

(d) **Reagent Blank.—**
0.2 c.c. absolute alcohol
0.2 c.c. metadinitrobenzene solution
0.2 c.c. 5N potassium hydroxide.

(e) **Klett Blank.—**
0.4 c.c. absolute alcohol
0.2 c.c. 5N potassium hydroxide.
Stopper all tubes and shake.

Place in the dark in a constant temperature water bath at 25° C. for 105 minutes. This causes the Zimmermann reaction, a characteristic red color which can be measured quantitatively.

Immediately add 8 c.c. of 80% alcohol to each tube, diluting in the order in which the tubes are to be read.

Mix by inversion and read on a Klett-Summerson photoelectric colorimeter within 10 minutes, using a 540 filter.

Calculation.—

$$\frac{\text{Corrected reading* of unknown}}{\text{Corrected reading* of standard}} \times \frac{\text{24-hr. volume}}{100} = \text{the 17-ketosteroids in mg. per 24 hours.}$$

Normal.—

The normal range for adults is: **males,** 10 to 20 mg., average 15 mg. per 24 hours; **females** 5 to 15 mg., average 10 mg. per 24 hours; for **children,** near 0 until the age of 8, 1.5 to 5 mg. by the age of 12 years, and then a gradual increase to adult levels at about the age of 16 years. There are no marked sex differences until this time.

There is a moderate day-to-day variation in excretion,[4] thus rendering meaningless the reporting of results to several decimal places, and diminishing the significance of "slightly high" and "slightly low" level reports.

The result of this test represents "total neutral" 17-ketosteroids, the end point for most clinical tests. Further fractionation is possible with separation into ketonic and nonketonic fractions, using Girard reagent T. The nonketonic fraction is usually 10 to 15 per cent of the total neutral results, although occasionally it may be 25 per cent. This separation does not add to the clinical usefulness of the test. However, the ketonic fraction may be further separated into alpha and beta fractions with digitonin. The beta fraction is usually under 5 per cent, but may be increased under certain conditions, and if increased to over 50 per cent, with a total excretion of over 50 mg. per day, is considered to be evidence for the presence of an adrenal cortical carcinoma. The simpler Allen[5] test is also reported to be positive in malignant adrenal tumors.

---

*Corrected reading is the colorimeter reading corrected for pigment and reagent blanks.

[4] Werner, S. C.: J. Clin. Endocrinol. 1: 951, 1941.

Studies of 17-ketosteroid urinary excretion in various endocrine diseases[6] have shown low levels in hypophyseal infantilism, Simmonds' disease, Addison's disease, especially in women where excretion should be close to ''0,'' myxedema, and occasionally in anorexia nervosa. While it is true that values in Simmonds' disease are generally lower than those in anorexia nervosa, there is overlapping of the ranges in the two diseases, so that in an individual patient the test may be helpful but not decisive.

High levels are found with adrenal cortical carcinoma or malignant adenoma, and moderately high figures are found in adrenal cortical hyperplasia, especially with the adrenogenital syndrome. In carcinoma, the excretion is usually over 50 mg. per day, and may be as high as 1,000 mg. plus per day. If the excretion is over 50 mg. per day, and if further fractionation shows that over 50 per cent of this is the beta fraction, a tentative diagnosis of adrenal cortical carcinoma seems justified. In adrenal cortical hyperplasia, excretion of from normal to 100 mg. per day is seen. The Allen[5] test may help to differentiate between adrenal carcinoma and hyperplasia. Occasional instances of verified adrenal cortical carcinoma have been reported in which the 17-ketosteroid excretion has been normal. In spite of this, the test has its greatest clinical importance in this condition.

Slightly low levels are found in male eunuchoidism, male castrates, ''burned-out'' gigantism and acromegaly, diabetes mellitus, in the male climacteric, and in chronic debilitating diseases. The level tends to fall in old age.

Slightly high levels are found in Cushing's syndrome, simple hirsutism (occasionally to 25 to 30 mg. per day), active acromegaly and gigantism, arrhenoblastoma, precocious puberty, pregnancy, and in hyperthecosis.

The 17-ketosteroid excretion is affected by a number of nonspecific processes, such as inanition and debilitating illnesses. A temporary sharp rise usually follows acute trauma such as fractures, surgery, etc. Slight elevation is observed upon physical exertion.

THE VAGINAL SMEAR[7]

The vaginal mucosa of the adult woman is lined by a stratified squamous epithelium 15 to 20 cells in depth. The basal layer is composed of small well-stained cells with well-defined comparatively large nuclei. The superficial layers are lined by large flattened foamy cells with or without small pyknotic nuclei. These cells are filled with glycogen. The middle cell layers of the vaginal mucosa are composed of moderately large round to ovoid cells with a central nucleus and with varying amounts of glycogen in the cytoplasm. The thickness of the vaginal mucosa, the glycogen content of the superficial cell layers, the pH of the vaginal secretions are directly under hormonal control. When hyperestrogenism is present as during pregnancy or in conditions which may sometimes be manifest by cystic glandular hyperplasia of the endometrium, there are frequently an associated increased thickness and succulence of the vaginal mucosa, an increased glycogen content of the superficial cell layers, and a low pH (acid) of the vaginal secretions. A vaginal smear taken at this stage will show only the superficial, desquamative, large, flat cells with minute pyknotic nuclei (Plate XXXV). On the other hand, in certain types of hypoestrogenism, as in types of amenorrhea, hypopituitarism, senile vaginitis, in childhood, in the climacteric, there is a concomitant atrophy or immaturity of the vaginal mucosa. The vaginal mucosa consists of a thin layer of epithelial cells which varies in depth from one to six cells. There is failure of renewal of much of the "functionalis" cell layers, the glycogen content of the cells is minimal, and the pH of the secretions is high (alkaline). A vaginal smear taken at this stage will show few if any of the superficial desquamative cells but many small round well-stained basal cells with vesicular nuclei and many leukocytes and also occasional large oval cells from the middle layer of the vaginal mucosa (Plate XXXVI). As these basal cells mature they push upward and become larger and the nuclei become smaller. They become desquamative epithelial cells with pyknotic nuclei as they mature. Degree of maturation differs according to estrogen production or deprivation as the case may be. There are occasional exceptions to the rule for we must consider the selective action of estrogen utilization, i.e., specific organs of the body are unable to assimilate the available estrogen.

[7] This section and the succeeding section were abstracted in part from Chapters 25, 53, and 54 of "Office Endocrinology," ed. 4, by Robert B. Greenblatt, M.D., published by Charles C Thomas, Springfield, Ill., 1952.

For the vaginal smear in the diagnosis of uterine cancer, see pp. 2173 ff.

The Technic and Interpretation of the Vaginal Smear

A small wooden spatula or ordinary cotton applicator is moistened with tap water. Use a speculum if necessary. Spread the folds of the vulva apart, insert the spatula into the vagina and rub gently along the lateral vaginal wall. Only the top layer, or surface epithelium should be obtained. The secretions procured are transferred to a glass slide, by passing the spatula across it. The slide is stained for 15 seconds with aqueous fuchsin and then washed. After the slide is dried, it is then ready for examination. The purpose of the vaginal smear is to determine the size and shape of the cells and nuclei; i.e., the proportion of the size of the nucleus to the size of the cell. It is well to rule out vaginitis due to monilia or trichomonads, as well as cervicitis, as this will prove of value in interpretation. Pick a clean section of the vagina, free of cervical secretion. Hence the value of using the speculum.

The interpretation of the findings in vaginal smears offers a little difficulty at first but proficiency is soon acquired. Reading of the smears varies from the negative "castrate" or 1 plus reaction, on to a positive "estrus" smear or 4 plus reaction. There are occasional inconsistencies and variations in vaginal smears from the human vagina. It is thought that in some patients there may be compensatory extraneous sources of estrogen-like substances, probably adrenal in origin. In general, the vaginal smear is a simple and reliable procedure for determining the presence of normal ovarian activity or estrogen deficiency.

Scale of the Vaginal Smear

4 Plus Reaction—large foamy desquamative epithelial cells with poor-staining cytoplasm, with or without small pyknotic nuclei; classified as positive, follicular, or estrus smear.

3 Plus Reaction—desquamative and large oval-shaped cells.

2 Plus Reaction—oval-shaped cells and occasional castrate cells.

1 Plus Reaction—basal cells, small round immature cells with large, deep-staining nuclei, and relatively small amount of cytoplasm, frequently accompanied by many polymorphonuclear leukocytes; classified as negative, estrogen deficient, or castrate smear.

Preparation of Stain

Any dye suitably diluted and filtered will suffice. Gentian violet, methylene blue, carbol fuchsin, or pinacyanole will do. Greenblatt uses a 0.5 per cent alcoholic solution of pinacyanole in 100 c.c. of absolute ethyl or methyl alcohol. The preparation will keep indefinitely. Any slides which fade may be easily restained. In the stain for simple vaginal cytology studies, vaginal smears were covered with a few drops of 0.5 per cent alcoholic solution of pinacyanole, a few drops of water were added for 10 seconds, and the slide then washed.

Physiology of the Vaginal Mucosa

Cuboidal cells line the basal membrane. Continual desquamation of the surface vaginal cells occurs. Glycogen stain of the vaginal mucosa:* superficial layers of epithelial cells are loaded with pink granular material, glycogen. An indication of the utilization of the body estrogen may be found in the amount of glycogen deposition in the vaginal mucosa. This is directly proportionate to the amount of estrogen present in the body; e.g., in pregnancy the glycogen content is very high. Among the various components into which glycogen breaks down is lactic acid which is responsible for the acid reaction of the vagina (normal pH: 4.5). Decrease in glycogen storage occurs with decrease of estrogen production; therefore if there is no glycogen present to be broken down, no acid is being produced, and the medium of the vagina shifts from acid toward alkaline. This indicates some incorrect function; and may be due either to estrogen deprivation or the presence of infection.

Vaginal Mucosa and the Vaginal Smear

1. **Newborn baby**—much glycogen is present because of mother's estrogen content. Mature vaginal epithelial smears.

2. **Child**—vaginal mucosa of several layers. Pus cells, castrate and desquamative cells in smears.

3. **Adolescence**—menses and ovulation occur. Glycogen is present, epithelial cells are large, desquamative.

4. **Postpartum period**—normal amenorrheic period with lactation from 3 to 9 months. Vaginal mucosa is atrophic. Castrate, pus cells in smears are

present throughout puerperium. (Sometimes the amenorrhea continues—prolonged puerperium—this indicates that the pituitary has never become reactivated.)

5. **Menopause**—small cells, castrate, and pus cells. Glycogen deficit, atrophic vagina. (The women who have normal vaginal mucosa at this stage usually can do without estrogens).

SUCTION CURETTAGE

The Technic of Suction Curettage as an Office Procedure

Many types of curettes are in use; either the Randall curette which is smooth, or the Novak curette which possesses small teeth, is generally employed. Examine the uterus for size and position, and rule out pregnancy. Use a speculum, small or large, and clean the cervix with Merthiolate. Without touching the vaginal wall insert the sterile curette and pass it through the cervix into the uterus. The position of the curette depends on the position of the uterus; i.e., whether it is anteflexed or retroverted. Use a 10 c.c. or 50 c.c. sterile syringe with a metal adaptor or a Luer-Lok syringe. Obtain the endometrium by suction, gently scraping the surface of the endometrium and then withdrawing the curette. Wash out the curettings with normal saline. The blood and mucus are thus eliminated, and there remain only the purplish pink curettings which are then placed in 10 per cent formaldehyde and sent to the pathologist for histologic study.

The Interpretation of the Curettings as a Guide to Therapy

The study of the curettings is important for diagnoses. To interpret the curettings correctly, it is vital to understand the physiology of the menstrual cycle. The first fourteen days of the normal cycle is the estrogenic stage or the proliferative phase of the endometrium and coincides with the maturation of the follicle. When the endometrium is in the proliferative or estrogenic stage, the glands are round, uniform, and test-tube-like and are lined by a single layer of columnar epithelium which frequently has a pseudostratified appearance. The cytoplasm of the cell is deep staining and the nucleus lies at the base of the cell (Fig. 315). The supporting stroma of the endometrial glands are small and compact with deep-staining pyknotic cells resembling adenoid tissue.

From the fourteenth to the seventeenth day is the presecretory phase, which coincides with rupture and ovulation. The cells lining the glands become somewhat fuller and the nuclei descend from the base to the mid-part of the cells (Plate XXXVII). Collections of granules form at the base of the cell, and the cytoplasm becomes paler and somewhat vacuolated. Best's carmine stain now shows deposit of glycogen at the base of the cell.

From the eighteenth day to the onset of menstruation is known as the luteal or secretory phase. It coincides with the ripening of corpus luteum and the endometrium is being prepared for nidation and gestation, hence it is frequently referred to as the progestinal phase of the endometrium. The test-tube-like glands become tortuous, the nucleus moves back toward the base. The cytoplasm at the apex becomes granular, and frequently the cell membrane at the apex ruptures with expulsion of the granules into the lumen of the gland (Plate XXXVIII). Hence the secretory phase, and Best's carmine-stained sections now show the glycogen at the apex of the cell or in the lumen of the gland. Papillary projections into the lumen may be observed giving the gland a saw-tooth appearance. If the ovum is not fertilized, it dies by the twenty-fifth to twenty-sixth day; there is a sudden drop in estrogen and progesterone production and

menstruation occurs. Endometrium obtained at this time, therefore, is frequently referred to as premenstrual. The supporting stroma cells become loose and may take on an edematous appearance, with a vesicular nucleus and a pale spongy, eosinophilic cytoplasm. This decidua-like reaction is sometimes very striking.

In general the best time of the month in which to perform a suction curettage is on the first day of a menstrual period (especially in sterility cases in order not to disturb a possible pregnancy). The type of endometrium obtained at that time often facilitates diagnosis and is indicative of therapy; i.e., it may be of significance or value depending on whether the endometrium is follicular (Fig. 315), mixed or imperfect progestinal (Fig. 316), hypoestrogenic (Fig. 317), hyperestrogenic (cystic glandular hyperplasia) (Fig. 318), estrogenic endometrium with pseudoluteinization of stroma (Fig. 319), hyperprogestinal (progestinal endometrium with decidua-like stroma) (Fig. 320), presecretory (Plate XXXVII), or progestinal (Plate XXXVIII). Suction curettage may be performed during the last week of the cycle preferably on the first day of the menses.

The Value of Suction Curettage in Amenorrhea, Menorrhagia, Dysmenorrhea, and Other Endocrine Disorders

Amenorrhea—perform the suction curettage at least 30 to 40 days after the last menstrual period.

Menorrhagia—perform the suction curettage at any time, preferably as soon as possible after the start of a phase of bleeding.

Dysmenorrhea—perform the suction curettage as close to the onset of menses as possible.

It must be borne in mind that the endometrium per se is not responsible for the bleeding but the study of the endometrium is important for it mirrors ovarian activity. If the endometrium is atrophic, it indicates that there is an estrogen deficit which may be hypopituitary in origin or due to primary ovarian failure. If, for instance, a persistent estrogenic endometrium is obtained on the twenty-fifth day, it indicates that ovulation has not taken place, and that the proliferative phase has accordingly continued. If a cystic glandular hyperplasia is present, it indicates that there is excessive local response to the circulating blood estrogens. An imperfect progestinal or mixed type of endometrium may signify faulty corpus luteum production. A true secretory endometrium is proof of the occurrence of ovulation and corpus luteum formation.

Vaginal Smear Technic in Estrogen Treatment (Method of Papanicolaou[1])

Obtain the vaginal secretion by using a pipette made of glass tubing 8 inches long and ⅜ inches in diameter. slightly curved at one end. Attach a strong rubber bulb to produce suction, at the other end. Take the sample from the region 5 to 6 cm. within the vagina and spread on a glass slide as a heavy film, much heavier than the ordinary blood film. The new technic, based on a study of vaginal smears conducted in cooperation with Herbert F. Traut, of the Department of Gynecology of Cornell Medical College, and of New York Hospital, has advantages over the previous method described by these writers.[2, 3]

In the older methods described by these writers, the staining of the cells was too deep to permit a sharp definition of their outlines in smears that were relatively thick or contained much blood. In most cases of carcinoma and in many other pathologic conditions there is a profuse vaginal discharge frequently mixed with blood which forms a heavy film on the slides. In such rich and bloody smears there is considerable crowding and overlapping of cells which, when deeply stained, cannot be well differentiated. This applies more particularly to the small endometrial cells which are often found in menstrual and uterine bleedings and have a pathognomonic value in the diagnosis of adenocarcinomas of the fundus[2] and of other gynecologic conditions. These cells also have great importance in evaluation of the normal menstrual cycle, of sterility, and of estrogenic and other endocrine therapy.

After long experimentation it was found that a much greater transparency and an equally good color differentiation of the cells can be obtained by the use of solutions of stains in 95 per cent alcohol instead of aqueous solutions. Various alcoholic stains were thus developed; two are described below.*

Reagents.—

Fixative.—

Equal parts of 95% alcohol and ether.

80%, 70%, and 50% Alcohols.—

See page 2120.

Harris Hematoxylin.—

See page 2105.

---

*For a revised method, see page 2173.

0.5% Aqueous Hydrochloric Acid Solution.—

Add 0.5 c.c. hydrochloric acid to enough distilled water to make 100 c.c.

Orange G.—

1. *For normal slides.*
   Dissolve 0.5 gm. orange G in
   100.0 c.c. of 95% alcohol.
   Add 0.015 gm. of phosphotungstic acid (if orange G 6 is used; if orange G 8 is used, add 0.010 gm. of the acid).
2. *For cancer diagnosis.* Use 0.025 gm. of phosphotungstic acid, and orange G 5, to obtain a sharper contrast of the abnormal cell types.

Stain EA 36.—

0.5% alcoholic light green SF yellowish, N.A.	45	c.c.
0.5% alcoholic Bismarck brown, N.A.	10	c.c.
0.5% alcoholic eosin yellowish, N.A.	45	c.c.
Acid phosphotungstic, Merck	0.2	gm.
Saturated aqueous solution of lithium carbonate	1	drop

Stain EA 25.—

0.5% alcoholic light green SF yellowish, N.A.	44	c.c.
0.5% alcoholic Bismarck brown, N.A.	12	c.c.
0.5% alcoholic eosin yellowish, N.A.	44	c.c.
Acid phosphotungstic, Merck	0.17	gm.
Saturated aqueous solution of lithium carbonate	1	drop

Mounting Medium (Clarite, Canada balsam, or gum damar).

Technic.—

Make up the 0.5% alcoholic solutions first. Since the solubility of the dyes in 95% alcohol is low, heat the solutions at the time of preparation. Keep the solutions in stock without filtering. Filter stains EA 36 and EA 25 to eliminate undissolved particles of stain.

Fix smears immediately (before drying) in equal parts of alcohol and ether for 5 to 15 minutes. (Although smears may be kept in the fixative indefinitely, a prolonged fixation of a week or more affects the staining reaction of the cells.)

Rinse consecutively in 70% and 50% alcohol, then in distilled water.

Stain in hematoxylin for 5 to 10 minutes. (Staining for only 2 minutes is often sufficient, but, as a rule, better results are obtained with longer staining of 5 to 6 minutes for normal smears, and of 8 to 10 minutes for smears used for diagnostic purposes, more particularly for cancer diagnosis. For sections, even longer staining is advised. This timing applies more specifically to Harris hematoxylin, prepared with domestic hematoxylin and ammonium alum. In order to obtain more uniform staining, used hematoxylin should not be discarded, but filtered from time to time. The loss from filtering and evaporation is gradually replaced by the addition of fresh stain.)

Rinse in distilled water.

Rinse 3 to 4 times in 0.5% hydrochloric acid solution.

Rinse thoroughly in water.

Rinse in distilled water, then in 50%, 70%, 80%, and 95% alcohols.

Stain 1 minute in orange G solution.

Rinse 5 to 10 times in each of two jars containing 95% alcohol to remove excess stain.

Stain in EA 36 or EA 25 for 2 minutes.

Rinse 5 to 10 times in each of three jars containing 95% alcohol. Do not use the same alcohol which was used after the orange G.

Rinse in absolute alcohol, then xylol.

Mount in Clarite, Canada balsam, or gum damar.

Nuclei of cells are deep blue or purple; cytoplasm is light blue or blue-green; keratinized cells are various shades of red.

The advantages offered by this staining method are the following: (1) The epithelial cells and the erythrocytes are more transparent. Overlapping cells can be more easily differentiated. (2) The color of the acidophilic cells varies from red to orange. This helps in the identification of certain smear types. Basophilic cells stain green or blue-green. (3) Cells or fragments of tissue penetrated by blood take a characteristic orange or orange-green color, which permits an easier recognition of small amounts of blood, even when erythrocytes are not distinctly seen. (4) Smears which were subjected to partial or even complete drying can be stained fairly satisfactorily. The differential coloring is not entirely lost.

Short Method.—

Stains EA 36 or EA 25 can be used for short staining by those who want an immediate examination of a slide. No fixative need be used. Dip the slides directly in the staining solution or cover them by stain from a drop bottle. Thus the smears are fixed and stained simultaneously within a few minutes, although they may be kept in the stain for a longer time without being overstained. Wash off the excess stain in 95% alcohol and carry the slides through absolute alcohol, then xylol, and mount in Clarite. The nuclei are stained faintly, but the cells show good differential staining and retain their transparency. Smears stained by this simple method can be restained by a repetition of the procedure described above, including hematoxylin. This will improve the nuclear staining as well as the cellular differentiation and will permit the use of the same smears for a more detailed cytologic study.

Interpretation.—In the normal or menstruating woman, several types of smears are found at different times in the menstrual cycle. During menstruation, large numbers of erythrocytes are seen, with a few flat epithelial plates having pyknotic nuclei. With cessation of external bleeding, there is a great increase in leukocytes, and the epithelial cells are relatively scanty. At about the ninth or tenth day of the cycle, the vaginal secretion becomes much richer in mucus, and leukocytes practically disappear. About ⅓ to ½ of the epithelial cells show cornification. At the time of ovulation, a few leukocytes may appear, and the proportion of cornified to noncornified cells remains about the same. After ovulation, around the fifteenth day of the cycle, leukocytes are again very scanty, and a large proportion of the epithelial cells are cornified. As menstruation approaches, leukocytes again appear in the smear, and epithelial cells become very abundant. The latter often occur in clumps, and tend to be folded or to have scalloped edges; cornified cells are not so abundant as before. These findings may be changed by the presence of infection or parasitic infestation in the vagina, by lesions of the cervix producing discharge, etc. However, if the complete cycle of changes can be demonstrated, it is assumed that the entire mechanism of cyclical ovarian activity is functioning normally.

It is the appearance of vaginal smears made in the absence of adequate ovarian activity that is most interesting from the practical therapeutic point of view. They reflect the fact that there is pathology present. Such smears show flat epithelial cells. The nuclei, instead of being small and pyknotic, are rather large, open, and do not stain as deeply. Numerous leukocytes are present. Under treatment with estrogens, the epithelial cells become flatter, cornified, with small pyknotic deeply stained nuclei, and the leukocytes diminish in number. If one takes a portion of the mucous membrane of the vagina for biopsy, it will be found that it has resumed the appearance which is characteristic of the premenopausal years.

One must bear in mind, however, that a diagnosis must not be made from one examination and that many extraneous factors may cause irritation of the vagina, thus changing the characteristics of the smear. Just as all other laboratory procedures teach us, experience and common sense will place this procedure in its proper position as a diagnostic aid and as a measure for controlling estrogenic therapeusis.

Preparation of Gonad-Stimulating Hormone of Pregnant Mare Serum (Cartland-Nelson Method)

This is a method of fractional precipitation of the hormone from plasma using acetone or alcohol, removal of impurities by proper adjustment of acidity, and final precipitation of the hormone fraction in the presence of increased concentration of acetone or alcohol. The hormone fractions are dry, white, water-soluble powders, are stable, and may be used to prepare sterile solutions for laboratory and clinical studies.

This method was worked out by Cartland and Nelson.[1] The following chart from Cartland and Nelson gives the details of the process.

FLOW SHEET OF FRACTIONATION PROCEDURE FOR PREPARATION OF GONADOTROPIC HORMONE

16.5 liters citrated blood plasma (assay 119,000 rat units); adjust pH to 7.4 and add 16.5 liters of acetone; let stand 16 hours, separate precipitate and wash with 16.5 liters of 50% acetone

50% acetone supernatant + washings Add HCl to pH 6.0; let stand 16 hours in cold room; supercentrifuge	50% acetone ppt., pH 7.4 1,055 gm. crude protein. Assay, approximately 5,000 units (discard)
50% acetone supernatant, pH 6.0 Add acetone to make 70%, chill 16 hours, and centrifuge	50% acetone ppt., pH 6.0 45 gm. mostly protein. Assay, approximately 1,500 units (discard)
70% acetone ppt. pH 6.0 Wash with alcohol and ether and dry. Solids, 44.2 gm.; total N, 550 mg. Assay, 110,000 rat units. Redissolve in 1,000 c.c. 10% acetone and centrifuge from insoluble material	70% acetone supernatant Solids, 265 gm. salts and extractives. Assay, approximately 1,000 units (discard)
10% acetone solution Add acetone to make 50%, adjust pH to 6.0, chill 16 hours, and centrifuge	Insoluble in 10% acetone Solids, 5.38 gm. (inactive, discard)
50% acetone supernatant, pH 6.0 Dilute to 2,700 c.c. with 50% acetone, and add acetone to make 65%, chill for 16 hours, and centrifuge	50% acetone ppt., pH 6.0 Solids, 2.86 gm. Assay, 1,600 units
65% acetone ppt., pH 6.0 Wash with alcohol and ether and dry. Solids, 9.81 gm.; total N, 261 mg. Assay, 106,000 units	65% acetone supernatant Solids, 17.5 gm. Assay, 500 units (discard)

Biological Assay Method.—Follicle stimulation, ovulation, corpus luteum formation and estrus changes in the uterus and vagina may be produced in immature female rats by the injection of the mare serum hormone. Female rats of the Wistar strain colony were used by Cartland and Nelson. Weight should be 30 to 40 grams at 21 to 23 days of age. They are injected subcutaneously on each of three successive days with 1 c.c. doses of suitable dilutions of the hormone in physiologic saline. Ninety-six hours after the first injection the rats are sacrified and the ovaries dissected free of oviducts and bursae, examined for corpora lutea, and weighed. A rat unit is defined as the total dose of hormone which, administered as described above, will produce at autopsy a pair of ovaries weighing 65 mg. which is approximately five times the weight of the ovaries of the uninjected controls. A satisfactory procedure of assay is to estimate the approximate strength of a given extract by a series of preliminary injections and, on the basis of the results obtained, inject two groups of ten to twenty rats each with amounts estimated respectively to be greater and less than the 1 unit dose by approximately 25 per cent. The dose necessary to produce an ovarian weight of 65 mg. is determined by interpolation and, if desired, this may be checked by a further test.

---

HYPERSENSITIVENESS

In the present incomplete state of knowledge concerning the phenomena of hypersensitiveness, a biologic classification is not possible. They must simply be listed by their generally recognized designations and further studied as to their mutual relationships.

Five forms are recognized: atopy, anaphylaxis, hypersensitiveness of infection (tuberculin type), contact dermatitis (dermatitis venenata), and serum disease, with which is associated drug idiosyncrasy characterized by eruption and fever and other symptoms of serum disease after an incubation period following contact with the drug. See Table 135[1] for the outstanding features of these forms.

ATOPY

Clinical forms of human hypersensitiveness not occurring in lower animals, and subject to hereditary influences, are known as atopy. Only asthma and hay fever are included, but eczema and certain forms of drug and food idiosyncrasy may later be placed with these.

Etiology.—In explanation of protein sensitization, many theories have been advanced, practically all of which are based on the belief that the susceptible person has received a previous sensitizing dose of a foreign protein. A second or provocative dose of a homologous protein, given after a certain interval, produces recognizable symptoms. It is considered necessary that both the sensitizing and the provocative dose should enter the body in an unmodified form in such a way as to be subject to parenteral digestion; for instance, by injection or inhalation. Cases of sensitization in which there is no history of a previous injection are explained by the fact that protein substances may enter the blood by way of the digestive tract unchanged, if they are present in excessive amount, or if there are gastrointestinal abnormalities. This latter consideration explains many cases of food sensitization satisfactorily, as the possibility of absorption of unchanged protein from the stomach has been demonstrated beyond doubt, especially in infants.

TABLE 135[1]

	OCCURRENCE	AGE AT ONSET	HOW ESTABLISHED	HEREDITY	MECHANISM	GUINEA PIG	HUMAN SKIN	DESENSITIZATION
Anaphylaxis	Occurs in lower animals, not demonstrated in man	May be acquired in utero	Induced experimentally in practically all individuals among guinea pigs, rabbits and dogs	Not especially subject to heredity	Antibodies associated with or identical with precipitin	Guinea pig uterus can be sensitized with the antibody	Cannot be sensitized with the antibody	Always possible in guinea pig and dog; difficult in rabbit
Atopy	Peculiar to man affecting 7 per cent of whites	Determined by heredity	Not induced at will	Subject strictly to heredity	Reagins not associated with precipitin	Guinea pig uterus cannot be sensitized with the reagin	Can be sensitized with the reagin	Has not been accomplished at will
Hypersensitiveness of infection	Observed in all animals susceptible to tuberculosis	Determined by infection	Results from infection	Not especially subject to heredity	Not yet found; not anaphylactic antibodies	Guinea pig uterus said to have been sensitized	Human skin cannot be sensitized passively with serum of sensitive person	Has been accomplished
Contact dermatitis Dermatitis venenata	Peculiar to man, affecting 70 per cent of whites or more	At any time of life, upon sufficient contact	Develops after contact with excitant	Not subject to atopic hereditary influence	Not yet found	**Bloch reports** positive experiments with guinea pig and rat	Human skin cannot be passively sensitized with serum of sensitive person	Has not been accomplished
"Ordinary" serum disease with possibly an ordinary form of drug idiosyncrasy	Peculiar to man, affecting 90 per cent of whites	Susceptibility present at birth	Develops during the course of contact with foreign protein	Not subject to atopic hereditary influence	Not yet demonstrated	Anaphylactic antibodies sometimes demonstrable in patients' blood	Human skin can sometimes be passively sensitized with serum of sensitive person	Not possible

[1] Coca, Walzer, and Thommen: Asthma and Hay Fever in Theory and Practice, Charles C Thomas, Springfield, Ill.

The etiological classification of hay fever, pollinosis, and allergic coryza is given by French[2] as follows:

I. Allergic

$$\text{(a) By inhalation} \left\{\begin{array}{l}\text{animal emanations}\\ \text{pollens (hay fever)}\\ \text{sachets and perfumes}\end{array}\right.$$

$$\text{(b) By ingestion} \left\{\begin{array}{l}\text{drugs}\\ \text{foods}\end{array}\right.$$

(c) By absorption from foci—bacterial

$$\textit{II. Nonallergic} \left\}\begin{array}{l}\text{infections}\\ \text{vasomoter rhinitis}\end{array}\right.$$

To animal emanations are ascribed 10 to 15 per cent of all cases of allergic coryza: 70 to 75 per cent are due to pollen hypersensitiveness. Foods and drugs and bacterial proteins are included in order to make the classification complete. It is stated, however, that no case of pure, uncomplicated coryza has ever been observed as due to food or to drugs.

''Atopens and excitants are considered under the following headings:[1]

''I. Inhalants
  A. Pollens
  B. Animal Danders
    1. Horse
    2. Cat
    3. Dog
    4. Goat
    5. Rabbit
    6. Wool
    7. Feathers
    8. Cow
    9. Hog

---

[2] French: Clin. Med. & Surg., p. 571, Aug., 1928.

The evidence afforded by a careful study of a large series of perennial hay fever cases seems to show that the sensitivity of the patient is acquired during the second and third decades of life, or around the age of twenty to thirty years. Multiple sensitivity is the rule.

According to Coca, Walzer, and Thommen,[1] inhalants usually play little or no part in causing atopic symptoms during the first or second year of life. Food or occasionally contact offenders such as silk or wool are more often the cause of these reactions. Stuart and Farnham[2] have found the greatest percentage of food sensitivity in the second year (26 per cent of 57 positive cases in children). There is then a rapid decline, with a negligible incidence after the eighth year. Inhalant hypersensitivity, however, is infrequent during the first three years (3.5 per cent of 87 positive cases), rising rapidly thereafter until the eighth year, followed by a general decline. During the fourth and fifth years, frequencies of both types of sensitivity closely approximate each other.

Peshkin[3] also found food sensitivity most frequent in children in the second year, with a great frequency of inhalant hypersensitiveness in his series of children under fourteen years of age (98 per cent sensitive cases)—a larger incidence than food sensitivity in the same group (71 per cent of sensitive cases). Although food sensitivities occur frequently in adults, they are in a decided minority in comparison with inhalants as actual causes of asthma.

Heredity.—In certain cases of allergy there seems to be a hereditary tendency. Whole families have been found to possess an idiosyncrasy to a given protein or to several proteins, the type varying with the different members. In other instances, asthma, urticaria, hay fever, and migraine have been present in the same family. In this connection it is interesting to note that sensitization has been passed from donor to recipient in cases of blood transfusion, and also from a nursing mother to her child.

Hartwell[4] demonstrated that an excess of protein may affect the child without inconveniencing the mother. In his experiments with rats he added caseinogen in excessive quantities to the diet of the nursing mother rat. The mother remained in good health, but some of the young rats soon died, and the remainder were not successfully weaned; they suffered from convulsions and extreme exhaustion before death, a fact of great interest in view of the possible causative relationship between protein sensitization and simple or epileptic convulsions in infants and others.

Anaphylaxis[5]

Anaphylaxis is a specific sensitiveness which can be induced either actively by previous contact with the antigen or passively by contact with antibodies from another individual. Anaphylactic antibodies can be demonstrated in certain tissues, characteristically different in different species of animals; these antibodies are capable of sensitizing the unstriated muscle of guinea pig uterine strip.

[2] Stuart, H. C., and Farnham, M.: Am. J. Dis. Child. 32: 341, 1926.

[3] Peshkin, M.: Am. J. Dis. Child. 31: 763, 1926.

[4] Hartwell: Lancet, July 2, 1921.

[5] Coca, Walzer and Thommen: Ibid.

H. G. Wells[3] identifies anaphylactic sensitiveness by the following criteria:

(1) The substance injected must produce symptoms only in sensitized animals. If symptoms are produced in nonsensitized animals by injection of the same substance, anaphylaxis has not been demonstrated. (2) Symptoms must be characteristic anaphylactic reactions as observed in the usual reactions with typical soluble proteins. They must be the same for all antigens with the same test animal, but must differ characteristically with each species of animal. One must demonstrate: (3) passive sensitization by injection with sera of sensitized animals, (4) typical reactions in virgin guinea pig uterus strip, (5) by using atropine and epinephrine, amelioration or prevention of bronchial spasm in guinea pigs, (6) exclusion of possibility of capillary thrombosis or embolism when observing symptoms, (7) desensitization after recovery from anaphylactic shock.

Serum Disease

There is no generally accepted definition of this term, because of lack of unanimity as to the nature of physiologic reactions to the injections of foreign serum. The application of the term should be limited to those reactions following the first injection of foreign serum after a definite period of incubation; typically after about one week.

Frequency.—Incidence varies with different kinds of sera, from less than 3 per cent up to 6 per cent, by subcutaneous injection.

Age.—Incidence is the same throughout life, as opposed to atopic conditions (including atopic sensitiveness to horse serum) where the incidence increases from birth to middle life.

Incubation Period.—Following a first injection, the incubation period varies from three hours to longer than three weeks, with the majority of reactions occurring between the eighth and twelfth days.

Symptoms.—Fever, eruption, edema, and joint pains may all occur in one individual, but more frequently one or the other is missing. *Fever* may be as high as 106°. It may occur a day or two before the eruption, or only in the later stages. *Eruption* is usually urticarial. It may be limited to the site of the injection or may affect symmetrically all parts of the body. Local eruptions appear earlier than general eruptions. According to von Pirquet and Schick, *joint symptoms* are pain and tenderness usually without swelling. *Edema* usually affects only the face and dependent parts. Although albuminuria may accompany edema, it is never severe. *Mucous membranes* are rarely affected. Diarrhea and changes in the conjunctiva are the only changes reported in a few instances. *Lymph nodes* are enlarged, painful, and tender. Neutrophiles are sometimes lower during the attack.

Heredity.—Since about 90 per cent of the white race is susceptible to the development of serum disease, the influence of heredity does not enter into a consideration of the problem.

---

Contact Dermatitis (Dermatitis Venenata)

By contact dermatitis is meant the form of cutaneous hypersensitiveness that is typified by the reactions to poison ivy in this country, and to primrose in Europe.

By atopic eczema is meant eczema occurring usually (though not exclusively) in children, excited often by some food, and subject to hereditary influences identical with or similar to that which controls the other atopic conditions of asthma and hay fever.

These two forms of cutaneous hypersensitiveness must be distinguished from each other. Atopic hereditary influence apparently controls occurrence of atopic eczema, but plays no role in the etiology of contact dermatitis. Atopic eczema frequently occurs in individuals with family history of this condition or of asthma or hay fever in later life. On the other hand, contact dermatitis may affect all or the majority of those who have been in contact with the specific excitant. In atopic eczema, application of the excitant to unaffected skin usually causes no reaction, whereas in contact dermatitis the entire skin surface is frequently susceptible to surface application of the excitant. The lesion thus produced is alike in all areas. Injecting intracutaneously specific excitant of the atopic eczema into unaffected areas of the skin usually results in wheal formation, and reagins are usually found in the blood. In contact dermatitis, however, reagins usually are not present in the blood and the intracutaneous injection of the excitant does not produce wheal formation (Cooke).

In this country, excitants of contact dermatitis are oleoresin of poison ivy and the active principle of sumac, poison oak, primrose, pollen oil, and others; certain chemicals, especially nickel salts and arsenic. These cause the condition known as ''dermatitis venenata.''

The idea that some people have a natural immunity against Rhus poisoning is erroneous. This is a typical allergy and desensitization rather than a true immunity, natural or acquired, as the case may be. Rhus poisoning is due to a single genus, *Rhus* or *Toxicodendron.* A classification adopted by the U. S. Herbarium in Washington, D. C., under the genus name *Toxicodendron,* lists the following species: (1) *Toxicodendron toxicodendron* (the former *Rhus toxicodendron or Rhus quercifolia*), (2) *Toxicodendron radicans* (eastern ivy), (3) *Toxicodendron diversilobum* (western poison oak, *Rhus lobata* or *Rhus diversiloba*), (4) *Toxicodendron vernix* (swamp sumac, *Rhus vernix, Rhus venenata*).

This subject has been reviewed by Turner.[1] He states that the toxic substance common to all these plants is urushiol. It is a dialyzable but nonvolatile oily resin. It is not air-borne, all statements to the contrary notwithstanding. Poisoning occurs by indirect as well as direct contact, and as little as 0.001 mg. will cause dermatitis. The difficulty of avoiding poisoning is increased by the fact that the plant is pleomorphic. It is thus the plant's toxicity, pleomorphism, and ubiquity which make poisoning extremely difficult to avoid by the highly susceptible. The effectiveness of two chemical herbicides, ammonium sulfamate and 2,4-dichlorophenoxyacetic acid, proved to be the first really possible solution of this public health problem. In other words, with these two herbicides, eradication of the plant in frequented areas is now possible.

---

[1] Turner, C. E.: Am. J. Pub. Health 37: 7-12. 1947.

Hypersensitiveness of Infection

Hypersensitiveness of infection is a specific sensitiveness in man and lower animals that is mediated by a special mechanism.* (The word "mechanism" is used in the sense of the specific element through which the hypersensitive state is established.) In other words, the physiologic reactions of hypersensitiveness are all conceived to be caused by the interaction of a pair of specifically related substances; for example, an antigen and an antibody, or antibody-like substance, the susceptible tissues not being directly irritated by either of the two substances alone.

The term "hypersensitiveness" is used in its immunologic sense; that is, in the sense of specific sensitiveness as distinguished from its general medical sense of nonspecific hyperesthesia and also from the sense of increased reactivity.

The word "allergy" could have been used in the same sense, but this has been prevented by two circumstances. One of these has been Doerr's insistence upon a strictly etymologic interpretation of the term, making its meaning too broad; the other circumstance is the fact that in this country, at least, the word has been generally applied to the various forms of hypersensitiveness, exclusive of anaphylaxis in lower animals.

Preparation of Materials

The methods of preparing the materials and of carrying out the cutaneous tests differ according to whether the intradermal injection method or scarification method of performing the tests is to be employed.

The material generally used for the so-called "scratch" method is a powder representing the dried precipitate obtained upon treating an extract or solution of the original material with acetone. The relative effectiveness of the dry preparations and the untreated fluid preparations, which will be described presently, has been investigated in two different institutions, by Larsen, Paddock, and Alexander[1] and by Aaron Brown.[2] These observers agreed that the fluid preparations were distinctly superior to the powders, and Brown concluded that the intradermal method was superior to the scratch method when the fluid preparations were used in both.

The fluid preparations are now available commercially, but as the physician frequently finds it necessary for the diagnosis of an allergic condition to prepare a special extract, sometimes of an unusual material, the general principles which are given in making the test extracts may be followed.

The preparation of the fluid extracts must be varied according to the nature of the original material, as well as of its active substance. Since the excitants of atopic hypersensitiveness are usually insoluble in fat solvents, and, since a clear, aqueous extract is often not obtainable in the presence of fatty substances, these fatty substances are removed from the original material with some fat solvent such as ether, toluol, or carbon tetrachloride.

---

*J. Allergy 1: 1, 1929.

[1] J. Immunol. 7: 81, 1922.

[2] J. Immunol. 7: 97, 1922.

For most materials, the aqueous extracting fluid is a 0.4 per cent sodium chloride, made neutral, according to the formula of Alice Evans,[3] with phosphate buffer salts.

The extracting fluid just referred to is kept in concentrated form in two solutions, 1 and 2.

Stock Buffered Saline Solutions 1 and 2

1. Sodium chloride	50.0	gm.
Monobasic potassium phosphate (KH_2PO_4)	3.63	gm.
Dibasic sodium phosphate ($Na_2HPO_4 \cdot 12H_2O$)	14.31	gm.
Distilled water to make	1,000.0	c.c.
2. 4% carbolic acid.		

Diluted Buffered Saline

For use, add 1 part of No. 1 and 1 part of No. 2 to 8 parts of distilled water. The pH of 7.0 remains constant when sterilized by boiling. It is not suitable for pollens or house dust.

Alkaline Extracting Fluid (Coca's Fluid)

For pollens

Sodium chloride	5.0	gm.
Sodium bicarbonate	2.75	gm.
Phenol	4.0	gm.
Distilled water	1,000.0	c.c.

Pass CO_2 through the fluid until a sample of it remains colorless to phenolphthalein. Keep in tightly stoppered bottles.

Preserving Fluid

For fruit and vegetable juice

Stock:

Sodium chloride	25.0	gm.
Sodium bicarbonate	12.5	gm.
Phenol	20.0	gm.
Distilled water	1,000.0	c.c.

Diluted:

Use 1 part of the stock to 4 parts of juice for testing. Toluol must be added to prevent the growth of bacteria. If cereals are used (or flour, etc.) add the toluol to the meal before adding it to the stock. Extraction time is twenty-four hours. For danders, it is forty-eight hours, and for pollens two to three hours. Sterilize by filtration through Berkefeld or Seitz filters. If the material cannot be filtered, dialysis may be used.

Preparation of Allergens

House Dust

Store in well-covered ash cans containing an open jar of granular calcium chloride. Use the alkaline extracting fluid. Pass carbon dioxide through it for ten to fifteen minutes before using. Use enough extracting fluid to wet the material thoroughly. Add toluol to kill the bacteria. Extract for twenty-four hours. Squeeze through a press. Filter through filter paper. Dialyze for two to three days against the alkaline extracting fluid, changing the fluid twice daily, and bubble carbon dioxide through the outside fluid constantly. (Use No. 1200 cellophane sheets for dialyzing. These may be obtained from E. I. Du Pont de Nemours and Co., New York.)

---

[3] Evans, Alice: J. Infect. Dis. 30: 95, 1922.

Extract first with ether to remove the fatty substances. The ether extract should be filtered to retain the small particles.

Animal Danders

1. **Horse Dander.**—Sift the curryings of cleanly kept horses through a kitchen strainer. Extract through a Buchner funnel with water-free ether until most of the coloring matter has been removed. Extract further with toluol or calcium chloride. Wash out with water-free ether. Evaporate the ether. The dander is in the ether, and remains in a cakelike mass. Break this up and remove the hairs by fine sifting. Keep the powder can dry over granular calcium chloride or in air-tight jars. This can be kept for years.

2. **Dog Dander.**—Use the clipped hair of cleanly kept dogs. Suspend in liberal quantity of water-free ether. Stir vigorously. Strain through kitchen strainers. The dander is in the ether. Proceed as for horse dander. Use 50 gm. of dog dander in 500 c.c. buffered saline. Extract for four days. Dialyze. It should contain 0.14 mg. N per c.c.

3. **Rabbit and Cat Hair.**—Epithelial scales remain attached to the hair. Extract from the ether-washed hair.

4. **Sheep's Wool** contains an extraordinarily large amount of fat. It can be extracted in water-free ether very easily by using the whole hair in the ether.

Feathers

Obtain different types of feathers from the dressers of these fowls. Feathers must not be immersed in water at any time. Stir the dry feathers in water-free ether. Treat the sediment the same as the animal danders.

Cereals

Material	Quantity	Buffered Saline	N Content in mg. per c.c.
Buckwheat	280 gm.	1,800 c.c.	2.70 mg.
Corn meal	708 gm.	600 c.c.	0.45 mg.
Orris, powdered	460 gm.	1,900 c.c.	0.18 mg.
Rice polish*	225 gm.	2,000 c.c.	0.30 mg.
Wheat flour	350 gm.	2,600 c.c.	0.75 mg.
Oatmeal	584 gm.	1,500 c.c.	0.40 mg.
Rye flour	145 gm.	400 c.c.	1.00 mg.

Extract the cereals and orris roots with ether to remove the coloring matter. Moisten the ether-treated meal well with toluol. Suspend in buffered saline twenty-four to forty-eight hours. Dialyze the oat extract. (Cereals should all be dialyzed.) Proceed as above with filtration, etc.

Seeds and Nuts

Use unroasted seeds and nuts (coffee beans, cocoa beans, etc.). Pass raw nuts and beans through meat chopper. Extract with ether frequently enough to remove the oil. Grind in a coffee grinder. Treat with ether. Grind to a powder.

Material	Quantity	Buffered Saline Extracting Fluid	N Content of Extract per c.c.
Almond	90 gm.	1,000 c.c.	3.89 mg.
Cocoanut	1 nut	1,500 c.c.	0.23 mg.
Caraway seed	50 gm.	500 c.c.	0.53 mg.
Cotton seed	40 gm.	1,000 c.c.	2.30 mg.
Mustard	1 lb.	1,000 c.c.	6.40 mg.
Green peanut	300 gm. of flour	2,500 c.c.	4.80 mg.
Green pea	420 gm. of flour	1,000 c.c.	2.90 mg.
Vanilla bean	1 lb.	1,000 c.c.	0.28 mg.
Black walnut	85 gm. of flour	600 c.c.	1.40 mg.

---

*Louisiana State Rice Milling Co., 396 Greenwich St., New York.

Mustard and pepper should be treated for one week with ether to remove most of the irritating oil. Use a liberal excess and change once or twice daily. Proceed as above.

Milk

Separate the casein (casein is undesirable). Use fresh unpasteurized milk. Remove fat in a Sharples supercentrifuge at 35,000 r.p.m. Mix 800 c.c. of this milk with 2.5 c.c. of 1 per cent rennin solution. Place in a water-bath at 37° C. without stirring for one-half hour. Strain through a sterile towel. Sterilize the filtrate by filtration through a Berkefeld filter after adding 7 c.c. of saturated sodium carbonate solution. For use, dilute 1:10 and 1:100.

Egg

Dilute the egg white 1:10 and 1:100 with buffered saline solution. Sterilize with toluol over a period of three or more days. Filter sterile. Nitrogen content should be 0.32 mg. per c.c.

Meats

Treat ground-up meats with toluol to remove the fat. Let the extracts stand until precipitation is complete. Dilute with buffered saline.

Juicy Vegetables and Fruits

Press the pulp in a strong towel to obtain the juice. Four parts of juice are added to one part of preserving fluid. Let it stand under toluol six days or until precipitation is complete. Use diluted.

Poison Ivy

Use freshly collected leaves. Spread in a warm dry room on newspapers for several days until dry. Place in tin pails containing a layer of finely granulated calcium chloride over which is paper or cotton. Lids must fit tightly. Leave until dry. Prepare a coarse meal by rubbing up the leaves through a coarse meshed wire sieve. Omit the leaves and midribs. Store over calcium chloride or in stoppered jars. This preparation cannot be used after several months. Mix 10 gm. with 100 c.c. absolute alcohol. After twenty-four hours (or more), filter. It is then ready for use. (Chlorophyll can be removed with animal charcoal.)

Protein and Pollen Tests

Skin Tests for the Determination of Hypersusceptibility to Proteins and Pollens

1. Proteins.—

The proteins for the test may be made as described above, or purchased from various biological supply houses. The selection of proteins for the test is made by the laboratory. The following list is suggested:

Treatment No. 1.—Bacteria.

Catarrhalis
Diphtheroid
Micrococcus tetragenous
Streptococcus hemolyticus
Streptococcus nonhemolyticus
Streptococcus viridans
Staphylococcus albus
Staphylococcus aureus
Staphylococcus citreus
Pneumococcus Type I
Pneumococcus Type II
Pneumococcus Type III

Treatment No. 2.—Hair and Feathers.

Cattle hair
Dog hair
Guinea pig hair
Rabbit hair
Chicken feathers
Duck feathers
Goose feathers
Horse dander
Sheep wool

Treatment No. 3.—Eggs and Beverages.

Casein
Cheese
Egg whole
Egg white
Lactalbumin
Egg yolk
Cocoa
Coffee
Milk (cow)
Milk (goat)
Tea

Treatment No. 4.—Grains.

Barley
Buckwheat
Lentil
Oats
Rice
Wheat
W. Gliadin
W. Globulin
W. Glutenin
W. Leucosin
W. Proteose

Treatment No. 5.—Meat and Fowl.

Beef
Goat
Lamb
Pork
Veal
Beef serum
Horse serum
Chicken
Duck
Goose
Guinea fowl
Squab fowl
Turkey

Treatment No. 6.—Vegetables.

Asparagus
Bean
Beet
Cabbage
Carrot
Cauliflower
Cucumber
Egg plant
Garlic
Lettuce
Lima beans
Mushrooms
Mustard
Orris root

Treatment No. 7.—Vegetables and Nuts.

Parsnip
Pea
Potatoes
Spinach
Squash
Sweet potatoes
Tomatoes
Turnip
Almond
Brazil
Chestnut
English walnut
Peanut
Pecan

Treatment No. 8.—Fish.

Bluefish
Clams
Dogfish
Haddock
Crab
Halibut
Herring
Lobster
Mackerel
Oyster
Perch
Pike
Scallop
Salmon
Shad
Shrimp
Smelts
Sole

Treatment No. 9.—Fruit.

Banana
Cantaloupe
Fig
Grapefruit
Orange
Peach
Pineapple
Raspberry
Rhubarb
Strawberry

Have on hand a box of sterilized toothpicks, a bottle of 0.4% sodium hydroxide (N/10), sterile needles, gauze, alcohol, sterile water.

Give the patient a list of the proteins and instruct him to abstain from eating any of the proteins for the test to be made on the following day.

In other words, when the patient first reports for the test, make tests with treatments Nos. 1 and 2. Instruct him to eat no eggs or beverages (treatment No. 3) in the twenty-four hours' time between this day's test and the one to be made the following day. On the following day, make the tests with treatment No. 3.

Instruct him to abstain from foods on Numbers 4 and 5 for the next twenty-four hours, etc.

Do not limit the patient's food too much; for example, do not take eggs, beverages, grains, and meat from his diet in one day.

The exact order of the treatments is not important.

Method of Making the Test: Cleanse the skin of the flexor surface of the forearm with alcohol.

With a sterile needle, scratch the superficial skin, making scratches about ½ inch in length, and ½ inch apart. Make one scratch for each of the proteins in the test, and one extra scratch for the control. Do not scratch so deeply as to draw blood.

Place 1 drop of 0.4% sodium hydroxide on each scratch, including the control. Using a different toothpick for each scratch, place some of the protein extracts on their respective scratches, and rub into the skin. Do not put any protein on the control scratch. Note on which scratch each protein is placed, so as to avoid confusion in reading the results.

Allow to stand in contact with the skin for twenty to thirty minutes. Wash off with sterile water, and read.

Reading the Results: All scratches which look like the control scratch are negative. A ++++ reaction is one in which there is decided swelling around the scratch, with a wide area of inflammation.

All other degrees of reaction are judged by comparison with the ++++ and the negative reactions. Write the result of each protein after the name of the protein on the report blank.

Some laboratories prefer to inject intradermally instead of making scratches. Material for intradermal injections may be purchased from various biological houses.

2. Pollens.—

Pollens and Hay Fever.—The impression prevails among many lay and professional persons that roses, which come in the early summer, and goldenrod, which comes in the late summer, are largely responsible for hay fever. Wodehouse[1] called attention to the fact that flowers which cause hay fever are not necessarily objects of admiration, but are often associated with others, more conspicuous, which flower at the same time. The latter are thus often blamed whereas the former should be sought. When roses bloom, one usually finds nearby certain species of grass which cast out enormously more pollen than is produced by roses. At the close of summer, when goldenrod is in bloom, the less conspicuous ragweeds fill the air with infinitely more pollen from their greenish flowers.

Many plants other than grasses and ragweeds contribute to production of hay fever. Each climatic area has its own group, which flower in most localities in three distinct seasons. The *early spring* type is usually mild and of short duration. Most frequent offenders are elm, oak, poplar, birch, maple, walnut, and willow, which scatter enormous amounts of pollen over a relatively short span. This type of hay fever is therefore less important than the other two types. The second, or *early summer* type, accompanies the flowering of the grasses, which shed their pollen shortly before the trees complete their flowering, and continue until about haying time. The flowering period of these grasses is generally short, although usually longer than that of the trees, and since there are so many varieties, and their flowering periods are slightly different, the actual length of early summer type of hay fever is usually greater than that associated with the trees. Pollen irritation of grasses is more intense than that caused by tree pollens. The third period corresponds with the flowering of such plants as ragweeds, cockleburs, and goldenrods in the East, and ragweeds, false ragweeds, cockleburs, sagebrushes, and many others in the West.

---

[1] Wodehouse, R. P.: Pollen Grains. Their Structure, Identification, and Significance in Science and Medicine. McGraw-Hill Book Company, Inc., New York and London, 1935, p. 134. By permission of author and publisher.

Wodehouse further states that trees which contribute their pollen to the cause of hay fever in the early spring are all wind pollinated, except the maples and willows. The former employ insects to effect pollination. The willows are both wind and insect pollinated. Birches, gray, black, and yellow, though they have flowering periods of scarcely over a week each, have been known to produce birch hay fever. Elms may be productive of hay fever. Poplars flower before the first unfolding of the leaves. Arizona cottonwood, which is a poplar, is regarded in southern Arizona and California as a frequent cause of hay fever. Pines, spruces, and cedars, with large quantities of pollen, scarcely ever cause hay fever with the exception of the mountain cedar. Walnuts of the East, black walnut and butternut, are not a serious factor, while the California black walnut is regarded as the most frequent cause of spring hay fever in the Sacramento, Napa, and Russian River valleys of California. There are many cases of oak hay fever, but in comparison with the enormous quantities of pollen which these trees shed the cases are fewer than would be expected. Sycamores are, in Wodehouse's opinion, quite harmless. In the southern states the hackberries or nettle-trees are responsible for some cases of hay fever.

The early summer hay fever is due to grasses. The low spear grass and the sweet vernal grass, which follows soon after the first flowering of low spear grass, are important contributors to this hay fever. Then comes the June grass, likewise the orchard grass, which both flower about the same time in May and continue through most of June, shedding large quantities of light, air-borne pollen. After these come redtop and timothy, flowering late in June and continuing through most of July. Bermuda grass and Johnson grass also cause hay fever in the warm and more arid regions of the United States. The late summer hay fever, Wodehouse believes, is usually due to ragweeds, the types of which are the common or dwarf ragweed of the eastern states and the giant ragweed, both flowering at almost the same time, the giant preceding the dwarf by only a few days. They are found in northeastern United States and reach almost across the continent in the northern states and Canada. They have a counterpart in the western ragweed and western giant ragweed. There are also so-called false ragweeds, of which there are probably twenty-five species in the United States. Wodehouse calls attention to the fact that the marsh elders belong to the same family as the ragweeds and false ragweeds but differ from them in that the pollen-bearing and seed-bearing flowers exist in the same heads and they lack the long spikes of pollen-bearing flowers typical of other members of the family. Therefore, they do not possess as efficient a pollen-dispersing apparatus as the others. Cockleburs are related to the ragweeds. Sagebrushes and mugworts are another group of hay fever plants, of which there are about two hundred species. They are commonest in dry regions and in greatest abundance in the Rocky Mountain states. The well-known sagebrush is an example of this weed. There are chenopods and amaranths which contain many hay fever plants.

In order to make a diagnosis of the exact species of plants which disturb hay fever sufferers, one must produce a skin reaction with an extract of the pollen which has caused the hay fever. This may be accomplished by purchasing these extracts from some well-known and reliable firm, such as Arlington Chemical Company, of Yonkers, New York, Hollister-Stier Laboratories, Wilkinsburg, Pa., or others; or one may prepare them himself if he is able to identify the pollens and prepare the proper extracts therefrom.

Methods of Collecting Pollen.—We are indebted to Dr. R. P. Wodehouse for the privilege of abstracting, from his well-known book *Pollen Grains* published by McGraw-Hill Book Company, Inc., New York and London, 1935, pages 101-105, his directions for collecting pollens in large amounts.

Special methods are needed to collect pollen in large amounts for the preparation of hay fever-pollen extracts, etc. *It is best to collect from the first flowers to open* rather than from those that bloom toward the end of the flowering season. These are more vigorous and less likely to be infested with insects. This is particularly true of the oxeye daisy and sorrel dock. The flowering period of forest trees is very short and under the influence of local weather conditions. If the weather turns suddenly warm and dry, anthesis may be completed within two or three days. These early flowering trees are pines, junipers, elms, and poplars. With these trees, the flowers reach the bursting point and remain in this condition until warm dry days come, then suddenly open and complete their pollination within one or a very few days. Collect these flowers in the cool, damp days immediately preceding anthesis.

Methods of collecting pollen vary according to whether the flowers are wind- or insect-pollinated, and whether they will continue to live and shed pollen after cutting, or whether pollen shedding ceases as soon as the flowers are cut.

Natural Shedding.—Most anemophilous and some entomophilous plants can be made to shed pollen quite naturally indoors. The anemophilous plants are the conifers and most other gymnosperms, the Gramineae, Cyperaceae, Typhaceae, Chenopodiaceae, Amaranthaceae, most of the early flowering trees, the Ambrosiaceae, and *Artemisia*. Among the entomophilous plants are some species of goldenrod, thistle, and sunflower. Cut off the flowering stems and place in water in the shedding room. Use long, shallow pans about a foot wide with a central bar arranged lengthwise to act as a catch to hold the cut ends of the stems beneath the water. Place the plants in the pans in a nearly horizontal position so that the flowering tips lean out far enough to clear the edges of the pans. Place sheets of paper under the flowers to catch the pollen. Gently tap the flowers once a day until pollen ceases to drop off, then draw out the papers and remove pollen.

Handle most of the grasses in this manner. Cut in the early morning while the dew is still on them, stripping off the leaves in the field, and trimming the stems to the proper length to fit the shedding pans. Bundle loosely, keeping the stems moist by adding water. In very dry weather, keep them immersed in buckets of water until the shedding room is reached. Do not stack the cut plants together longer than necessary, and do not bundle tightly. Respiration is rapid during this period, and generation of so much heat and moisture may "burn" the plants and completely destroy them in less than an hour.

Since many grasses exhibit a marked periodicity throughout the day in their shedding, collect all of them in the morning. Place in the shedding pans as quickly as possible, to prevent drying and consequent acceleration of the opening of the anthers with shedding of the bulk of the day's pollen.

Some grasses, like Indian rice and tall oat grass, shed little or no pollen after being cut. Place them in shedding pans for two or three days, during which time most of the anthers will have dropped off unopened. The rest can be removed and the flowers gently shaken. Brush up the anthers, partially dry, and shake on sieves to remove any pollen that can be freed. Then pass the anthers through a coffee mill with plates adjusted just tight enough to roll them and loosen the pollen. If properly handled and the anthers are not too dry and brittle, most of the pollen can be separated by sifting. The proportion of immature, anaphylactogenically less active grains obtained by this method depends upon the skill and care with which the grinding and sifting are done.

Plant-Breeder's Method.—(For plants which do not shed naturally indoors.) Tie paper bags over the flowers in the field just as they begin to pollinate. Bags must be moisture-proof, but porous enough to permit of escape of moisture from within. Leave on only a few hours, then remove, empty the pollen, and dry it.

Most insect-pollinated flowers are more difficult to handle. Use the following method for roses. Gather the flower buds just as they are about to open. Dry slowly on sheets of paper in a warm, dry, well-ventilated room. Pull off the tightly closed corollas from their receptacles, and empty the pollen on to a sieve. Brush through to separate it from the anthers and other floral parts.

Carbon-Tetrachloride Method.—(For entomophilous plants.) (Wodehouse, 1916.) Dry but do not completely desiccate the staminate flowers. Remove from their floral receptacle and free as far as possible from all extraneous material. Soak the mass of flowers in carbon tetrachloride in an open pan or mortar, beat gently with a pestle to loosen pollen, then empty onto a piece of fine muslin stretched across another pan, and press out the carbon tetrachloride, carrying the pollen through the muslin. Wash the crushed flowers repeatedly with carbon tetrachloride to loosen and suspend all the pollen. Pour onto a Büchner funnel fitted with smooth filter paper, and draw off the carbon tetrachloride rapidly by suction. The pollen collects on the filter paper in a solid cake. Wash with fresh carbon tetrachloride to remove lipoids, and pass an air current through to dry it. Break up the cake, sift the pollen through a 200 mesh sieve, and desiccate. Contaminations are usually negligible.

Desiccation.—Never omit complete and prolonged desiccation, since moisture in the pollen will cause it to cake and become useless; desiccation prevents deterioration which air-dried pollens undergo. As soon as possible, brush up the pollen, sift, and dry in a vacuum desiccator over calcium chloride or sulphuric acid until all moisture is removed, then transfer to airtight containers with as little exposure to air as possible. Even desiccated pollen may take up moisture so rapidly that it is difficult to weigh it in ordinary atmosphere.

Preparation of Pollen for Microscopic Examination.—Great interest has been evoked by the study of hay fever, its diagnosis by skin reaction, treatment, etc. The following material is condensed from Wodehouse, *Pollen Grains.**

Methyl-Green Glycerin Jelly.—Pick up a small amount of pollen on the flat end of a toothpick, place on the center of a glass slide, and add a drop of alcohol. Allow to evaporate partly and add a second and third or even fourth drop if necessary. Wipe off the oily ring which is deposited around the specimen, using cotton moistened with alcohol. Before the specimen is completely dry, add a small drop of hot melted methyl-green glycerin, stir the pollen in with a needle and distribute evenly. Keep the jelly hot by passing the slide over a small flame, using just enough heat to sting but not burn the knuckle. Pass a No. 0 cover glass several times through the flame, holding vertically with forceps, then place over the specimen, and gently heat. The cover should settle into position, the gelatin reaching the periphery just when the pressure of the cover begins to be taken up by the pollen grains. The amount of jelly must be learned by experience. Small amounts leave the grains crushed or flattened or the mount incompletely filled, while large amounts cause too thick a preparation for oil immersion lenses.

---

*Wodehouse: Pollen Grains, McGraw-Hill Book Company, Inc., 1935, pages 106-109.

Naturally-shed pollen is preferable, although satisfactory results are obtained from herbarium specimens if they were quickly and completely dried. Pollen may usually be obtained by tapping the dry flowers over the slide or crushing a few anthers on it. If this is unsuccessful, remove a few anthers or, with the Compositae, a few florets from the specimen, and place on slide. Moisten with alcohol, add a drop of water, and heat to boiling. Tease out the pollen, remove anthers and debris, leaving pollen in the water. Draw off the water with cotton or filter paper and add glycerin jelly.

Glycerin Jelly (Brandt[1]).—Soak gelatin 2 or 3 hours in cold water, pour off excess water, and melt by heat. To 1 part of this add 1½ parts of glycerin, and while still hot, filter through spun glass pressed into the lower part of a heated funnel. Add 2 or 3 per cent phenol. Keeping mixture hot and fluid, add drop by drop a saturated solution of methyl green in 50 per cent alcohol, until the glycerin jelly becomes as dark as green ink. Or add the dye to a good commercial preparation of glycerin jelly. Pollen grains rarely become over-expanded in this medium because the relative proportions of glycerin and water are properly balanced.

Contrast Stain.—Only the exine stains with the above, leaving the intine and cell contents unstained. To obtain a contrast between exine and cell contents, stain pollen first by placing on slide in a weak aqueous eosin solution.

Pollens mounted in methyl-green glycerin jelly are not permanent preparations. They show greater brilliancy for the first few days after mounting, retaining their brilliancy for several months. The dye fades out in from about 9 months to 2 years, after which they are completely bleached. They may be restored by heating the slide to remove the cover glass, and working in a small drop of hot methyl-green glycerin jelly with a needle, and adding a fresh cover glass.

Aqueous fuchsin is just as selective as methyl-green and is *permanent.* Fischer's (1890) method follows: After washing the pollen on the slide with alcohol, add a drop of weak basic fuchsin solution in water, and stir pollen with needle. When the grains have taken up all the dye, draw off water with cotton. Do not allow to dry. Add a drop of melted glycerin jelly, stir in the pollen, keeping the slide warm. Cover with No. 0 cover glass.*

Atmospheric Pollen Slides.—Place a small drop of melted glycerin jelly containing either methyl-green or fuchsin on a slide, spread out to occupy an area equal to and of the same shape as the cover glass which is to be used, expose in a horizontal position protected from rain and sun by a shelter at least 4 inches above it. After 24 or 48 hours, examine in the laboratory with a hand lens, and remove extraneous material like soot or sand. Heat the slide, controlling temperature with knuckle to drive off excess moisture. Cover with No. 0 cover glass.

To make a pollen count, place the slide on the microscope, use mechanical stage, pass from left to right and back again progressing the width of a single field in a forward direction with each passage from side to side. Use low power. Identify pollen grains if necessary with high power. Continue counting until the entire surface has been covered.

Examination of Dry Pollen.—Shapes of unexpanded pollen grains must be observed dry in air with or without a cover glass. These observations are useful in seeing how much oil naturally occurs on the surface of the grains and as a check against the method described below. Shapes of the grains can be learned with this method and something of the mechanical action of their organs of volume-change accommodation. For a detailed examination, stain, and bring into a medium of suitable refractive index as follows:

Aniline-Oil Gentian Violet Method.—Place pollen on slide, add two or three drops of aniline oil tinted with gentian violet to a pale purple color. Heat gently over a small flame, controlling temperature with knuckle. Heat until grains are deeply stained. Cool to room temperature. Draw off excess oil with filter paper. Wash by repeatedly adding xylol and drawing it off until all oil and unabsorbed dye have been removed. Mount under Canada balsam. Grains are unexpanded, but are brilliantly stained and in a medium suitable for oil immersion observation.

---

*A very satisfactory glycerin jelly for this purpose is prepared by Elmer and Amend, New York.

Skin Tests to Determine Sensitization to Pollens

The following list of pollens is suggested:

Dandelion
Sweet white clover
Daisy
June grass
Sunflower
Sweet vernal grass
Ragweed short
Ragweed giant
Timothy
Alfalfa
Rose
Orchard grass
Corn
Red top
Goldenrod
Sweet clover
Golden glow
Cockleburr

The test is performed like the protein test, except that the 0.4% sodium hydroxide is omitted, since the pollens are in a liquid state. The control scratch, however, has a drop of sodium hydroxide solution on it. Read as in the protein tests.

Cytology of Allergic Secretions From the Nose and Paranasal Sinuses*

The shock organs or tissues of the body are those in which the lesions of allergy occur. In these shock organs the pathologic picture is characterized by edema and eosinophilic infiltration. In the nasal and paranasal sinuses, as well as all other organs which are termed shock organs, bronchial, conjunctival, salivary gland, pancreatic, intestinal, and genitourinary systems, these eosinophiles migrate through the epithelium and are easily found in the secretions of these organs. This reaction of the shock organs can be demonstrated by an examination of the secretions for eosinophiles. Warthin Jones[1] in 1846 first recorded this observation. Since then, many others have repeatedly called attention to it, namely, Ehrlich[2] in 1879, Bizzozero[3] in 1887, Gollasch[4] in 1889, Schmidt[5] in 1891, Lewy[6] in 1891, and Neusser[7] in 1892.

It is accepted that suppurative infections of the upper air passages can be differentiated from nonsuppurative infections by means of the smear examinations of the secretions. Many of the nonsuppurative, hyperplastic, or polypoid diseases of the nose are of allergic origin. The cytologic examination of secretions from nasal sinuses is always a biopsy. This is a very important contribution to the diagnosis of allergic conditions because many cases of hemorrhage and gastrointestinal disease of allergic origin may be confirmed by cytologic examinations of the nasal secretions.

Method of Collecting the Specimen.—Specimens should be taken separately from each side of the nose. Secretion is easily collected by having the patient blow his nose and collect the secretions on a piece of wax paper or cellophane handkerchief. This specimen represents a collection of both nasal and sinus secretions. If no secretion is secured by blowing the nose, it may be necessary to obtain the specimen by swabbing with a cotton applicator. The insertion of a saline tampon into the nose may stimulate the flow of secretion.

A number of conditions determine variations; such as, the quantity and quality of the secretion available for examination. During the periods of reactions the secretion may be thin and watery with very little, if any, mucus present. This material may show eosinophiles only after many examinations; often they are found clumped in small masses or clusters. If mucoid material is obtained, an abundance of eosinophiles may be found. If the mucous membrane itself is examined, the maximum infiltration of the eosinophiles is noted just beneath the basement membrane. They migrate from the basement membrane to the surface where they are uniformly distributed. They are then collected in the mucous secretion which is rolled or propelled toward the nasopharynx by ciliary action. Very profuse mucoid secretion is attended with very few cells. Immediately after a period of reaction and during the quiescent stage following, an abundance of thick mucus may be found collected in the nasal cavity; this secretion usually contains an abundance of eosinophiles.

The color or consistency of the secretion is not an index of the cytologic contents. Clear secretion may contain many eosinophiles or many neutrophiles or it may contain varying proportions of both types of cells. Yellowish secretion contains a marked predominance of eosinophiles.

Staining Technic

Method No. I

The method given below was developed by Hansel.[1] Hansel found that, because of variations in the pH, minerals, and viscosity of secretions from the nose and paranasal sinuses, Wright and Giemsa stains are often very inconsistent.

Allow smears to dry in the air, or dry gently over a flame.

Mark across the slide next to the label with a paraffin stick to prevent overflow of stain.

Cover completely with Hansel stain* and allow to stand for 30 to 45 seconds, giving the longer period to thicker or milky smears.

Add distilled water to take up the stain, as in the Wright stain technic, and allow to stand 30 seconds.

Pour off the stain and flood the slide with distilled water to remove the excess stain.

Flood the slide with 95% ethyl or methyl alcohol.

Drain off and dry the slide over a flame.

Wipe the back and edges of the slide with a piece of wet paper towel to remove excess stain.

Caution: If the alcohol is left on too long, or used to excess, it will wash the blue stain out of the neutrophiles and cause them to appear pink. Pink neutrophiles present a clear homogeneous cytoplasm. There are no true granules and they should be readily distinguishable from the eosinophile, which stains definitely red with deep red granules and a prominent blue nucleus. Free red granules often appear from broken eosinophiles.

Mount the slide in gum damar or Canada balsam.

Stains should be kept in amber bottles, of the dropping variety. The stopper should be turned when not in use to prevent evaporation.

---

*Made by the Lide Laboratories, Inc., 634 N. Grand Blvd., St. Louis 3, Mo.

[1] Hansel, F. K.: Clinical Allergy, St. Louis, 1953, The C. V. Mosby Company, p. 411.

Method No. II

The method is essentially the same as that used for blood films. Smears must be absolutely dry before staining. Fix 1 minute in methyl alcohol after drying. Use Giemsa stain as the stain of choice. Eosinophile granulations are brownish red with a blue nucleus. Neutrophiles show a clear violet cytoplasm with a deep blue nucleus. Giemsa stain is diluted in the same manner as for blood films; namely, one drop of stain is added to each c.c. of neutral distilled water. About 1.0 c.c. or 1.5 c.c. of stain are needed for each slide which should be fully flooded. Allow the stain to remain in contact with the slide for thirty minutes. Pour off and wash gently in neutral distilled water. A few drops of ethyl alcohol should be poured over the slide to clear excess stain. Stand the slide on end to dry, mount in gum damar or Canada balsam, and then examine under low-, then high-power magnification. Thick grossly visible areas on the slide may be examined first with the low power and then with the high power. Note the character of eosinophiles. If stained too long or too heavily, they may appear quite dark. Do not mistake neutrophiles for eosinophiles. Neutrophiles contained in dense masses of mucus may show false staining, probably due to degeneration. They may take the eosin stain in excess and appear quite like eosinophiles, but upon close examination it will be noted that true eosinophilic granules are not present. The cytoplasm stains very faintly, but the nuclei stain well. The margins of thick collections of cells stain very well.

In the interpretation of the cytology of the secretions one must take into consideration the type and quantity of secretion in the specimen and correlate the findings with the clinical history and nasal changes. The clinical type of allergy under consideration and the possible relationship of acute and chronic infection must always be evaluated. An appreciation of the significance of the cytology of secretions can be accomplished only by individual experience and then only after the examination of many hundreds of specimens. If one has this work done by a laboratory or by a technician the clinician sacrifices the real value of cytologic findings, for individual interpretation must be correlated with all the clinical facts.

In the inspection of a smear, in one containing only eosinophiles, for instance, it will be noted that the cells are irregularly distributed. Sometimes they are scattered, arranged in clumps or arranged in streaks. (Plate XXXIX, A, B.) When mixed with neutrophiles they may likewise be irregularly distributed. Only certain parts of the slide may show significant areas. It is not unusual, for instance, to find a slide completely covered with neutrophiles except in certain small areas where eosinophiles are clumped in masses.

In recording the cytologic findings the question arises as to what percentage of eosinophiles constitutes a diagnostic number. In view of the irregularity of distribution, it is quite impossible to make an accurate evaluation in terms of percentages. One can learn only by individual experience how to evaluate the cytology. In making an accurate record of the cytologic findings on a history the only method is a colored photograph, but since this is not practical, the next best method is the use of the terminology employed in recording the results of skin tests. The plan was adopted, therefore, of recording the cytologic findings of eosinophiles and neutrophiles in terms of ±, 1+, 2+, 3+, and 4+. Although many epithelial cells may be noted in specimens, we have attached no definite significance to them. In using this plan of recording the cytology, due consideration must be given to the type of specimen under examination. A scanty amount of secretion may show a small

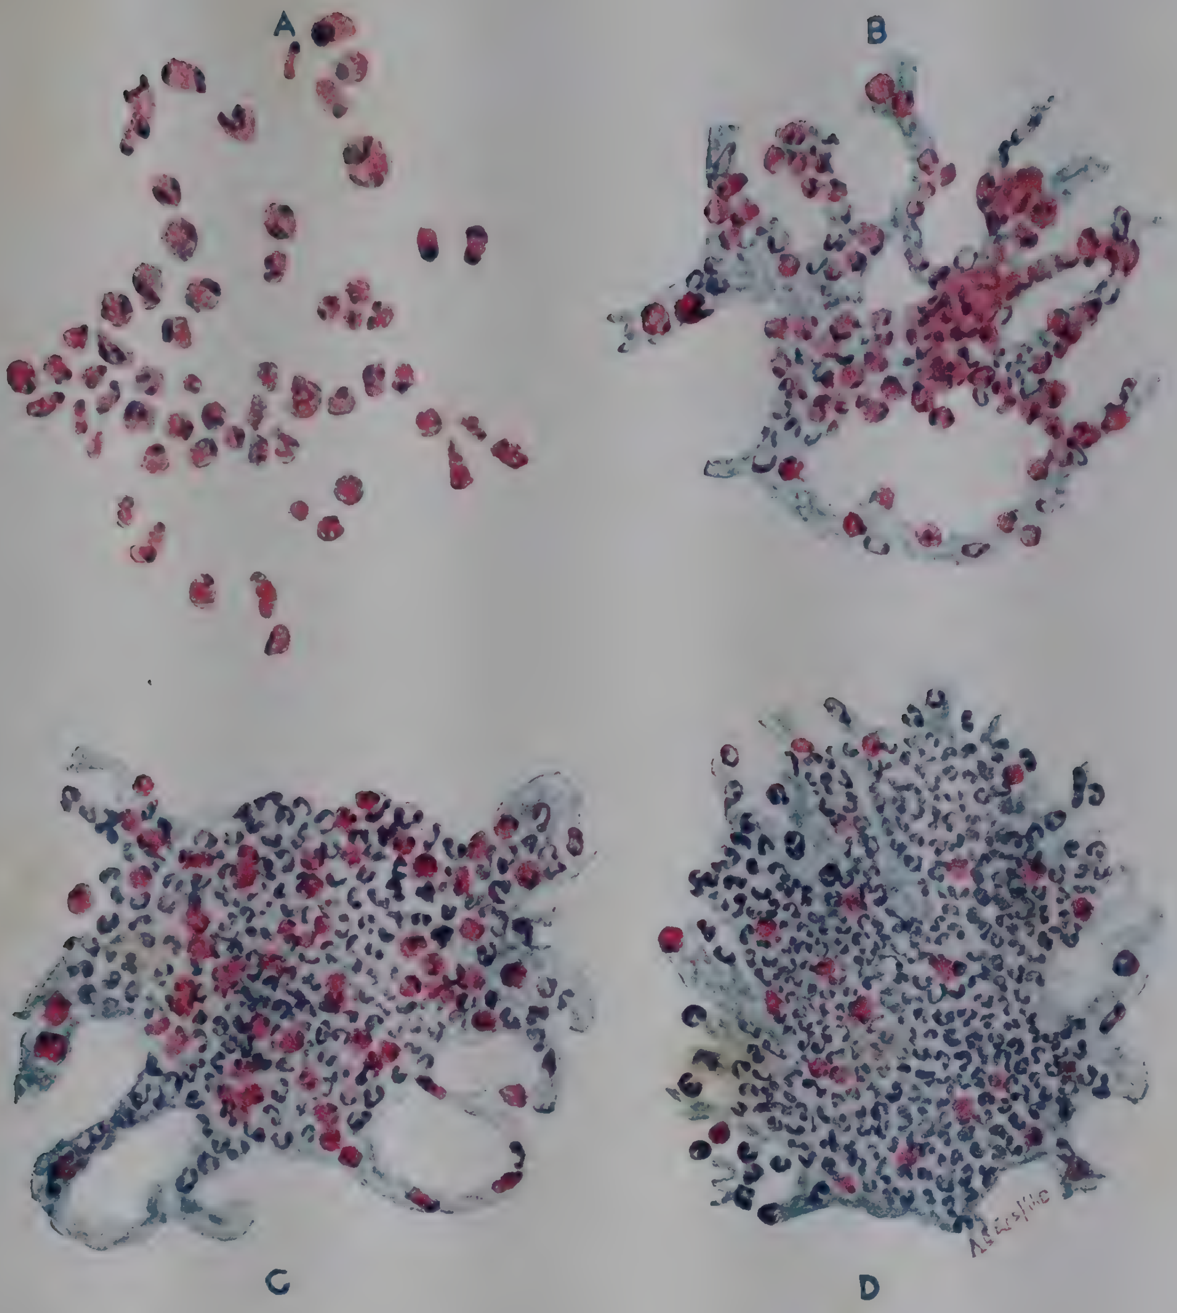

Plate XXXIX.—Nasal Secretion. Giemsa Stain, ×400. Four Representative Fields Showing Eosinophiles and Neutrophiles. All Diagnostic of Allergy.

A. Eosinophiles arranged in a cluster. These clusters are frequently found in thin watery secretion but may assume this arrangement in association with neutrophiles.

B. Eosinophiles with a few scattered neutrophiles, enmeshed in streaks of mucus. This arrangement is most frequently observed.

C. Eosinophiles and neutrophiles, with a slight predominance of the latter. This picture is observed in the resolution stage of acute infection or in chronic infection; commonly noted in polyp cases.

D. Marked predominance of neutrophiles. Approximate diagnostic minimums of eosinophiles. Usually seen in complicating acute infection, but may be noted in chronic infection. This number scattered over several fields often observed in the resolution stage of acute infectious rhinitis in nonallergic patients, especially children.

(From Hansel: Journal of Allergy, May, 1934.)

*Hansel, F. K.: Clinical Allergy, St. Louis, 1953, The C. V. Mosby Co. By permission of the author and the publisher.

but significant number of eosinophiles, while a good specimen may show a four-plus number. Table 136 and Plate XXXIX show the method of recording the cytologic findings in terms of eosinophiles and neutrophiles.

Mild reactions occur in the mucous membrane without definite symptoms, as seen by the presence of large numbers of eosinophiles during quiescent periods. Eosinophiles may occur in nasal secretions in patients with almost symptom-free seasonal and nonseasonal allergy and with symptom-free asthma, although during quiescent periods between exacerbations, most patients show no typical changes in the nasal mucous membrane.

When both eosinophiles and neutrophiles appear in the same secretion, a superimposed acute or chronic infection is indicated. Neutrophiles usually outnumber eosinophiles about ten to one. Thus a one-plus or plus-minus neutrophilia represents about ten times as many eosinophiles. Four-plus neutrophiles means the field is completely covered with these cells.

Neutrophiles are found in normal noses in winter when infections are prevalent and environmental influences must be considered. Obstruction and dryness cause a few neutrophiles at any time during the year. Neutrophiles are found more frequently in older patients. Marked obstruction in the nose in severe reactions causes retention of secretions with consequent stagnation and possibly secondary infection with resultant neutrophilic response. In seasonal hay fever with marked obstruction, a number of neutrophiles may be present. With hyperplasia of the membrane with many ciliated epithelia replaced by nonciliated types, secretions may remain in the nose for long periods and secondary infections may develop. Nasal polyps produce the greatest degree of stagnation and secondary infection, although in many of these cases eosinophiles may be found in the nasal secretions in preponderant numbers. Cytology of secretions in such cases may be the deciding factor in determining presence or absence of complicating acute or chronic infection. If acute infection is present, make repeated smears over a period of several weeks before deciding definitely as to the existence of a chronic type of infection. Persistence of marked predominance of neutrophiles indicates chronic infection. During the resolution stage of acute colds in nonallergic patients, eosinophiles are found mixed with neutrophiles in the secretions, the number sometimes approaching the number found in allergic patients during acute stages of infection. Repeated follow-up smears must be made to differentiate between the two types. Eosinophiles disappear before the neutrophiles in nonallergic cases, while in allergy the eosinophiles increase as the neutrophiles disappear. Finally a pure eosinophilic response is present. Chronic infections may obscure the picture. An acute exacerbation of allergy and an acute cold may be so similar that in many instances it is quite impossible to differentiate them on the basis of clinical history.

A pure eosinophilic response is indicative of a pure allergic process. A few eosinophiles and no neutrophiles is a very significant finding and indicates that a scanty amount of material has been obtained. A large number often clumped in large masses can be found. The eosinophilic-neutrophilic cellular collections noted in smears represent varying degrees of superimposed infection. Secretion with a few scattered eosinophiles and neutrophiles (E±, N±, 1+) is highly suggestive of allergy and should be checked by further smears. The slight neutrophilic response should be correlated with the clinical history and the nasal changes. The presence of a few eosinophiles and numerous neutrophiles (E±, N 2 to 4+) indicates superimposed infection usually of the acute type. (Plate XXXIX, D.) During acute infection the eosinophilic response in allergy is markedly decreased or almost absent during the first few days of the process. The presence of many eosinophiles with a comparatively small number of neutrophiles (E 1+, N± or 1+) indicates the existence of definite allergy with mild infection, usually not of great significance. This may indicate anatomic abnormality or the end-stage of an acute infection. Secretion with many eosinophiles and an abundance of neutrophiles represents a definite allergic process with superimposed acute or chronic infection. Only repeated observations may determine which type of infection is present. A large number of eosinophiles with a comparatively small number of neutrophiles indicates an active allergy with mild infection, usually of no particular significance (E 2 to 4+, N± to 1+) (Plate XXXIX, B). Large numbers of eosinophiles and neutrophiles (E 2 to 4+, N 2 to 4+) may represent the resolution stage of an acute infection or a chronic infection. (Plate XXXIX, C.) This cellular response is frequently found in cases of nasal polyps.

With atypical symptoms and no characteristic changes in the nose, or with thickening or polypoid changes, where a possibility of allergy exists, cytology of the secretions must be relied upon to establish a diagnosis definitely. In infection, with no eosinophiles, allow the infectious process to subside before making a diagnosis.

Hansel* summarizes the question of demonstration of eosinophiles as proof of allergy in nasal secretions as follows:

1. Eosinophiles in secretions from the nose and paranasal sinuses are good presumptive evidence of allergy.
2. Neutrophiles present with eosinophiles indicate superimposed infection.
3. Proportion of eosinophiles and neutrophiles is an index of the nature of the infection.
4. Acute and chronic infections can be differentiated by repeated observations of the cytology of the secretions.
5. Clinical data do not substantiate pure eosinophilic response as a result of bacterial hypersensitiveness.
6. Hyperplasia and polyposis with persistent absence of diagnostic number of eosinophiles are usually not allergic.

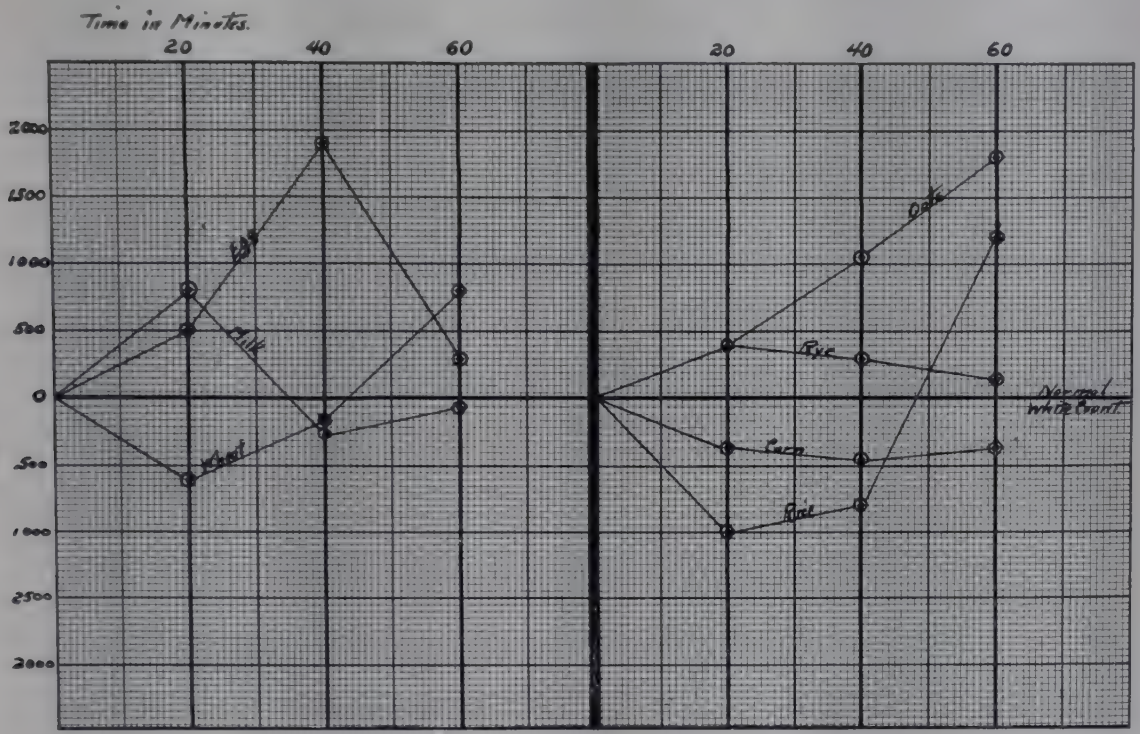

Fig. 321.—Leukocyte response to various food products. In both graphs, the curves which extend below the normal line are indeterminate, or borderline; the other curves show a normal reaction to ingestion of food. Thus milk, wheat, corn, and rice are indeterminate, while the other curves are normal. (Courtesy French K. Hansel, St. Louis.)

The Leukopenic Index

Hansel[1] states that the term *leukopenic index* was originally suggested by Vaughan[2] to apply to a series of total leukocyte counts performed as a diagnostic measure in food allergy. Normal individuals usually show a leukocytosis of 1,000 to 2,000 or more cells within 30 to 60 minutes following the ingestion of food. Widal[3] observed that after the administration of food to individuals sensitive to these food proteins there was a drop in the leukocyte count within 20 to 60 minutes after the ingestion of this food. Vaughan noted that if an individual is allergic to a food, there is usually a leukopenia of 1,000 or more cells following its ingestion.

Using the above information, the leukopenic index test was devised.

Technic.—

The patient reports in the early morning without breakfast. After a quiet rest period of about 30 minutes, two fasting white counts are taken at 15- or 20-minute intervals, and their average is determined. (It goes without saying that all counts made on the same patient throughout the test must be made by the same person with the same white counting pipette, and counted in the same counting chamber.) The patient then eats an average portion of the food for which he is being tested. Total white counts are taken at 20-minute intervals for one and one-half hours. During the entire period of the test, the patient is not permitted to talk or move about.

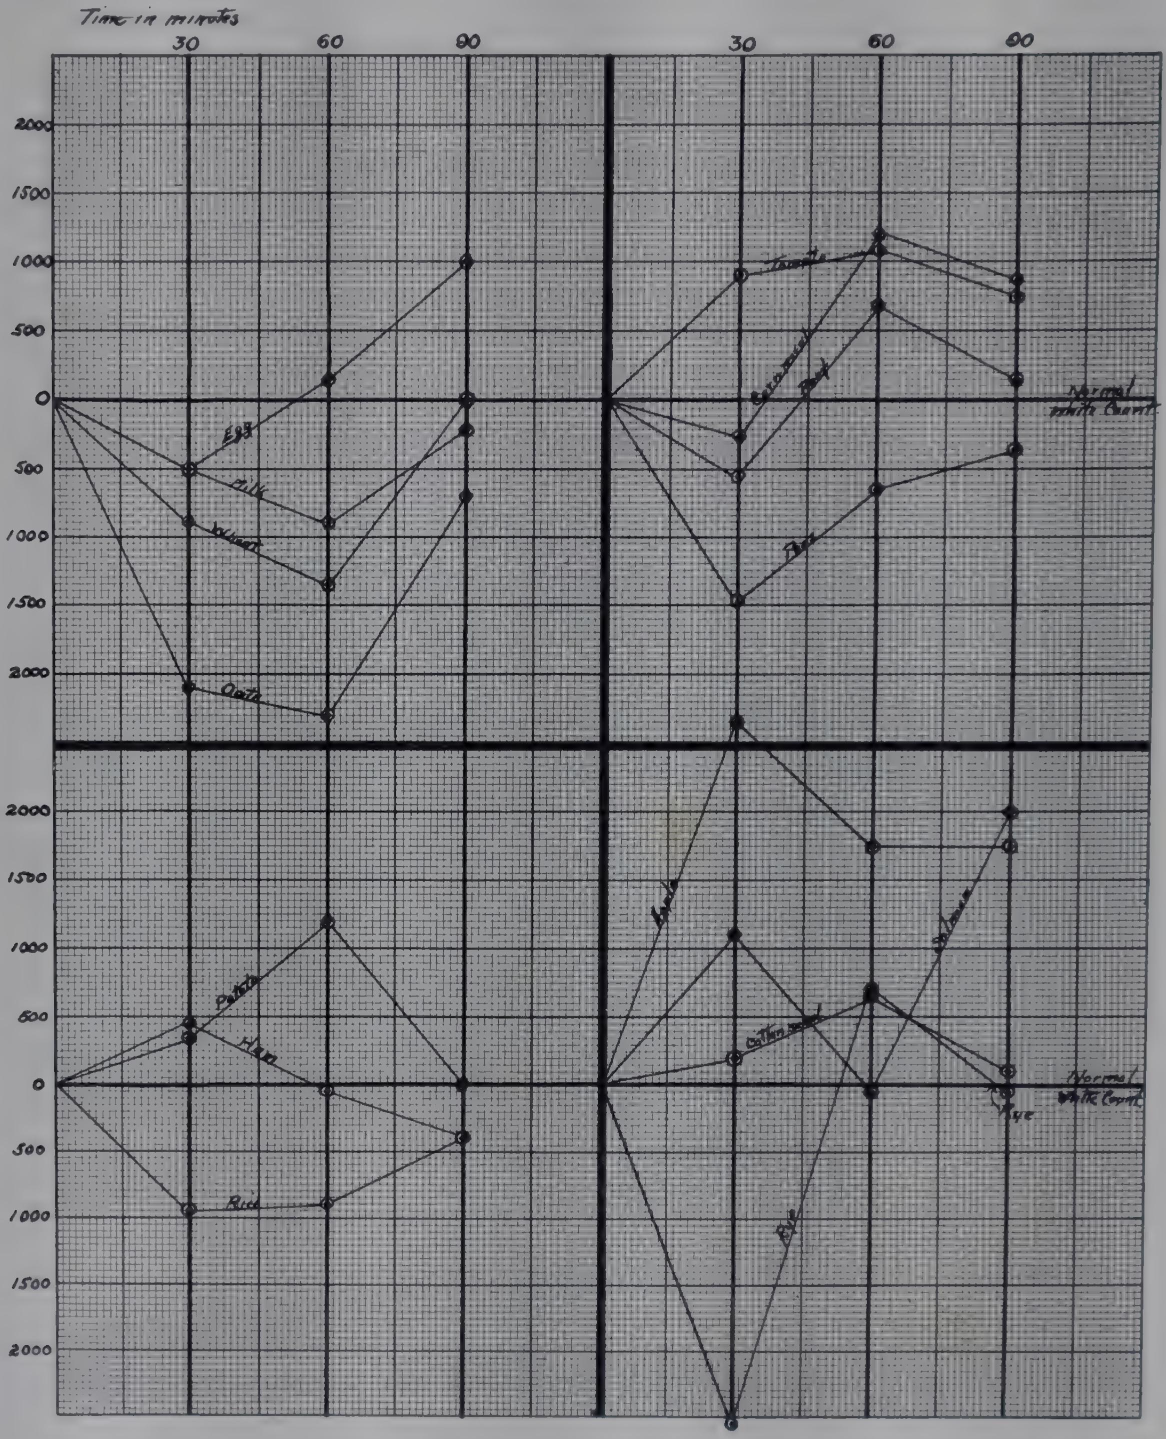

Fig. 322.—Leukocyte response to various foods. All curves dropping below the 1,000 mark are incompatible, or allergic responses. Those below the normal line, but showing a drop of 1,000 or less, are indeterminate, or borderline; those rising above the normal line are compatible or normal: Thus, egg, milk, cornmeal, beef, ham, and rice are indeterminate; while wheat, oats, peas, and rye are definitely allergic reactions. The other curves are normal. (Courtesy French K. Hansel, St. Louis.)

Using the average of the two first counts as the patient's normal leukocyte count, a graph is plotted to show the rise or drop in the white count throughout the test. Various types of curves have been noted. Hansel states that the type of curve is more important than the actual maximum drop or rise in the leukocyte count. They may be designated, as suggested by Rinkel and Gay,[4] as compatible, incompatible, or indeterminate. The compatible curve is one which shows a definite leukocytosis of 1,000 or more cells. This is a normal response. An incompatible curve shows a fall or leukopenia of 1,000 or more cells. This is a definite allergic reaction. The indeterminate curve may be of various types. First, there may be an initial leukocytosis followed by a definite leukopenia. Second, there may be an initial leukopenia followed by a leukocytosis. These indeterminate curves vary usually between a leukocytosis of 1,000 cells and a leukopenia of 1,000 cells. These are borderline cases.

According to Hansel, after the test has been completed, the patient should be questioned regarding the occurrence of symptoms, headache, itching of the skin, etc. The patient should record the foods eaten after the test so that upon the return visit it may be ascertained when the symptoms occurred after eating additional food.

In a statistical analysis of the leukopenic index, Sullivan reported his observations made in 500 tests performed at the Vaughan-Graham Clinic in Richmond, Virginia. In 89 per cent of this series of cases the variation between two fasting counts was no more than 500 cells, whereas 1.2 per cent of the cases had a variation of 2,000 or more cells. The amount of variation between the two fasting counts was definitely greater in those cases showing a high fasting count than in those with a low fasting count. It was pointed out that definite information may be obtained in 80 per cent of all cases in which the test is performed. An individual allergic to foods does not normally have a low fasting white count.

The determination of the leukopenic index has proved a very valuable procedure in the diagnosis of food allergy in its relation to respiratory, gastrointestinal, and other manifestations of allergy. The test is, coincidentally, also a constitutional test. The effect of the ingestion of the test food upon the production of symptoms also has great diagnostic value in many instances.

The test is particularly valuable in those instances in which the skin test is negative. In a study of 60 allergic patients on whom 191 leukocytic indices were made, Vaughan compared the results obtained with the skin reactions to the corresponding foods. In 118, or 62 per cent of the indices, the leukocyte responses corresponded with the skin reactions. In 87 the skin reactions were negative and there was no digestive leukopenia. In 31, the skin test was positive and ingestion of the food was followed by a digestive leukocytosis. The character of the skin test, therefore, confirmed the leukopenic index in 62 per cent of the cases. After including an additional 5.2 per cent which showed variable discrepancies, Vaughan concluded that the actual diagnostic effectiveness of the leukopenic index is 67.2 per cent.

Bronchial Secretions

The same set of facts pertaining to the observations on the cytology of the secretions of the nose and paranasal sinuses may be applied to the study of bronchial secretions; that is to say, the cellular content in the latter conditions should be given the same close study that we give nasal secretions and the same conclusions concerning allergic reactions may be drawn therefrom.

The eosinophilic and the eosinophilic-neutrophilic responses in bronchial secretions should be correlated with the clinical history and the physical findings. Often it is a question of whether or not an acute infection complicates an attack of bronchial asthma. Pure eosinophilic response would suggest a contact with some allergin or an eosinophilic-neutrophilic response would suggest either an acute or chronic infection, this to be determined by correlation of the cytology of clinical history, physical findings, etc.

Methods for the Study of Irritation and Toxicity of Substances Applied to the Skin and Mucous Membranes

Recent advances in chemistry and technology have led to the development of many new substances whose properties make them desirable for use in cosmetics. These include solvents, surface active agents, and new constituents for vehicles and bases. These solvents and wetting agents are capable of altering physical surface relationships between the absorbing medium (skin) and the substance to be absorbed. The division of Pharmacology, Food and Drug Administration, Federal Security Agency, Washington, D. C., in connection with its activities in World War II, examined the toxicity of several hundred compounds or preparations submitted as insect repellents, lousicides, or scabicides. This led to development of new methods. In the course of the tests additional data must be obtained from histopathologic examination, chemical studies on tissues and urine, and by physiologic function tests. Additional toxicity data on the preparation are obtained by administering it by other routes.[1, 2] Analysis of these data permits (a) an evaluation of the extent of injury, and (b) an estimation of the likelihood of repair.

These methods have been outlined by Draize.[3]

Test for Acute Toxicity.—

The rubber sleeve technic was developed specifically for testing the toxicity of hair waving solutions. It is also suitable for acute toxicity studies of any preparation intended for topical skin application. A sleeve made of rubber dam is so constructed that its ends fit snugly around the trunk of the animal. The body of the sleeve ''balloons'' slightly, furnishing a reservoir for the dose which is maintained without pressure in contact with the skin. The area of exposure represents 10 to 15 per cent of the total body surface. The sleeve is slipped onto the body of the animal which is then placed in a comfortable but immobilized

[3] Draize, J. H.: Proc. Sci. Section of The Toilet Goods Ass'n, No. 5, May 17, 1946.

position in a multiple animal holder.[4] Preliminary doses on a body weight basis are introduced in the sleeve and allowed to remain in contact with the skin for varying periods of time (maximum of 24 hours). A sufficient number of animals is used to obtain mortality ratios at various doses. The dose which gives 50 per cent mortality (LD_{50}) may then be calculated.[5] Further analysis of the data enables the determination of the slope of the dosage-response curve and the probable error of a given determination.

At the end of the period of exposure the sleeves are removed, the volume of any unabsorbed material is measured, and the skin reactions are noted. The subjects are checked for gross symptoms of systemic effects and are transferred to individual metabolism cages where they are observed for a minimal period of two weeks. Body weight, food consumption, and gross symptoms of effects are checked daily. Observations for changes in blood morphology are made. Urine is checked for the presence of protein, reducing substances, blood pigments, or other abnormalities. The tissues of animals which die several days after exposure or those sacrificed because of severe poisoning are examined for histopathology.

Tests for Subacute Toxicity.—

In these tests, relatively large doses are applied by daily inunctions for periods up to twenty days to an uncovered area of the clipped intact skin. The size of the doses employed depend on the data obtained in the acute exposures, and may vary from 1.0 to 6.0 c.c./kg./day. The area inuncted is approximately 10 per cent of the total body surface of the animal. The material is gently rubbed into the skin with a glass rod and involves manipulation of the hair shafts and mild pressure. Animals are observed for two weeks following the last exposure.

The repetition of a dose, as in this type of experiment, may yield valuable information on the action of the agent on the skin and in the development of progressive systemic effects. In some cases there is gradual deterioration of the skin so that it becomes a less effective barrier as the doses are repeated. In other cases, the agent may produce a mummification or a coagulative effect in the skin so that absorption of subsequent doses of the agent becomes retarded.

The same observations and tests on the subjects are made as are performed in the experiments for acute toxicity. The urine and blood are examined, as in the above, and microscopic examinations of tissues of the severely poisoned subjects are made.

Further tests were made with an observation period of ninety days.

In these longer experiments for subacute toxicity, inunctions are made at dose levels of 0.5, 1.0, 2.0 and 4.0 c.c./kg. daily (Sundays excluded) for a 90-day period, to the clipped intact skin of animals. The areas treated with the material are approximately 10 per cent of the entire body surface. The conduct of these tests is similar to the 20-day experiments. The longer experimental period enables observation of the slow progressive deterioration produced by some agents after prolonged administration. Special emphasis is placed on blood morphology to ascertain the possible effect of the agent on the hemopoietic organs or on the blood itself. The tissues of all animals on these experiments are examined for histopathology.

The toxicity of more than 500 compounds or preparations intended for topical skin application have been studied in Draize's laboratory during the past five years.

The acute toxicity data (LD_{50}) for a few selected compounds administered orally and by topical skin application to the rabbit are given in Table 137.

The data in Table 137 illustrate that compounds differing widely in chemical structure and behavior may be readily absorbed by the skin. There does not appear to be a consistent relationship between toxicity following the oral and the topical route of administration. Although the LD_{50} is lower for the oral route in the case of a large majority of the compounds, occasionally a compound may exhibit a lower LD_{50} when administered by the topical skin route.

TABLE 137.—TOXICITY FOR RABBITS OF SOME ORGANIC COMPOUNDS

	LD_{50}	
COMPOUND	ORAL (ACUTE)	SKIN (ACUTE)
1. Beta-butoxyl-beta thiocyano diethyl ether	0.03	0.25-0.50
2. Beta thiocyano ethyl esters of fatty acids C_8—C_{18}	0.05	5.0 (C_{16} acid, ester)
3. Isobornyl thiocyanoacetate	0.63	10.0
4. 2-Ethyl-1,3 hexanediol	2.6	10.0+
5. Diethylene glycol monobutyl ether-acetate	2.6	5.5
6. Diethylene glycol mono ethyl ether	2.75	7.5
7. 2-Methyl-2,4-pentanediol	3.25	9.0
8. Diethylene glycol	4.4	10.0+
9. Dimethyl phthalate	4.4	10.0+
10. Dimethyl gamma pyrone-butyl ester	5.3	10.0+
11. 2-Ethyl butanol	1.2	1.5
12. Dibutyl oxalate	2.5	0.5

Some compounds which appear to be relatively nontoxic on acute exposure to the skin may upon repeated application (inunction) be severely damaging. Compounds which behave in this manner often produce no gross skin damage with the first exposure but produce severe skin damage (even to necrosis and desquamation) upon repeated exposure. The regenerated skin following damage is often more resistant to the future action of a given compound.

Primary Irritation.—

A modified patch test technic on the intact and abraded skin of the albino rabbit is used to measure primary irritation of the skin. Four areas on the back, approximately 10 cm. apart, are designated for the position of the patches. The skin is clipped free of hair, and in the area of two of the four patch positions, four epidermal incisions (two perpendicular to the other two) are made to produce an abraded skin. The patches consisting of two layers of gauze cut in squares (2.5 cm. on the side) are secured in position by thin bands of adhesive tape. The material to be tested is introduced under the patch—0.5 c.c. in the case of liquids and 0.5 gm. for solids. A balanced pattern is used for distribution of the four preparations to be tested on a series of six rabbits. This pattern is such that each compound appears once on a given subject. Three applications to intact skin and three to abraded skin are made for each preparation. The entire trunk of the animal is wrapped in rubberized cloth, which helps to hold the patches in position and retards evaporation of volatile substances during the 24 hours of exposure. The animals are immobilized in the special holder during the 24-hour patch exposure. Upon removal of the patches the skin reactions are assigned scores in proportion to their severity. Readings are also made after 72 hours and the final score represents an average of the 24- and 72-hour readings. The table of scores evaluates the erythema and edema produced, giving each factor equal weight. Maximal reactions are given values of 4 respectively. No values are given for agents which elicit severe escharotic or vesicant action. When such an agent is encountered a solution of it in a bland nonirritating solvent is prepared. Sufficient dilution is prepared so that the response may be graded by the scale.

Compounds producing combined averages of 2 or less are mildly irritating, whereas those with indexes of 2 to 5 are moderate irritants and those with scores of 6 or more are considered severe irritants.

Using this technic Draize's laboratory has determined the index of primary irritation to rabbit skin for approximately four thousand compounds or preparations during the past five years.

In general, compounds with similar chemical structures have a tendency to exhibit similar degrees of irritancy. There are, however, many exceptions. These exceptions are sufficiently numerous to warrant the conclusion that potential skin irritation may not be predicted solely on the basis of chemical structure.

TABLE 138.—INDEX OF PRIMARY IRRITATION (RABBIT)

COMPOUND	SCORE
Dibenzyl ketone	1.0
Isobutyl benzyl ketone	1.3
Methyl isobutyl ketone	1.7
Di-isobutyl ketone	8.0
Alpha tetralol (1,2,3,4-tetrahydro-1-naphthol)	2.3
Beta tetralol (1,2,3,4-tetrahydro-2-naphthol)	3.7
Alpha decalol	7.7
Beta decalol	3.7
1-Methyl (1,2,3,4-tetrahydro-2-naphthol)	1.3
1-Ethyl (1,2,3,4-tetrahydro-2-naphthol)	2.3

In Table 138 are given data on the primary irritation of a series of closely related ketones and naphthyl derivatives. It will be noted that compounds which have closely related chemical structures may exhibit very different indexes of skin irritation.

Primary Irritation of Mucous Membrane.—

This is measured on the rabbit eye and penis. In the measure of injury to the eye a modification of the scoring system used by Friedenwald et al.[6] was devised. Injuries to the cornea, iris, and the conjunctival and palpebral mucosae are scored separately.

Technic.—

0.1 c.c. of the substance is instilled in the conjunctival sac. Readings are usually made at 1, 24, and 48 hours after instillation. Injuries to the cornea are graded on the degree of opacity produced and total area involved. Injuries to the iris are graded on the extent of congestion, swelling, and its ability to react to light. The conjunctivae are graded on the degree of redness, chemosis, and the amount of discharge. In scoring the eye for over-all effect the maximal injury for cornea, iris, and conjunctiva receive scores of 80, 10, and 20, respectively.

These technics enable one to describe the extent of toxicities. In many instances a preparation may be recognized as unsafe following a few tests. In other cases injuries are insidious in that they develop much more slowly and require more complete investigation than this before a decision can be reached concerning their safety for use.

SEMEN APPRAISAL

The examination of seminal fluid with special regard to defective spermatogenesis in otherwise healthy men has been elaborately studied by Cary and Hotchkiss.[7] They present a method of fixing and staining a microscopic specimen which differentiates component parts of the cell without distorting the protoplasm and enables any physician familiar with the use of the oil immersion lens to recognize and classify abnormal sperm cells, and, in specimens of doubtful character, to count the percentage of these cells as an added index of deficiency or improvement.

The examination of the semen is divided into three steps: (1) collection of the specimen; (2) the gross or macroscopic investigation; (3) the microscopic study.

---

[6] Friedenwald, J. S., Hughes, W. F., Jr., and Herrmann, H.: Arch. Ophth. 31: 279, 1944.

[7] Cary, W. H., and Hotchkiss, R. S.: J. A. M. A. 102: 587, 1934.

1. **The Collection of the Specimen** may be accomplished by use of any one of the three following methods, with preference in the order named.

(a) A specimen produced at the office of the examiner. If accuracy is stressed, and a quiet, suitable room is provided, many men are not averse to this method, and the physician is in constant control of the ejaculate.

(b) Collection outside the office by external emission. For this purpose we lend the patient a glass graduate and a small (1 ounce) wide-mouth bottle. After collection in the glass graduate, specimen is allowed to liquefy so that it will not adhere to the glass surface, and it is transferred to the bottle, which is then corked, placed under the clothing about the torso, and brought to the office.

(c) Condom Method. Patients are advised to prepare the condom in advance by washing the preservative powder from the surface that is to receive the specimen, carefully drying it. This precaution is taken because not only do foreign bodies hinder the microscopic examination, but there is a chance of harm to the specimen by the various ingredients in these powders. After coitus the condom is tied, gently wrapped in a handkerchief (not clinging, absorbent cotton), concealed under the garment next to the skin, and thus delivered.

Patients are warned not to attempt artificial warming of the specimen; but gentleness in handling and maintaining, as far as possible, an even body temperature should be borne in mind. The laboratory should be ready for examination of the specimen when it arrives. The necessary implements, cleansed in plain hot water and thoroughly dried, should be kept ready for the examination. At the appointed hour, all the apparatus should be ready, including the microscope, to avoid thermal shock to the semen and the annoyance of misty lenses.

2. **Gross Examination** includes a notation of the amount, which, when complete, and from men under forty years of age, should exceed 3.5 c.c. Lesser amounts should arouse suspicion of deficiency and premature weakening by vaginal acidity, otherwise negligible. Extended periods of sexual abstinence may impart a slightly yellow tinge to the normal grayish opaqueness. Normal specimens commonly show a slight degree of viscosity, which is easily demonstrated by slowly expelling a drop of semen from a pipette. Absence of viscosity with a lessening of opaqueness points to reduced cell content, although the reverse deduction does not hold.

An alkalinity of pH 8.1 to 8.4 has been so constant that it seems an unnecessary refinement except in research study; the significance of wider variations in reaction is not yet known. It has been pointed out also that the loss of carbon dioxide alters the body chemistry of the specimen.

3. **Microscopic Examination.**—Two specimens, one thick and one thin, are promptly prepared for microscopic examination by gently protecting a full drop and a fractional drop with cover glasses, the former permitting a gross impression of the density and motility of the cellular content, the latter allowing a preliminary study of individual cell morphology. In the thicker preparation, semen of relatively high fertility presents a field teeming with spermatozoa, many of which are rapidly propelled by fast-whipping tails. While universal cell activity would constitute the ideal, one usually notes in comparatively vigorous specimens that these fast travelers are colliding with a certain number of inactive (average 25 per cent), and a variable number of sluggish and impotent cells, which gradually sink toward the lower strata of the field. Familiarity with this picture under standard, dry, high-power magnification constitutes the measure by which motility is judged. It is a practical observation that a motile field, though definitely subnormal, is apt to convey a favorable impression on the inexperienced or occasional examiner, but reverse errors in interpretation are rarely made. The practical aspects of motility are that a large number of highly motile cells are essential to fertility, and when a specimen of normal quantity and rich cellular content shows 25 per cent or more of these dynamic cells, a rating of relative fertility must be assumed unless strongly disproved by other indices to be described. Such specimens usually meet other major requirements of fecundity.

Richness of cellular content, in terms of millions per cubic centimeter, has been given emphasis by Macomber, Meeker, and other workers as a further index of appraisal. While significant degrees of oligospermia are usually apparent to the experienced examiner on microscopic examination, there is no verbal picture that will adequately provide such an index. It may be said, however, that such specimens usually present other evidences of subnormality, such as lowered motility, increased number of abnormal cells, early crystal formation, and sometimes considerable indescribable debris. Such specimens may contain several round, granular cells in each field. These may be leukocytes or cells from the seminiferous tubules. The larger granular cells are spermatocytes; there are usually four nuclei, which may be demonstrated by the staining process later described. Cell counts are probably modified by the amount of the seminal fluid, and, while in agreement with other observers that counts above 70,000,000 per cubic centimeter are found in fertile specimens, Cary and Hotchkiss hesitate in setting a medium arbitrary count below which fertility is impossible. On the other hand, they have found a count as high as 112,000,000 in a highly defective specimen which measured less than 20 minims total quantity. This specimen promptly improved after treatment, and pregnancy followed.

Duration of motility is one essential to fecundation that can be easily determined. For this purpose the edge of the cover glass on the thicker smear should be protected by a layer of petrolatum or new smears should be made from hour to hour from the total specimen. A normal specimen exhibits little cessation at the third hour after emission, and considerable cellular activity should be found at the fifth or sixth hour. Complete or considerable subsidence of motility within this limitation should be regarded as a further index of deficiency, but it should be noted that the few motile cells that were originally active in a highly defective specimen occasionally survive for many hours. Reciprocal studies between the direct male specimen and its behavior in the female secretions tend to indicate that duration is practically synonymous with early vigor of motility; but there may be exceptions to this rule.

These writers believe that there is an urgent need for an improved staining process to define more clearly the exact morphology of the spermatozoon.

After many trials with various agents it was found that Schaudinn's solution was ideal for the fixation process, for it not only preserved the normal morphology of the cells, but also removed the objectionable débris. The next problem was to devise a balanced stain that would demonstrate all portions of the spermatozoon, yet spare the chromophilic substance from overstain.

The following technic permits illustration of the head, midsection, and tail of the sperm:

A. Prepare thin cover slip smears.

B. Fixation in Schaudinn's solution:

1. Immerse for one minute in 7 per cent solution of corrosive mercuric chloride, 2 parts and absolute alcohol, 1 part.
2. Immerse for half a minute in 50 per cent alcohol.
3. Immerse for half a minute in distilled water, 3 ounces, and tincture of iodine, 2 drops.
4. Wash in tap water.

C. Staining process:

1. Immerse for half a minute in aqueous solution of eosin, 5 per cent.
2. Immerse for one minute in 50 per cent alcohol, 3 ounces, and concentrated hydrochloric acid, 2 drops.
3. Wash in distilled water.
4. Immerse for two and one-half minutes in hematoxylin.
5. Immerse for one minute in distilled water, 3 ounces, and glacial acetic acid, 2 drops.
6. Wash in distilled water.

Dry and mount.

In appraising seminal specimens, deduct the percentage of abnormal forms found from the total cell count. The resultant figure, when correlated with other data, is of great importance in the more accurate evaluation of the semen. For instance, 40 per cent of inactive cells with 25 per cent abnormal forms would indicate more serious impairment and need for greater improvement in a specimen with a count of 60,000,000 or less than would obtain with a cell count of 100,000,000.

The Weisman Method of Counting Spermatozoa

Weisman* uses a simple method which obviates the necessity of blood counting pipettes and special diluting fluid. Dilution with ordinary tap water serves not only to dilute the sperm cells so that they may be easily counted in a Neubauer blood-counting chamber, but it also causes immediate cessation of motion of the sperms, facilitating the count.

Technic.—

Place 1 c.c. of well-mixed whole semen in an ordinary test tube, graduated at 20 c.c. Add ordinary tap water, cold, up to the 20 c.c. mark.

This technic kills all the spermatozoa at once and by dilution of 1:20 diminishes the error which occurs when using the small amounts of semen usually utilized in the blood-counting pipette technic.

Fill the counting chamber. Count the sperms in the same fashion as white cells (pages 575 ff.). Count and recheck the sperms in 1 sq. mm. (the sixteen small squares in one corner of the chamber); multiply by 10 to obtain the number of sperms found in 1 cu. mm. Multiply this by 1,000 to find the number in 1 c.c. of diluted semen. To obtain the number in 1 c.c. of whole undiluted semen, multiply this by 20. In other words, multiply the actual average count in the 1 sq. mm. field by 2 and add five zeroes.

MEDICOLEGAL EXAMINATION OF SEMINAL STAINS

The identification of seminal stains is frequently of great value in medicolegal work in cases of alleged rape, sexual homicide, or even adultery. Specimens are sent to the laboratory often dried on clothing, sometimes admixed with blood, sometimes in dry masses adherent to hair. Spots on the specimen may be found very readily if submitted to examination by ultraviolet light. Seminal stains give a greenish white fluorescence which may aid in finding the stained areas. This fluorescence is not specific for semen.

Seminal stains are detected definitely by finding spermatozoa under the microscope. The spermatozoa are not readily destroyed unless the stain has been subjected to too much washing or exposure. After they become dry they are very brittle, and the tail is easily separated from the head.

---

*Weisman, A. I.: J. Lab. & Clin. Med. 27: 669, 1942.

To identify them absolutely, it is necessary to find perfect bodies with head and tail complete. It is best if motility can be shown (only possible when specimen is fresh and moist). Great care must be exercised in handling stains that are to be examined for the presence of spermatozoa.

If it is possible to obtain a fresh specimen, spermatozoa may be found by putting a small sample of the semen in a drop of physiologic saline and examining microscopically; motility may be found in recent specimens. The slide may be stained by various methods.

The spermatozoa, or male germ cells, are developed in the convoluted tubules of the testes. They are actively motile in the seminal fluid, which is a secretion of the accessory sexual glands, and are seen in enormous numbers in the normal ejaculate. A spermatozoon is a slender elongated flagellated structure 50 to 70 microns in length and possesses a head, neck, and body or connective piece, and a tail.

The head is pear-shaped, measuring from 3 to 6 microns in width. The neck consists of the anterior centrosome; the body is rodlike and connects the head and neck with the tail. The tail is divided in two portions, the chief piece and the end piece.

Spermatozoa are actively motile in the fresh state.

Seminal fluid or semen is a mixture of secretions of the epididymis, the ductus deferens, the seminal vesicles, the prostate, the bulbourethral or Cowper's glands, and the urethral or Littre's glands. Average amount of ejaculate is 2.5 to 5 c.c., and each cubic centimeter should contain 100,000,000 or more spermatozoa.

Methods of Staining Spermatozoa

Method of Cary and Hotchkiss[1] (1934).—

A. Prepare thin cover-slip smears as used in the preparation of blood for staining.

B. *Fixation in Schaudinn's solution:*

While still wet immerse for one minute in a 7 per cent corrosive mercuric chloride, two parts, and absolute alcohol, one part. Immerse for half a minute in 50 per cent alcohol. Immerse for half a minute in distilled water, 3 ounces, and tincture of iodine, 2 drops. Wash in tap water.

C. *Staining process:*

Immerse for half a minute in a 5% aqueous solution of eosin. Immerse for one minute in 50 per cent alcohol, 3 ounces, and concentrated hydrochloric acid, 2 drops. Wash in distilled water. Immerse for two and one-half minutes in hematoxylin. Immerse for one minute in distilled water, 3 ounces, and glacial acetic acid, 2 drops. Wash in distilled water. Dry and mount.

This method gives excellent contrast between the nuclear material, which stains blue, and the cytoplasm, which stains red.

Method of Meaker.[2]—

Fix with heat. Wash with 0.5 per cent Chlorazene, to remove mucus. Wash with water. Wash with 95 per cent alcohol, and dry. Stain with carbol-fuchsin and bluish eosin (carbol-fuchsin two parts, filtered bluish eosin one part, alcohol one part). Wash with water. Stain with methylene blue (methylene blue one part, water four parts). Wash with water.

Method of Gelarie.[3]—

This is a one-minute method for the staining of spirochetes, spirilla, spermatozoa, and related organisms.

[2] Meaker, S. R.: Human Sterility, Baltimore, Williams and Wilkins, 1934. Weisman, Abner I.: Spermatozoa and Sterility, p. 59, Paul B. Hoeber, Inc., Medical Book Department of Harper & Bros.

[3] Gelarie, A. J.: A New, One Minute Method for Staining Spermatozoa, etc., Am. J. Obst. & Gynec. 21: 1065, 1936. Weisman, Abner I.: Spermatozoa and Sterility, p. 60, Paul B. Hoeber, Inc., Medical Book Department of Harper & Bros.

Preparation of the solutions:

Fixing Solution.—Dissolve 2.5 gm. of recrystallized zirconyl chloride ($ZrOCl_2$) in 100 c.c. of 10 per cent sodium chloride solution.

Citric Acid Solution.—Make a 10 per cent solution of recrystallized citric acid in distilled water to which a few crystals of thymol are added to avoid fungous formation.

Staining Solution.—Dissolve 0.25 gm. of gentian violet in 100 c.c. of N/10 solution sodium lactate. The pH of this mixture should be approximately 8.4; if it is not, it should be so adjusted.

Solution of K_2HgI_4.—Dissolve 0.5 gm. of mercuric iodide in 100 c.c. of 0.5 per cent potassium iodide solution.

Counterstain.—Dissolve 0.2 gm. of methylene blue in 100 c.c. of distilled water and add 0.2 gm. of carbolic acid. (For photographic purposes use aqueous carbol-fuchsin instead of methylene blue.)

Technic.—According to Gelarie, the material to be examined is smeared on the slide in a thin layer and allowed to dry in the air (not over the flame). Cover with the zirconyl chloride solution, allow to stand for five seconds, and then wash with water. This acts as a fixative. Then place a few drops of the 10 per cent citric acid solution on the smear, allow to remain for ten seconds and wash again with water. The slide is now ready for staining. Place a few drops of the staining solution on the slide, allow to remain for thirty seconds, and then wash off with water. Follow by momentarily covering the smear with a few drops of the complex mercuric iodide solution and again wash with water. While a good stain is obtained at this point, uniformly excellent results may be secured by counterstaining with aqueous carbol methylene blue solution for five seconds. Then wash the slide, dry, and examine by means of the oil immersion lens. Counterstaining is not recommended for obtaining exact detail of spermatozoa, however, due to overstaining of the organism. Without it the different parts—head, neck, and tail—with their components can be readily distinguished.

Although the above technic is simple, it is believed that some of the more complicated stains show up much more detail of the spermatozoal head.

Method of Holbert.[4]—Holbert's method is similar to that used by Williams: Make a thin smear like a blood smear. Shake until dry. Flame gently. Flood slide with 0.5 per cent Chlorazene for two minutes. Wash gently with running water. Flood slide with 95 per cent alcohol. Let stand for one minute. Tip off excess alcohol and allow to dry. Stain with 0.5 per cent aqueous gentian violet for three minutes. Rinse with water. Rinse with 95 per cent alcohol. Rinse with water. Counterstain with 1 per cent aqueous rose bengal for one minute. Wash with water. Allow to dry. **This method is recommended.**

Methods of Williams and his co-workers.[5, 6]—

Williams has three methods of obtaining spermatozoa. The smear is made in the same way as a blood smear, dried in the air, fixed with moderate heat, and treated with 0.5 per cent Chlorazene solution for two to four minutes to remove the mucous film that overlies the spermatozoa. Wash slide gently with distilled water and then with 95 per cent alcohol. Stain as follows:

Method I. Crystal violet and rose bengal.—

Cover film with 0.25 per cent aqueous solution of crystal gentian violet for two to three minutes. Wash with water. Decolorize with 95 per cent alcohol for half a minute to two minutes. Wash with distilled water. Counterstain with 1 per cent rose bengal (aqueous) for eight seconds. Wash in water and examine under microscope.

If the spermatozoa have not taken up sufficient rose bengal to impart a distinct reddish color to the acrosome and the nuclear membrane, repeat the staining interval with rose bengal until this is accomplished. Care should be taken not to overstain with rose bengal; if overstained, the contrast between the nucleus and the acrosome will be lost.

---

[5] Williams, W. W., McGugan, A., and Carpenter, H. D.: J. Urol. 32: 201, 1934. Weisman, Abner I.: Spermatozoa and Sterility, p. 61, Paul B. Hoeber, Inc., Medical Book Department of Harper & Bros.

[6] Williams, W. W.: New England J. Med. 217: 946, 1937. Weisman, Abner I.: Spermatozoa and Sterility, p. 61, Paul B. Hoeber, Inc., Medical Book Department of Harper & Bros.

Method II. Wollschwarz, methylene blue and rose bengal:

Stain in 1 per cent solution of Wollschwarz for five minutes as follows:

Prepare three solutions: A, B, and C.

	A	B	C
Wollschwarz (1 per cent aqueous)	4.0 c.c.	4.0 c.c.	4.0 c.c.
Sulphuric acid, 2 per cent	0.025 c.c.	0.05 c.c.	0.075 c.c.

The smear on the microscope slide is marked off into three divisions with a glass-marking pencil, and the solutions of stain having the different concentrations of sulphuric acid are applied to each of the divisions, respectively. (Dilutions A and C may be omitted.) Wash with water. Counterstain for six to eight seconds with Loeffler's methylene blue that has been diluted in fifteen parts of water. This acts as a mordant to the Wollschwarz, serving to fix it in the nucleus. It imparts a rather greenish hue to the otherwise yellowish-stained nucleus. Wash with distilled water. Counterstain with 1 per cent aqueous rose bengal for six seconds, or until the rose bengal is set in the acrosome and the nuclear and cell membranes to give the desired contrasts. Examine slide after each application of stain so as to guide its intensity. Wash with distilled water. Dry, mount in neutral Canada balsam, and apply coverslip, or examine without mounting.

Method III. Carbol-fuchsin, eosin-B, and methylene blue:

Prepare the two following staining solutions:

Stain 1.	Saturated alcoholic solution of eosin (bluish)	1.0 c.c.
	Ziehl-Neelsen carbol-fuchsin	2.0 c.c.
	Alcohol 95 per cent	1.0 c.c.

Mix the eosin and carbol-fuchsin solutions together in a dry watch glass. Immediately on mixing, an insoluble precipitate and a metallic film form. Filter the mixture, and to the filtrate add 1 c.c. of 95 per cent alcohol.

Stain 2.	Loeffler's methylene blue	1 part
	Distilled water	6 to 8 parts

Apply Stain 1 to the smear for two minutes. Wash film gently with distilled water. This is best done by immersing it in a basin. Counterstain with Stain 2 for four to eight seconds. Wash slide with distilled water, and dry.

Method of Pollák and Joël.[7]—

Use two separate smears and stain them differently. One stain brings out the structure of the entire spermatozoon, and the second affords better visualization of the cell structure. Thus the stains complement each other.

Stain I. Hemalum-eosin (for visualizing spermatozoal structure). Fix for two minutes with methyl alcohol and then rinse in water. Stain for twenty minutes with hemalum,* steep in running water for thirty minutes with fresh hemalum, rinse for ten minutes in water, stain for contrast for three minutes with a 3 per cent alcoholic eosin solution, differentiate in an alcohol sequence of 70, 90, and 100 per cent, clear in carbolxylene, and embed in Canada balsam under a cover glass.

Stain II. Azure-eosin (for the cellular structure). Fix for two minutes with methyl alcohol, stain for twenty minutes with a diluted Giemsa-Romanowsky azure-eosin solution, rinse in distilled water, and embed in Canada balsam under a cover glass. The staining solution is prepared fresh each time; to 5 c.c. of distilled water add ten drops of the Giemsa-Romanowsky solution.

Examination for Spermatozoa in Seminal Stains

If the stain is such that a fragment can be removed with the point of a knife, the examination is fairly easy. Remove a portion of the scaly stain with a knife point and place it on a glass slide on which has previously been placed a drop of distilled water. Allow the stain to soak in the water for several hours. Keep the specimen moist under a bell jar or in a large closed Petri dish. Separate the scales very cautiously with a teasing needle, allow to dry, fix in methyl alcohol, and stain with dilute Giemsa stain (1 drop in each c.c. of neutral distilled water) for thirty minutes, repeating the stain for an additional thirty minutes if necessary. If restaining is attempted, dilute fresh stain. Wash gently with distilled water, stand the slide on end, and allow to dry. Examine for spermatozoa under the oil immersion objective.

---

*Hemalum is similar to hematoxylin, but not identical. It is a 2 per cent solution of crystalline hematin in 95 per cent aqueous solution of $KAI\ (SO_4)_2.12\ H_2O$, 100 c.c.

[7] Pollák, O. J., and Joël, C. A.: J. A. M. A. 113: 395, 1939. Weisman, Abner I.: Spermatozoa and Sterility, p. 62, Paul B. Hoeber, Inc., Medical Book Department of Harper & Bros.

If the stain is on unstarched cotton or linen cloth, the finding of spermatozoa presents a much more difficult problem. Select a thread of the cloth near the center of the stain, select the side of the cloth which contains the more seminal fluid. Place a thread from the dry stain on a glass slide in a drop of distilled water. Make many such preparations. Each specimen is allowed to soak in the water for from two to twenty-four hours. Provision must be made to prevent drying of the water during this time.

At the end of the digestion period tease the fibrils apart *very cautiously* with fine pointed needles. Take care not to break the spermatozoa. Continue with the staining process just described.

The cloth itself may be stained according to the **method of Baecchi.**[*] A piece of the cloth containing the stain is cut 1 cm. square, and placed in 1 per cent acid fuchsin or methylene blue solution. It is then washed in 1 per cent hydrochloric acid, after which it is dried in the air or dehydrated in absolute alcohol. Next it is cleared in xylol, then mounted in Canada balsam. If the spots are not fresh, they are placed for one-half hour to twenty-four hours in 20 to 30 per cent ammonium hydroxide solution and then in distilled water preliminary to the staining process.

Hektoen and Rukstinat[**] describe a **method** of making a stained specimen from spots of spermatozoa on cloth. Their method makes use of Mallory and Wright's chloride of iron-hematoxylin stain.

1. Soak the stained cloth in 1 per cent ammonium hydroxide solution in water for from twelve to twenty-four hours.
2. Select a single thread and stain two minutes in 5 per cent aqueous solution of erythrosin.
3. Wash quickly in distilled water.
4. Stain with 10% aqueous solution of ferric chloride two minutes.
5. Transfer directly to 2% aqueous solution of hematoxylin for two minutes.
6. Wash quickly in distilled water.
7. Transfer to 0.5% aqueous ferric chloride and tease out fiber to its finest shreds. Remove from this solution when threads are reddish pink or light brown.
8. Wash in distilled water quickly.
9. Dehydrate in absolute alcohol.
10. Clear in creosote.
11. Mount in balsam.

Better results are obtained if the differentiation is carried out slowly in 0.5% ferric chloride solution than in stronger solutions. Boiling the cloth for one minute in water after soaking in ammonia solution helps preserve the tails. When the stain takes well, the head of the spermatozoon is from a dark purple to black in the posterior two-thirds, while the anterior third is pink, and the tail is from a pink to lavender. The connecting piece frequently is evident. The threads of the cloth may stain more or less pinkish.

Weisman[1] refers directly to the technic of Hankin[2] and Windsor.[3] This is a special technic for warm climates. Hankin examined the suspected stains directly on the cloth, after first fixing the material with a cellular fixative, then adding dilute sulphuric acid, and finally staining the material with gentian violet. Windsor fixed the cloth in Müller's solution and then stained it. Williams suggested the special Wollschwarz[1] stain. Soak and scrape the semen-stained cloth, obtaining a turbid suspension. Centrifuge the soakings. In an old specimen, some of the tails will be missing or bent or abnormally twisted. Care must be taken not to confuse the sperm heads with spores, pus cells, or artefacts.

The Florence Test for Identification of Semen.—

Reagent.—

Potassium iodide	1.65 gm.
Iodine	2.54 gm.
Distilled water	30.00 c.c.

Rub up the iodine and the potassium iodide in a mortar, then add the water. Filter before using.

Technic.—

Remove a minute fragment of the stained specimen by means of a pair of fine-pointed forceps and sharp-pointed scissors. Transfer to a slide. Treat with a small drop of distilled water. Allow to soak for 1 or 2 minutes. Add a small drop of the reagent to it in such a way that the two drops of fluid come in contact at their edges, and then cover immediately with a cover glass.

Examine microscopically for seminal crystals. These look like the hemin crystals obtained with Teichmann's test for blood (Fig. 292, page 1204).

Weisman[2] states that a positive reaction is not significant since other body fluids give such results with this test. Our own experience confirms this statement. A negative test, however, informs the investigator that the suspected substance is not semen, and this is the only value of the Florence test.

Peltzer[3] uses the following technic for the Florence method:

Moisten the suspected spots with hydrogen peroxide. If semen is present, much foaming occurs. Centrifuge substance. Place on slide and stain with 2 per cent aqueous eosin. If positive, long lance-like crystals appear. The addition of I-KI solution to the slide colors the crystals brown. The crystals disappear and are recrystallized by the addition of more I-KI solution. The presence of Florence crystals denotes the presence of body fluids, possibly semen.

The Puranen Test.—Puranen[4, 5] and Tarsitano[6] advocated the microchemical method for identification of spermatozoa. Naphthol yellow sulphur in aqueous solution reacts differently with human semen at neutral and slightly alkaline reactions. A positive reaction is denoted by formation of microcrystals, which are characteristically large, have a strong double refraction, and are of a definite orange hue.

Niederland's Test.[7]—This test employs dilute sulphuric acid. When added to a suspected specimen, the weak sulphuric acid solution is always positive in the presence of semen, but this test is also positive with practically all other body secretions. Weisman states that its only value lies in the fact that, when the test is negative, further search for spermatozoa can be abandoned. The crystals formed are probably sulphates of calcium and other salts found in semen and body fluids.

Marcille Method.[7]—This is nothing more than the Florence test coupled with the addition of Gram-eosin staining of the centrifuged precipitate after maceration of the specimen in physiologic saline solution.

Borgarius Test.—This test is similar to the Florence test, except that phosphomolybdic acid solution instead of the I-KI solution is used to precipitate crystals. The crystals obtained by this technic are characteristic, but they are also found with other body fluids.

The AuI_3 Test.—Villamil[8] has shown that solutions of AuI_3 give characteristic crystals with diluted semen as well as with solutions of spots and stains produced by semen. The crystals are distinct. He considers this reaction to be more sensitive than that obtained by most other microcrystalline tests.

Test for Hydrogen Ion Concentration.[9]—If a drop of distilled water is added to suspected semen and well mixed, the hydrogen ion concentration of the solution when tested with nitrazine paper and compared with a colorimetric chart will give evidence of definite alkalinity.

The Fluorescence or Ultraviolet Light Test.—Ito[10] first demonstrated that semen stains give a characteristic color effect under ultraviolet light. He obtained this same effect with other tissues and described its use in forensic medicine.

Simonin[11] showed that dried sperm gives a brilliant characteristic fluorescence under ultraviolet light, but stated that other organic liquids also give some fluorescence, so that the test is probably not specific. Husson[12] reported that seminal spots, irrespective of spermatozoa or azoospermia or the age of the spot, show a characteristic fluorescence in ultraviolet rays between 4200 and 4900 Å.

Microchemical Identification of Seminal Fluid

Method of Choice

Determination of acid phosphatase activity affords an excellent means for specific microchemical identification of seminal fluid and seminal stains. This procedure employs a new principle postulated by Ove Riisfelt of Denmark in 1946.* It is of definite medicolegal value in the identification of seminal fluid as an adjunct to the demonstration of spermatozoa; but it is of particular value in cases where spermatozoa cannot be demonstrated in the specimen.

Kaye** found that male ejaculate produces a very high acid phosphatase activity in comparison with the very low acid phosphatase activity of the other body fluids (saliva, perspiration, urine, etc.) and the common vegetable and fruit juice stains. The differences are so marked and definite that it leaves little room for doubtful interpretation of the results. The average seminal fluid contains approximately 2,500 King-Armstrong units of acid phosphatase per c.c., the upper limits ranging to 3,500 King-Armstrong units and the lower to above 500 units. Ejaculates in cases of aspermia give comparable high results.

Semen is characteristic in that it gives these high values, while other body fluids give values of much less than 5 King-Armstrong units per c.c. The enzyme is resistant to all known body fluids including vaginal secretion; it might, however, be inhibited by vaginal disinfectants and contraceptives. Seminal fluid aged two weeks in a condom-type contraceptive showed no appreciable loss of acid phosphatase activity. Known seminal stains proved to be strongly positive even after many months, six or more.

The materials listed in Table 139 contain less than 5 King-Armstrong units of acid phosphatase per c.c. of concentrated pure substance, and in the cases of vaginal fluids, perspiration, feces, nasal discharge, and pus, per unit square centimeter of saturated control cloth.[1]

TABLE 139

BODY FLUIDS	FOOD STAINS	
Vaginal fluids	Tea	Meat gravy
Urine	Coffee	French dressing
Blood (serum)*	Egg white	Beet juice
Blood (whole)	Egg yolk	Custard
Blood (menstrual)	Vegetable juice (V-8)	Starch
Saliva	Orange juice	Mayonnaise
Perspiration	Prune juice	Chop suey
Pus	Beer	Soapy water (Ivory)
Nasal discharge	Milk	Onions
Gastric juice	Cream	Albumin
Feces	Mushrooms	Choline
Rectal smears	Corn	
	Alkaloids, such as quinine, atropine, procaine	

*In carcinoma of the prostate with metastases, this value may be appreciably increased.

Walker Acid Phosphatase Test for Identification of Seminal Fluid[2]

Principle.—

The portion of the garment to be tested is immersed in a bath at pH 5.0 containing alpha-naphthyl phosphate as a substrate, and a suitable diazonium salt. The acid phosphatase of the semen acts on the phosphate ester to liberate alpha-naphthol. This immediately reacts with the diazonium salt to form a brilliant orange-red azo pigment, which is insoluble under the conditions of the test, and which becomes adherent to the background at the site of acid phosphatase activity.

Substrate-Reagent Bath.—

Dissolve 23 gm. sodium chloride
0.5 c.c. glacial acetic acid
2.0 gm. sodium acetate trihydrate
in 90 c.c. distilled water.

Add 1 c.c. of 1% aerosol containing a suspension of 30 mg. anthraquinone-1-diazonium chloride (III)* and 50 mg. of calcium-1-naphthyl phosphate.*

Dissolve the aerosol in warm water without shaking.

Preparation of Anthraquinone-1-Diazonium Chloride (III).*—

Dissolve 10 gm. 1-amine anthraquinone, Eastman technical grade, in 85% sulphuric acid and pour into a large volume of water. Collect the precipitate with suction and wash free from acid with water.

Treat the wet product with 20 c.c. concentrated hydrochloric acid to form a grayish-white crystalline sludge.

Diazotize at 30° to 40° C. by running an equivalent of sodium nitrite, 3.2 gm. in 50 c.c. water, under the surface, with stirring.

Pour the reaction mixture into 10 times its volume of water at 70° to 80° C.

---

*These can be purchased from Dajac Laboratories, 511 Lancaster, Leominster, Mass.

[1] Kaye, Sidney, Office of the Chief Medical Examiner, Commonwealth of Virginia, and the Department of Legal Medicine, Medical College of Virginia.

[2] Walker, Joseph T.: New England J. Med. 242: 110, 1950. Presented before the American Academy of Forsenic Sciences, Chicago, Jan., 1950.

Add 0.5 gm. sodium nitrite.

Filter rapidly.

Add sodium chloride to salt out the diazonium chloride in shiny, yellow platelets.

Collect the crystals, wash with cold water, alcohol, and ether, and dry.

Protect from light and store at room temperature, or in a refrigerator. Refrigerated they are stable at least 18 months.

The diazonium compound is available commercially as "Naphthanil Diazo Red AL." It contains 5% zinc chloride and 12% aluminum sulphate. The metal ions completely inhibit acid phosphatase present in the cell nuclei of liver and kidney, whereas the cytoplasmic acid phosphatase is altered slightly. This finding is suggestive of a third variety of acid phosphatase present in cell nuclei.

Preparation of Calcium Alpha- or Beta-Naphthyl Phosphate.*—

Dissolve 14.4 gm. of alpha- or beta-naphthol
in 15.0 c.c. of dry pyridine.*
Dissolve 15.3 gm. phosphorus oxychloride solution
in 10.0 c.c. dry pyridine

Add the phosphorus oxychloride solution drop by drop, or the entire material will be lost.

Add the naphthol solution in portions to the phosphorus oxychloride solution. Heat is developed and a white precipitate separates as a sludge.

Allow to stand at room temperature for 10 minutes.

Cool and add in portions to a solution of 30 gm. of calcium acetate in 200 c.c. distilled water and 100 gm. of ice.

An oily material separates, which slowly dissolves and comes out as a white precipitate.

Add 150 c.c. alcohol.

Collect the white precipitate with the aid of suction.

Wash with 95% alcohol and ether, and dry.

Technic.—

Immerse the garment to be tested in a substrate reagent bath. If acid phosphatase is present, a brilliant orange-red pigment will appear and adhere to the background at the site of acid phosphatase activity. The phosphatase activity of a fresh, dry seminal stain is so intense that within 30 seconds a distinctive, visible coloration occurs, and within 2 minutes the test is complete.

When the semen is mixed with blood, as occurs in rape, an interesting color change occurs. The blood turns to a dirty brownish-gray when immersed in the substrate bath. Wherever semen is present, this color is gradually replaced by the orange red of the phosphatase-catalyzed pigment. Bloody stains should be developed longer than others, so that the pigment formed by the semen may be visible above the background.

If the suspected stain occurs on an unfavorable background, such as a red wool dress, the red pigment of the developed test is not clearly visible. In this case, and in any case in which it is not desirable to apply the reagents directly to the specimen, a portion of the phosphatase of the stain may be transferred to a white filter paper, and its activity detected thereon.

Moisten the filter paper, press it firmly against the suspected area for several minutes, and then immerse the paper in the substrate-reagent bath. Some of the acid phosphatase of the stain on the garment will have diffused into the filter paper sufficiently to cause a print that can be developed.

If desired, place a small portion of the suspected material on dry filter paper. Moisten with a drop of water. Development of the paper will show a red rosette if semen is present.

---

*Reagent pyridine contains enough water to decompose the phosphorus oxychloride extensively. Dry by refluxing with anhydrous barium carbonate for several days, distill, and store with sodium hydroxide pellets.

Even if the fabric is tested directly with the substrate-reagent mixture, the procedure does not interfere with the subsequent microscopic search for spermatozoa. The seminal fluid takes on a peach-pink color, but the spermatozoa are not colored, for they do not contain sufficient acid phosphatase. If the specimen is then stained with carbolfuchsin, the spermatozoa stain with the dye. The test serves the double function of demonstrating high acid phosphatase activity and at the same time indicating where a search for spermatozoa is likely to be successful. The phosphatase activity is largely concentrated at the periphery of the stain. Spermatozoa are more plentiful in the central area, where they may be demonstrated microscopically.

Precipitin Test for Identification of Human Seminal Stains

Precipitin tests for the differentiation of semen of human and animal origin can be made by carrying out the test described below.

In the examination of stains in cases of suspected rape, finding spermatozoa is by far the most conclusive evidence of the presence of semen. The procedure described above for the identification of seminal fluid, however, is of value in proof of the presence of semen especially in cases of aspermia or in those cases where complete spermatozoa cannot be identified (twisted tails, etc.).

The injection of rabbits with the semen of man, swine, bull, or horse induces the formation of specific precipitins for the homologous fluid.* In most cases, precipitins develop also for the homologous blood serum, as already known. Extracts of human spermatozoa in salt solution appear to give the same result as the seminal fluid. Seminal precipitin reaction reveals the presence in semen of a substance or substances peculiar to it, and consequently the reaction may be of value in studying the nature of suspected spots and stains.

Precipitin for identification of human semen is made by injecting rabbits intramuscularly four or five times at intervals of three to four days with increasing quantities of human seminal fluid. The first injection is 2 c.c., the next 4 c.c., each successive injection being 2 c.c. more than the preceding one. Six or eight days after the last injection, the animals are bled (see removal of blood from carotid artery, page 2040), and the blood collected in sterile 50 c.c. Rockefeller tubes with cork stoppers. After the blood has clotted, the clot is shaken loose, and the tube is centrifuged at 1,500 revolutions a minute for 20 minutes to separate the serum. The serum is removed with all sterile precautions and placed in another sterile test tube. Serum precipitates are removed from the rabbit's blood serum by mixing it with equal parts of a 1:200 dilution of human blood serum in saline. Allow the mixture to stand at room temperature for one hour; then place in a refrigerator overnight. Centrifuge it at high speed for sufficient time to sediment the precipitate formed from the mixture of the rabbit and human serums. Use the supernatant serum for precipitin tests to identify seminal fluid stains.

Technic.—

Extract the suspected seminal stain in physiologic saline for four to eight hours, using very small amounts of saline. Concentrate the extract slightly, and then centrifuge to remove any sediment that may be present. Remove the supernatant fluid, placing it in a clean, dry test tube. Dilute with physiologic saline until, upon shaking, the amount of foam indicates a 1:1,000 dilution. Be sure the diluted extract is neutral.

Place 0.1 c.c. of antisemen precipitin serum in the bottom of a small heavy walled capillary tube. Allow the extract of suspected seminal fluid stain to run down the side of the tube so that it forms a layer above the serum but does not mix with it. Allow to stand at room temperature for one hour, observing the reaction at 10- to 15-minute intervals. At the same time run a control test using an extract of an unstained portion of the cloth on which the seminal stain was found. A positive reaction is indicated by a white precipitate at the point of contact between the two fluids. This reaction is like the reaction in the precipitin test for the identification of human blood (pages 1162 ff.)

Wchnschr. 18: 637, 1905; Dervieux, M.: Compt. rend. Acad. d. sc. 172: 1384, 1921. Hektoen, Ludvig: J. A. M. A. 78: 704, 1922. Hektoen, Ludvig, and Manly, Leonard, S.: J. Infect. Dis. 32: 167, 1923.

Determination of Blood Group or Type of Semen, Saliva, and Other Body Fluids by Agglutinin Inhibitory Methods

For individual identification of seminal stain the agglutinin inhibitory test is suggested. The results of this test are limited just as the agglutinin absorption test of blood stains. Landsteiner and Levine[1] and Yamakami[2] in 1926 demonstrated that spermatozoa have the power of specifically absorbing group agglutinins from blood serum just as human erythrocytes do. Thus semen from a Group A individual will absorb anti-A isoagglutinins from anti-A serum, and semen from Group B individuals will absorb anti-B isoagglutinins from anti-B serum, etc. This fact at once suggests that it may be possible to trace seminal stains to persons of certain blood group.

The agglutinin inhibitory test below is the method of Wiener.*

Agglutinin Inhibitory Test for grouping stains of semen, saliva, and other body fluids. Test tube method. This test is to be used for secretions only, and may not be used for blood.

Six small Kahn tubes are needed. Each tube must be marked specifically with proper identification. None of the materials used in this test should contain blood or body fluids. It is better to use entirely new glassware for the entire procedure. An extract must be made of the stain, using as small a quantity of physiologic saline as possible. Refer to pages 1169 ff.

In each tube, use 1 drop of the extracted stain or unstained portion with 1 drop of the antiserum. See Table 140.

TABLE 140

TUBES	1	2	3	4	5	6
1 drop of extract of:	Stain	Unstained portion	Stain	Unstained portion	Stain	Unstained portion
Add 1 drop	Anti-A serum	Anti-A serum	Anti-A serum	Anti-A serum	Anti-B serum	Anti-B serum
Allow to stand at room temperature for 1 hour.						
Add 1 drop of	A_1 cell suspension	A_1 cell suspension	A_2 cell suspension	A_2 cell suspension	B cell suspension	B cell suspension

Allow to remain in contact for 30 minutes at room temperature, shaking every five minutes.

Observe macroscopically for agglutination or lack of agglutination.

Confirm by placing a small amount from each tube on a properly labeled glass slide and examine under a microscope.

Cork the tubes and place in the refrigerator for 24 hours and read again.

Tubes 2, 4, and 6 are controls and should be *positive,* that is, there should be agglutination (antiserum against specific cells).

If the results in tubes 1 and 3 are negative, the stain contains agglutinogen A_1 (which removes anti-A_1 and anti-A_2 from anti-A serum).

If the result in tube 3 is negative, the stain contains A_2.

If the result in tube 5 is negative, the stain contains B.

If all the tubes are positive, the stain contains no agglutinogens, and therefore was derived from group O, or there was no inhibition. If both A and B agglutinogens are present, the stain was derived from a group AB person.

---

*Personal instruction.

[1] Landsteiner and Levine: J. Immunol. 12: 415, 1926.

[2] Yamakami, K.: J. Immunol. 12: 185, 1926.

This same test may be made on seminal fluid, saliva, urine, tears, sweat, etc. Some individuals are *nonsecretors.* Specimens derived from such persons will fail in the inhibitory experiment, and the secretion cannot be identified.

Explanation.—Isoagglutinogens present in secretions will absorb their corresponding isoagglutinins from known sera. Thus "A" isoagglutinogen will absorb anti-A isoagglutinin, leaving this serum inactive against A cells which are later added. However, if the stain does not contain the "A" isoagglutinogen, the anti-A serum will agglutinate the A cells which are later added. In the case of the subgroups, A_1 might remove both the anti-A_1 and the anti-A_2 agglutinating antibody from anti-A serum, while the A_2 isoagglutinogen will remove only the anti-A_2 isoagglutinin. Thus anti-A serum treated with a blood stain containing A_2 cells will no longer agglutinate A_2 cells but might agglutinate A_1 cells.

"B" isoagglutinogen will absorb anti-B isoagglutinin, leaving this serum inactive against the B cells which are added later.

If the test shows that anti-A serum no longer agglutinates A cells, and anti-B serum no longer agglutinates B cells, then obviously both isoagglutinogens were present and the stain was derived from a group AB individual.

With this information, we may compile Table 141.

TABLE 141.—RESULTS OF INHIBITORY TESTS TO DETERMINE GROUP OF SEMINAL STAINS, ETC.

TUBES						
1	2	3	4	5	6	CONCLUSIONS
	+		+		+	Controls are correct
+	+	+	+	+	+	Stain derived from group O, or inhibition failed to occur
−	+	−	+	+	+	A_1 agglutinogen present
+	+	−	+	+	+	A_2 agglutinogen present
+	+	+	+	−	+	B agglutinogen present
−	+	−	+	−	+	A_1 and B agglutinogens present
+	+	−	+	−	+	A_2 and B agglutinogens present

EVIDENCE IN SUSPECTED SEXUAL ASSAULT

In rape of a child or virgin, there is usually ample evidence in the form of hemorrhage and laceration of tissue. Further evidence may be obtained by looking for traces of semen either on the external portions or on the vagina. The length of time that spermatozoa may be found in the vagina after an alleged assault is varied, some reporting that spermatozoa are found as long as two days after intercourse. While this is true in rape cases without death from the assault, in those cases where death has occurred, spermatozoa apparently may not live very long in the vagina.

In these assault cases, spermatozoa may be found on the clothing by one or more of the tests already described. In addition to the examination of the victim and her clothing, the clothing should be further examined for fibers of the assailant's apparel. We should also examine the clothing of the victim and suspected persons for evidence such as grass, fibers, soil, etc., which may be related to the locality where the crime was committed. In many cases there will be found scratches and skin changes due to the fingernails of the assailant. Therefore, the suspected person should be carefully examined, particularly for skin, hair, and cosmetics, which may be identified as coming from the victim. The scrapings of the nails of the victim should also be examined.

The technic of examination of the victim's vagina for spermatozoa is as follows: Normal salt solution should be gently sprayed over the vagina and perineum of the victim, collected in a clean dish placed under the patient, and then examined. The vaginal wall should be gently washed with a small amount of salt solution injected into the vagina with a clean glass syringe and rubber bulb such as is used in blood cell washing in serologic work. The contents of the vagina should be withdrawn with the same syringe or pipette and, after centrifugalization, examined microscopically. The suspect should also be washed with salt solution sprayed over the entire penis and the collection washed, centrifuged, and examined microscopically.

DEFICIENCY DISEASES

The deficiency of vitamins is responsible for most of the diseases which we call deficiency diseases, but, at the same time, it must not be forgotten that amino acids and minerals and certain fats are also necessary to maintain health; and their absence, as well as the absence of vitamins, constitutes the entire picture of certain deficiency diseases. These latter substances are alluded to as accessory food factors.

Advances in the field of vitamins have come very rapidly. Vitamins have been divided for convenience into the fat-solubles and the water-solubles. The water-soluble ones may be subdivided into ascorbic acid and the B group and those outside of that still expanding list. Spies and Stone[1] have given us their viewpoint on this question. They call attention to the necessity of dissecting the symptom due to depletion of a single factor from the confusing mixture of symptoms characterizing the naturally occurring multiple deficiencies. To that end, studies were made upon human beings, so that many new data have been accumulated on the manifestations of an isolated acute deficiency, more so than on the chronic partial deficiency. These authors alluded to the fact that there are at least twelve identified compounds and mavericks still uncounted herded together under the unwieldly but encompassing name of vitamins. Some of the B complex vitamins function as parts of enzyme systems and thus are essential to the normal respiration of tissues. Other vitamins appear to have a more localized or particularized part to play and, as a group, are concerned with structural integrity more than energy utilization. Spies states that prior to the artificial synthesis of ascorbic acid and thiamine, controlled clinical studies led him and his co-workers to the conclusion that persons with any nutritional deficiency disease had deficiencies of not one but several nutrients. From this, they developed the concept of nutritive failure and so used this concept as a working hypothesis. Nutritive failure, as he uses the term, may be defined as follows: *nutritive failure* is a clinical term which means different things to different physicians. To Spies and his co-workers it designates that stage of malnutrition when the protective mechanisms within the body can no longer compensate for a deficiency of the nutrients and vague symptoms begin to appear. These symptoms arise from a derangement in the tissues as a result of deprivation of nutrients, and they vary greatly from patient to patient. Eventually the signs seen by the discerning physician are interpreted as pellagrous dermatitis or glossitis, beriberi neuritis or beriberi heart disease, hemorrhages or gingivitis of scurvy, cheilosis or the ocular symptoms of riboflavin deficiency. These characteristic symptoms make it possible for the physician to make an accurate diagnosis of a specific deficiency state and to realize that they occur as a response of the body tissues to the deprivation of certain specific chemical substances in food. Thiamine has been considered by some as a cure for nutritional nerve disorders, vitamin A as a cure for night blindness, vitamin C as a cure for scurvy, and niacine as a cure for pellagra. These workers long ago learned to treat the patient for nutritive failure rather than for only the prominent presenting symptoms of a single vitamin deficiency. Nutritive failure is a much more inclusive term than pellagra, beriberi, scurvy, or riboflavin deficiency in that it connotes varying degrees of a mixture of nutritional deficiencies operating simultaneously. It does not indicate why the nutrition has failed but simply that it has failed. The patient, not one disease, must be treated if he is to be completely rehabilitated.

---

[1] Spies, T. D., and Stone, R. E.: South. M. J. 40: 46-55, 1947.

One of the most interesting features of the contribution of Spies and Stone is their discussion concerning folic acid. It has been found to play an important role in correcting some macrocytic anemias associated with nutritive failure. A search for a potent antianemic substance of known chemical structrue had been carried on for many years but without success. Niacine, riboflavin, thiamine, pantothenic acid, pyridoxine, choline, inositol, para-aminobenzoic acid, and uracil, singly and combined, administered orally and intravenously, showed no indication of having antianemic properties in human beings. Many others were tried without showing any antianemic effects. Vitamin B_{12} has been used successfully in the treatment of pernicious anemia. Refer to page 720.

The *Lactobacillus casei* factor, commonly called folic acid, seems to fill a long-searched-for want. It has the appropriate chemical term ''pteroylglutamic acid.''

Spies and his associates have found a favorable therapeutic response to synthetic folic acid in the cases shown in Table 142.

TABLE 142

TYPE OF ANEMIA	NUMBER OF CASES
Addisonian pernicious anemia*	78
Tropical sprue	76
Nontropical sprue	2
Nutritional macrocytic anemia	46
Macrocytic anemia of pregnancy	3
Nutritional leukopenia	8
Cirrhosis of the liver with macrocytic anemia (7 cases did not respond)	5

*Refer to remarks in text below.

This favorable therapeutic response can be detected in the bone marrow soon after therapy is initiated. The numbers of megaloblasts and early erythroblasts decrease progressively and the late erythroblasts and normoblasts increase. Eventually the normal ratio of nucleated red blood cells and white blood cells of the marrow is re-established. Reticulocytosis can be detected in the bone marrow sometimes as early as the second day. Its beginning is frequently detected in the peripheral blood from about the third to the fifth day of therapy. A peak is reached on the sixth to tenth day. The height of the rise varies from case to case depending upon the severity of the anemia, the adequacy of the dose, and the presence or absence of complications. In addition to the reticulocytosis there is a gradual increase in the number of red blood cells and in the hemoglobin. When thrombocytopenia and leukopenia are present, increases toward normal are to be expected.

Spies and his co-workers suggested that folic acid will maintain the increased red blood cell and hemoglobin levels which have been produced either by folic acid or by liver extract in most cases and that it may control sprue more effectively than does liver extract. There is no obvious explanation for the decrease in erythrocytes and in hemoglobin which followed remission in two of the three patients who were in relapse at the time folic acid therapy was initiated by them. Spies suggested that the folic acid caused depletion of some other nutrient essential for erythrocyte maturation. Furthermore, *folic acid does not always prevent the occurrence of combined system disease nor does it reverse the degenerative process once it has begun.* They believe that folic acid works as a part of an enzyme system and as yet they have observed nothing which led them to change their point of view. It will not protect against the neural disturbances which frequently develop in pernicious anemia. One of the most significant features of their observations is this question which they presented at the conclusion of their last paper[2]—since folic acid conjugates are present in food and are probably stored in our bodies and since the normal person and persons with nutritional macrocytic anemia and the macrocytic anemia of sprue, in contrast to persons with pernicious anemia, seem able to liberate the *L. casei* factor, is it not likely that liver extract and substances that act similarly may contain a substance capable of liberating from the tissues the substances which in turn act on the cellular components in the bone marrow? Could it not be that the ineffective utilization of the naturally occurring conjugate of folic acid by patients with addisonian pernicious anemia is secondary to a deep-seated biochemical defect?

Vitamin B_{12} is discussed on page 720.

Vitamin A Deficiency

Deficiency of vitamin A leads to changes referable to ocular disturbance. Night blindness is a definite example of vitamin A deficiency. Xerosis, xerophthalmia, and keratomalacia are severe stages of the same disease. Vitamin A belongs to the group of their higher alcohols. It is formed by the metabolic activity of the animal organism from vitamin substances produced by plants, or carotenes, carotenoids, or pigments. Four of these carotenes may be converted into vitamin A; i.e., β-carotene, α-carotene, carotene, and cryptoxanthin.

Vitamin B Deficiency

Thiamine or Vitamin B_1 Deficiency.—B_1 deficiency leads to beriberi.

Beriberi

Beriberi is a food deficiency disease due to the absence from the dietary of a neuritis-preventing vitamin, B_1 (thiamine). It is found in the Orient where the diet is preponderatingly one of rice. The grain used there is polished rice, in which the vitamin-containing layers are rubbed off. The neuritis which occurs in beriberi involves not only the nerves of the extremities, but also the pneumogastric nerve. It is the manifestation of cardiac disturbances which differentiates this form of neuritis from the neuritis due to alcohol or arsenic.

---

[2] Loc. cit.

The disease was described in 1642 by Bontius, although the Chinese writers of the seventh century referred to it. It is found in Japan, Netherlands East Indies, and the Eastern Coast of Brazil, in India, Indo China, Malay Peninsula, Eastern China, Philippine Islands, East and West Coasts of Africa. More than three hundred cases occurred among the British soldiers in Mesopotamia during World War I.

The history of the connection between beriberi and vitamin B_1 dates from 1884 to 1941.* Takaki, Director-General of the Medical Service of the Japanese Navy, was one of the first to note the relationship of beriberi to a deficient dietary. By substituting other foodstuffs for a portion of the rice which had previously constituted a substantial part of the diet, he succeeded in virtually eradicating beriberi from the Japanese Navy as early as 1884. In 1897, Eijkman in Java demonstrated that a condition closely resembling beriberi could be produced in fowls by a diet consisting exclusively of polished rice. His work is well known, especially since his discovery occurred paradoxically quite by accident during the course of experiments designed to prove the infectious nature of the disease. His successor, Grijns, fully recognized the significance of his discovery, but it was not until Fletcher in 1905 and Fraser and Stanton in 1909 reported their definitive results in human beings that the dietary origin of beriberi became accepted to any great extent beyond the confines of the Netherlands East Indies. The next contribution occurred in 1911, when Funk succeeded in extracting from rice polishings a crystalline fraction of material which proved to be effective in curing experimentally induced polyneuritis in pigeons.

Funk advanced the deficiency theory as the cause not only of beriberi but also of scurvy, rickets, and pellagra, and proposed the term "vitamine" as a general designation of the accessory food factors which he considered essential for the prevention of these diseases. During this time, Vedder had been active in studying the problem in the Philippines, and it was there that he introduced Williams to the subject in 1910. Williams in the Philippines cured many cases of infantile and adult beriberi with potent extracts from rice polishings. It was in 1916 that Seidell introduced fuller's earth as an adsorbent to obtain a concentrated fraction. This contributed measurably to the ultimate isolation of the vitamin, as well as to the differentiation and isolation of other members of the vitamin B complex. In 1926, Jansen and Donath, working in the same laboratory in Java where Eijkman had pioneered thirty years earlier, isolated from rice polishings a crystalline substance which showed marked antineuritic activity. They used adsorption on acid clay, elution with baryta, and fractional precipitation with silver nitrate. They used rice birds for the bioassays because these small birds contract avian polyneuritis within ten to fourteen days when fed on an exclusive diet of polished rice. In 1932, Ohdake obtained a crystalline product which was far less potent than that of Jansen and Donath, but his formula was more accurate. In 1935, Williams and his associates determined the construction of the crystalline substance. It was in this year that large-scale production was undertaken with the cooperation of Merck & Co., Inc., and it became possible to conduct extensive analytical investigations on the crystalline material. Williams and his associates split the vitamin B_1 molecule into progressively smaller pieces until they obtained cleavage products whose identities could be determined. They then reconstructed the molecule from these organic compounds of definite structure to form a product identical with the vitamin as obtained from natural sources. These analytical investigations were facilitated by the knowledge, gained from earlier experience, that the vitamin is quantitatively split into two components by neutral sulphite solution at room temperature. By 1936, Williams was able to advance a revised formula which accurately denoted the molecular structure of the crystalline substance. In the next year Williams and his associates succeeded in synthesizing the compound. This synthesis was described by Cline, Williams, and Finkelstein in a paper emanating from the Merck Research Laboratories. As a result of the synthesis of thiamine hydrochloride by Williams and his associates, we now have an important therapeutic agent, identical in every respect with the naturally occurring vitamin.

---

*Historical facts from publication by Merck & Co., Inc., Rahway, N. J.

The disease is described under two types: (1) wet or dropsical beriberi, in which the victims are affected with general edema; (2) dry or atrophic type in which the absence of beriberi-preventing vitamins constitutes the leading features. In death from wet beriberi, the tissues are very moist. There are generally present pleural and pericardial effusions. The lower end of the stomach and the upper portion of the small intestines, in particular the duodenum, show marked congestion with hemorrhagic areas. The heart chambers show a dilatation with hypertrophy. The heart muscle has the faded-leaf appearance indicative of fatty degeneration, with microscopical segmentation and vacuolation of the fibers. Lungs show congestion and at times present the characteristics of pulmonary edema. The kidneys are congested. There is back pressure in the right heart with dilatation of the central vein of the liver lobules which at times is productive of atrophy of the adjacent liver cells. The muscles supplied by the affected peripheral nerves show more or less atrophy according to the duration of the disease. The peripheral nerves show nerve degenerations varying from slight medullary degeneration in a few fibers to a complete destruction of the nerve, giving a Wallerian degeneration; that is, vacuolation and formation of myelin droplets in the medullary sheath with fragmentation of the axis cylinder. The key to beriberi is the peculiar and striking selection of the vagus nerve in the degenerative processes as well as those of the peripheral nerves of the extremities. This vagal involvement produces disturbances of the heart particularly, and lungs in lesser degree, and thus differentiates beriberi from other forms of multiple neuritis.

The most common symptoms are those connected with degenerations involving the peripheral nerves of the extremities. The motor nerves are more involved than the sensory ones, there being rarely complete anesthesia, but rather a blunting sensation as though a piece of cloth were interposed between the examining instrument and the skin. There is weakening of the muscle power as shown by the grip of the hand or weakness of foot muscles. In more advanced cases we may observe foot- and wristdrop. The unsteadiness of gait is not true ataxia, as the patient does not clearly show the Romberg sign.

It is muscular weakness rather than incoordination. The gait is the "steppage" one of peripheral neuritis, the patient walking as though extracting one foot after the other from clinging mud. Later on, the gait becomes a shuffling one. The mind is clear. The knee jerk is absent. The extensors of arms and legs are more markedly affected than the flexors. Diagnosis is made by the edema, the cardiac involvement, and signs of peripheral neuritis.

There are certain types of neuritis which are vitamin B_1 deficiencies, such as polyneuritis associated with infections and disturbances associated with chronic alcoholism. Polyneuritis of pregnancy has been shown to be due to vitamin B_1 deficiency.

Vitamin B_2 Complex Deficiency

Vitamin B complex has been split into at least six fractions, of which three have been isolated, synthesized, and may be purchased, namely, riboflavin, niacin (nicotinic acid), and vitamin B_6. Vedder[1] has discussed the relationship of sprue to vitamin deficiency. In sprue, there is definite diarrhea. Vitamin B_1 is poorly absorbed in any case of diarrhea and one of the first symptoms of vitamin B_1 deficiency in practically all experimental animals is a diminished appetite and loss of motility of the digestive tract. Vedder believes that symptoms of sprue are delayed by the administration of B_2 complex either by mouth or parenterally.

Regarding vitamin D and sprue, this vitamin is fat soluble so that there must be failure of absorption in any case having steatorrhea. This aggravates the condition in cases of nontropical sprue.

Discussing vitamin K in connection with sprue, Vedder calls attention to the fact that this is a substitution product of naphthoquinone and is fat soluble. A sufficient supply must be afforded or prothrombin cannot be formed in the liver in adequate amount and this results in a failure of the blood to clot properly. It is poorly absorbed when steatorrhea exists because it is a fat-soluble vitamin. Snell states that a hemorrhagic diathesis has been described in connection with tropical sprue. In one case the normal prothrombin content of the plasma was reduced more than 50 per cent. From these considerations, Vedder concluded that a deficiency state of lesser or greater extent is demonstrable in all cases of sprue depending upon the severity and duration of the case, and that an important part of the symptomatology is caused by deficiency in the B_2 complex. Deficient parathyroid and adrenal secretion have been suggested as the cause of the intestinal dysfunction in sprue.

Sprue.—Refer to page 722.

Riboflavin Deficiency

The lesions of riboflavin deficiency were described by Sebrell and Butler in 1938.[2] These lesions were a cheilosis, a stomatitis at the angle of the mouth, a seborrheic dermatitis, a glossitis, and changes in the vascular supply of the cornea. These lesions are also found in pellagra, in which there is an associated riboflavin deficiency. Laboratory diagnosis of riboflavin deficiency has not progressed to the point where any particular technic may be recommended. However, certain methods of assay have been published. The literature on the chemical methods may be summarized as follows: Chèvremont and Comhaire[2] report that lactoflavin was detected in fixed tissue sections by the red color it develops when partially reduced with Zn and HCl. Further reduction converted it to the leuko compound. The color was restored by mild oxidation with H_2O_2. The injection of the metabolism-accelerating compound cyclopentyldinitrophenol into guinea pigs increased the lactoflavin content of the liver cells. Shaw[3] described a method for the estimation of riboflavin in commercial liver extracts, based upon converting the substance to luminoflavin by exposing a solution in N/2 sodium hydroxide to unfiltered ultraviolet radiation, and comparison of fluorescence with standard luminoflavin preparations. It was also found that riboflavin is not stable to nitric acid as was previously thought.

[2] Sebrell, W. H., and Butler, R. E.: U. S. Pub. Health Rep. 53: 2282, 1938.

Sullivan and Norris[4] described a photometer which utilizes a zero-potential circuit in connection with a blocking-layer photocell. This instrument gives a linear response to varying light intensities and offers advantages in regard to proper use of the photocell, reproducibility of results, and application to certain spectrophotometric measurements. Riboflavin may be extracted from dried milk products by refluxing with a dilute solution of acid in 75 per cent acetone. Certain unstable colored impurities may be destroyed by including from 1 to 3 per cent of hydrogen peroxide in the solvent. The resulting solution, after neutralizing and filtering, may be used for quantitative measurements since riboflavin is not preferentially adsorbed by the precipitated milk solids. By reduction with sodium hyposulphite, 90 per cent of the color of riboflavin is removed. Observation of the light absorption before and after reduction enables one to calculate the concentration of the solution to ± 0.05 γ per c.c.

Niacin (Nicotinic Acid) Deficiency

Pellagra is the principal disease which is an expression of niacin deficiency.

Pellagra

This is another food deficiency disease with a possible infectious factor as well. It is a chronic disease with periodic exacerbations. The symptoms consist of mild neurasthenic manifestations in the winter followed in the spring by disturbances of the alimentary tract, consisting of stomatitis, burning sensations going up the esophagus, gastric eructations, and recurring diarrheas. In addition to the neurologic and alimentary tract symptoms, there are the third and most important group, those of the cutaneous system. On the skin is a pellagrous eruption, characterized by strikingly symmetrical, sharply delimited patches of erythema, resembling sunburn. The sites of preference are backs of hands, extending up the forearms, bridge of nose, or neck. The neurasthenia tends to pass into a toxic psychosis or even a confusional insanity.

[4] Sullivan, R. A., and Norris, L. C.: Indust. & Engin. Chem., Anal. Ed. **11**: 535-540, 1939.

The first description of this disease was by Casal who, in 1735, described the disease as it existed in the Asturias. It was described by other Spanish observers. Casal called the disease *mal de la rosa.* In 1907 pellagra was described in the United States and since then a number of cases have been found here. It has been reported from Italy, Balkan States, Greece, Turkey, Spain, and Portugal. There were about 100,000 cases in 1906. It is widespread in Lower Egypt, where the inhabitants live on millet instead of maize.

The work of Goldberger in respect to establishing the relativity of a deficiency of the pellagra preventive factor (P.P.) is now as generally accepted as is the relation of vitamin B to beriberi. In 1925 Goldberger and Tanner announced the existence of a hitherto unrecognized factor necessary in the diet to prevent or cure pellagra. This P.P. factor is associated with the antineuritic factor which has been synonymous with the term, ''vitamin B.'' Yeast is at present the richest known source of the P.P. factor, as it is of the antineuritic complex. Both are water soluble. Goldberger determined the presence of P.P. factor in certain foods studied by him and his associates by noting the activity of each in preventing pellagra among significant groups of pellagrins, and also by determining the effectiveness of each to prevent blacktongue in dogs. Blacktongue in dogs, according to Goldberger, is the analogue of pellagra in human beings. There are no constant or characteristic pathologic changes in pellagra. In the second stage the urine shows an indicanuria and the feces an abundance of skatol. Gastric juice shows anacidity and deficiency in pepsin. At autopsy we find marked emaciation, with marked degenerative changes in the corium with slight cellular infiltration. There is superficial atrophy in the epidermis with thickening in the stratum granulosum. The spleen shows atrophy. Liver and kidneys often show fatty change. In general, the changes are those of a senile character. These cases show a multiplicity of symptoms. There is a history of more or less prolonged neurasthenic manifestations during the preceding winter, dizziness, insomnia, apprehension, occipital heaviness, and fatigue. Sensitiveness of the mouth and slight epigastric discomfort are noted. With the eruption, there is more marked alimentary tract disorders consisting of stomatitis, gastric disturbances, with a recurring diarrhea. The eruption shows localized, sharply delimited, strikingly symmetrical skin lesions of those parts of the body which are chiefly exposed to the sun's rays. There is a diagnostic triad in a typical case as follows:

1. Symmetrical sharply delimited erythemas of certain portions of the skin exposed to the sun. 2. Alimentary tract disturbances of stomatitis, epigastric and substernal soreness and burning, with pyrosis and a recurring diarrhea. 3. Neurological manifestations in which a prodromal neurasthenia is followed by paraesthesias, in which severe buring sensations are prominent, with alterations of deep reflexes, tremors, and, in more advanced stages, a confusional insanity. Burning sensations are to be noted in the mouth, gullet, and stomach as well as in the skin. Palms of the hands and soles of the feet often give a burning sensation.

Vitamin C Deficiency

The chief example of vitamin C deficiency is the disease known as scurvy, showing anemia, loss in strength, changes in the gums, with swelling and hemorrhages throughout the body. While scurvy has been known for centuries, occurring among sailors, inmates of institutions suffering from poverty, exposure, and lack of proper diet, a clinical form had not been seen until recently when hypovitaminosis C or a latent form of scurvy was recognized by its vague symptoms, inadequate intake of this vitamin, and by laboratory methods.

Vitamin C is ascorbic acid or cevitamic acid.

Vitamin D Deficiency

Vitamin D deficiency is manifested by the symptom complex known as rickets. Vitamin D deficiency causes a disturbance in the metabolism of calcium and phosphorus.

Laboratory Tests.—The determination of phosphate concentration of blood, together with calcium concentration of blood, is a useful test in diagnosis of suspected vitamin D deficiency and rickets. The calcium findings may be normal or increased in children, but when reduced, there is a likelihood of the onset of tetany. There is decreased serum phosphate in rickets, while the serum phosphatase is increased. In normal children, Howland and Kramer* found values between 4.5 and 6.8 mg. per 100 c.c., averaging 5.4 mg., but in rachitic children, the values ranged between 0.6 and 3.2 mg. per 100 c.c., averaging 2.0 mg. The average was thus less than 50 per cent of the normal average value. Howland and Kramer further established an empirical rule regarding the relation between the serum calcium and phosphorus. They showed that if the product of the serum phosphorus and calcium fell below 30, rickets developed, whereas if the product remained above 40, the child escaped this disease.

So far as blood phosphatase is concerned, it is elevated in rickets and is thought to be increased before changes in the phosphorus and x-ray changes appear. Thus it may be of great value in early diagnosis. It remains elevated long after treatment is begun, apparently returning to normal only after healing is complete or nearly complete.

(See pages 447 ff. for method of determining serum inorganic phosphate.)

Vitamin E

This vitamin has been known as an antisterility vitamin. Effect of lack of vitamin E in female rats causes premature death of the fetus. It is barely possible that a corresponding condition in human beings is habitual abortion although this has by no means been proved.

Vitamin K Deficiency

The absence of vitamin K induces hemorrhagic disease of the newborn. Vitamin K affects blood clotting only by its effect on the prothrombin concentration. Hemorrhagic states related to vitamin K deficiency are hemorrhages accompanying obstructive jaundice, hemorrhages in connection with diseases of the gastrointestinal tract such as sprue, celiac disease, ulcerative enterocolitis, and icterus gravis.

---

*Howland, J., and Kramer, B.: Am. J. Dis. Child. 22: 105, 1921.

Laboratory tests for vitamin K are concerned with the prothrombin time of blood plasma. (See facts on prothrombin test and liver function, pages 688 ff., 895 ff., 903, 958.)

CHAPTER X

BACTERIOLOGIC APPLICATIONS TO CLINICAL DIAGNOSIS

THIS CHAPTER HAS BEEN REVISED BY OSCAR FELSENFELD, M.D., M.S., PROFESSORIAL LECTURER, UNIVERSITY OF ILLINOIS COLLEGE OF MEDICINE*

GENERAL CONSIDERATIONS

This chapter includes the discussion of means and methods used in medical and sanitary bacteriology for the isolation and identification of disease-causing agents. When work along these lines is carried out, one must realize that bacteriologic technics applied to medical laboratories are regulated by the same rules as in any other field. With the exception of a very few procedures, for example, plating of stools, scrupulous adherence to the rules of sterility is imperative. One cannot produce good results in nonsterile dishes, contaminated plates, and carelessly plugged tubes. Adequate initial plating of the sample is of paramount importance. Only well-isolated colonies may serve for further study, and contamination must be avoided during the attempts to determine the species which produced the colony. It is surprising how these basic rules are often neglected in some medical laboratories. The Reviser of this chapter saw hundreds of plates streaked with three thick strokes of a loop and so thoroughly overgrown that not even repeated restreaks could assure the isolation of the organisms. He was faced with innumerable airborne molds grown on Sabouraud plates into which every technician in the laboratory breathed, every nurse delivering samples coughed, and every maid swept the dust of the floor. He also received, from otherwise excellent laboratories, tubes labeled ''pure cultures'' from each of which he was able to isolate four or five different organisms. One may suspect that the mistrust of some physicians toward certain laboratories regarding bacteriologic reports is based upon the insufficient attention devoted to such examinations.

This chapter, therefore, has been completely rewritten, in order to present up-to-date technics, and to underline those features which are not always matters of common knowledge. On the other hand, limited facilities result in limited reporting. This does not mean, however, that a small laboratory shall declare each gram-negative diplococcus a *Neisseria gonorrhoeae* or disregard every Salmonella because the typing of the latter can be carried out only in large establishments. Most State, Municipal, and Federal Public Health Laboratories will be glad to render advice or practical aid in difficulties encountered during bacteriologic work. Such aid must be freely called upon when working with limited means on stools, anaerobic organisms, tularemic material, viral and rickettsial diseases, atypical cocci, molds and yeasts, etc. Every laboratory worker must set before himself a goal of optimal achievements under the particular circumstances of his laboratory, and send all other cultures and materials to better equipped institutions.

---

*At present, Lieutenant Colonel, MC, USAR.

As to the general methods used in bacteriologic work, diagnosis is made by culturing; in some instances and with certain probabilities, by microscopic examination. The general procedure is to examine material taken under sterile conditions, except for stools, throat smears, cough plates, vaginal smears. First a microscopic examination is performed, using careful sterile technic, care being taken not to contaminate the material for further examination; then plates are inoculated. During the subsequent procedure suspicious colonies are "fished" into so-called differentiating media and studied for certain reactions and microscopic structure. In some cases enrichment fluids are used to increase the number of viable organisms, or concentration methods are applied. The final diagnosis is secured by serologic tests, which, unfortunately, are not used enough in many medical laboratories. Animal inoculations are infrequently carried out, because of the great efficiency of in vitro methods. Preliminary and final reports are issued in due time.

Of primary importance, as stated above, is the creation of sterile conditions, in order to avoid contamination. Media satisfactory as to composition, pH, and moisture are also of great importance. Microorganisms, perhaps with the exception only of *Pasteurella tularensis,* definitely refuse to grow on very dry surfaces. When, in addition to the above requirements, a good streak is used, proper transfers are made, and legible slides are produced, reliable reports will result.

Considerable difficulty arises from the unfortuante conception shared by some medical workers that everything isolated from a patient is necessarily pathogenic. The intestines, the vagina, the respiratory system, and all mucosae which have contact with the outside world are full of nonpathogenic microorganisms. Not even hemolysis is an indicator of pathogenicity. Many members of the *Bacillus subtilis* group, several coliforms, etc., will produce wide areas of hemolysis, without always being of importance. In other cases too much faith is placed upon microscopic examination. Not every Streptococcus, not every granulated rod, and not every sporeformer is a cause of disease.

When these basic rules are kept in mind, bacteriologic technic becomes a better means of laboratory diagnosis.

Preparation of Glassware for a Bacteriologic Laboratory

General Rules

All glassware must be cleaned and sterilized before use.

Rinse thoroughly in tap water.

Immerse in a 1:1000 nitric acid solution for one hour.

Rinse thoroughly in tap water to remove the acid.

Rinse in distilled water.

Plug test tubes, cylinders, flasks, etc., with nonabsorbent cotton.

Nonabsorbent cotton is used exclusively for making plugs.

Sterilize in the dry heat sterilizer at 170° C. for two hours.

Petri dishes should be wrapped in paper or put in metal cans before sterilization.

All syringes and needles must be wrapped in paper and sterilized in the dry heat sterilizer at 170° C. for 2 hours.

Slipknots must be made instead of double knots so that packages may be opened easily.

The contents of all packages must be marked, together with date of sterilization, before placing them in the oven.

Syringes and needles can be sterilized in cotton-plugged test tubes.

Pipettes and droppers should have a loose plug of nonabsorbent cotton, and should be wrapped in paper before sterilization. Place an X mark at the mouth end after wrapping. The use of metal cans is also recommended.

Pipettes kept in cans may be wrapped individually in paper, so that they do not become contaminated when the container is opened. If pipettes are kept unwrapped in the cans, the cans should be resterilized by dry heat after each opening. If care is exerted, however, when individual pipettes are taken out, it is satisfactory to resterilize the opened cans only once a day.

Some glass wool should be placed in the bottom of the pipette cans to prevent breakage of the pipette tips.

Slides and cover glasses should be washed in the manner described above, then immersed in a mixture of equal parts of ether and alcohol, then dried with an old linen cloth. The cloth must be free of lint. Or use the method described on page 612.

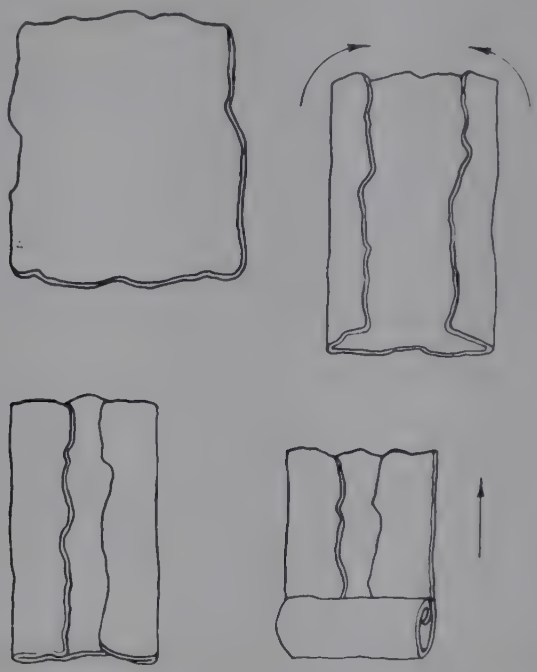

Fig. 323.—Rolling cotton plugs. (Courtesy Dr. Oscar Felsenfeld.)

Sterilizing Tubes and Flasks

Ordinarily test tubes, flasks, etc., in bacteriologic procedures are closed by inserting stoppers made of nonabsorbent cotton plugs. The method of plugging test tubes is to pull off a small piece of cotton, place it over the open end of the tube and thrust it in place by means of a glass rod, pencil, or forceps, so that the edges of the cotton will fit smoothly.

Such plugging can be used only for media stored in a refrigerator and utilized quickly, because it is an insufficient protection against evaporation. In all other cases rolled plugs must be made. An approximately quadrangular piece of nonabsorbent cotton is separated from the roll. Two sides of this piece are folded inward, to about one-fourth of its width. Then the cotton is firmly rolled along the longitudinal axis and the plug inserted by gentle rotation. See Fig. 323.

The inner end of cotton plugs for flasks is protected with one or two layers of gauze or cheese-cloth. A quadrangular piece of the gauze is cut. The inner end of the cotton plug is put in its middle, then the corners lifted and the whole inserted into the flask in such a way that the neck of the flask is not in contact with cotton.

Covering the plug and the neck of bottles with paper and fastening this cover with a string around the neck is helpful.

Some laboratories use rubber fingers to cover the plugs and the necks of flasks.

Paraffin renders excellent results. It is applied to tubes with live cultures to seal the plugs.

A closure has been devised which has been found quite serviceable. It is called the "Quicap" closure and it is especially designed for flasks. (See Fig. 324.) It consists of a moisture-proof sheet of DuPont cellophane which covers the opening of the flask and, when held in place by means of a Quicap collar, forms a tight, hygienic seal. These closures will withstand fifteen pounds of pressure for thirty minutes. To use these caps pick up the cellophane cover from the dispenser and place, with a Quicap collar, on top of the flask opening. Tilt downward and over the flask head. A slight upward pressure on the collar assures a snug fit.*

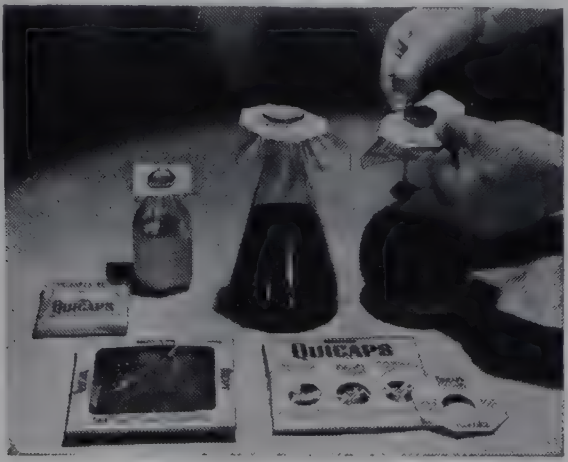

Fig. 324.—Quicap closures for flasks, etc. (Courtesy Quicap Co., Inc., Brooklyn, N. Y.)

Good protection against evaporation is afforded by screw-capped tubes. Snieszko** recommended their use. When media are sterilized in such bottles, the caps are screwed on partially to allow some air to escape. Caps are tightened immediately after the media are taken out of the sterilizer.

A very ingenious method of plugging culture tubes with nonabsorbent cotton is carried out by the use of Coiler cotton.† This is nonabsorbent cotton furnished in long strands. All that is necessary is to pull off a small plug and insert it in the test tube. It fits snugly into the usual test tubes for preparing culture media. (Fig. 325.)

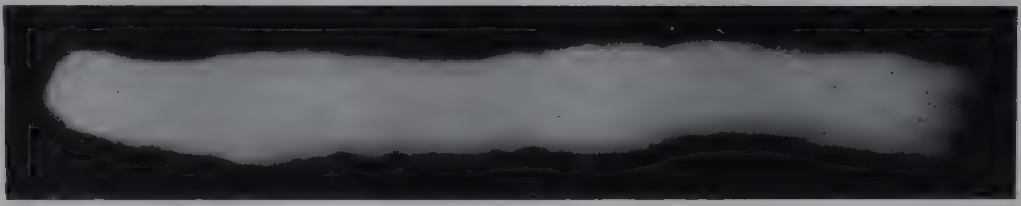

Fig. 325.—"Coiler" nonabsorbent cotton for plugging culture tubes. (H. J. Niehaus and Son, Kirkwood, Mo.)

Empty, plugged test tubes and flasks are sterilized by dry heat at 170° C. for 2 hours. Let the temperature of the oven fall to 100° C. before taking out the glassware, to prevent cracking of nonresistant glass, and to keep from burning the hands.

Sterilizing Glass Syringes

The life of a good, all-glass hypodermic syringe, sterilized under proper conditions, is from 50 to 200 hours boiling, depending upon the quality of glass, fineness of grinding, and fit of the plunger.

B-D Yale and Luer syringes can be repeatedly sterilized by boiling, autoclaving, dry heat, or by suitable chemical agents. If syringes are contaminated with spore-bearing organisms, boiling does not suffice.

Ordinary tap water, not containing an excess of alkali, has been found the best medium for sterilizing syringes by boiling.

---

*This equipment is made by Quicap Company, Inc., 233 Broadway, New York.

Science **100: 435, 1944.

†This can be procured from H. J. Niehaus and Son, Agents, P.O. Box 3817, Kirkwood, Mo.

B-D Yale and Luer syringes may be safely placed directly into the hot water; this saves time and hastens sterilization, and without separating barrel and plunger. The syringes, however, must be clean and the plunger pushed all the way down before placing in the sterilizer.

The separation and reassembly of parts has been the cause of much breakage and loss of time.

Should it be necessary to use water which has an excess of alkali, either sterilize the barrel and plunger together, or swab out with warm water, then with alcohol, and dip the end of the plunger in mineral oil and thoroughly lubricate the ground glass surfaces. The oil protects the syringe to some extent against erosion.

Precautions.—Do not boil in water to which bicarbonate of soda or sterilizing tablets containing this chemical have been added as it, in common with all alkalies, attacks glass.

Physicians who regard distilled water as the ideal medium in which to boil their syringes are reminded that distillation removes the silicate for which water has an affinity. When boiling glass in distilled water, a certain amount of silicate in the glass is taken up by the water and a slow process of deterioration takes place.

The routine procedure for bacteriologic use should be dry heat sterilization, at 170° C. for 2 hours, of paper-wrapped syringes, or syringes kept in test tubes.

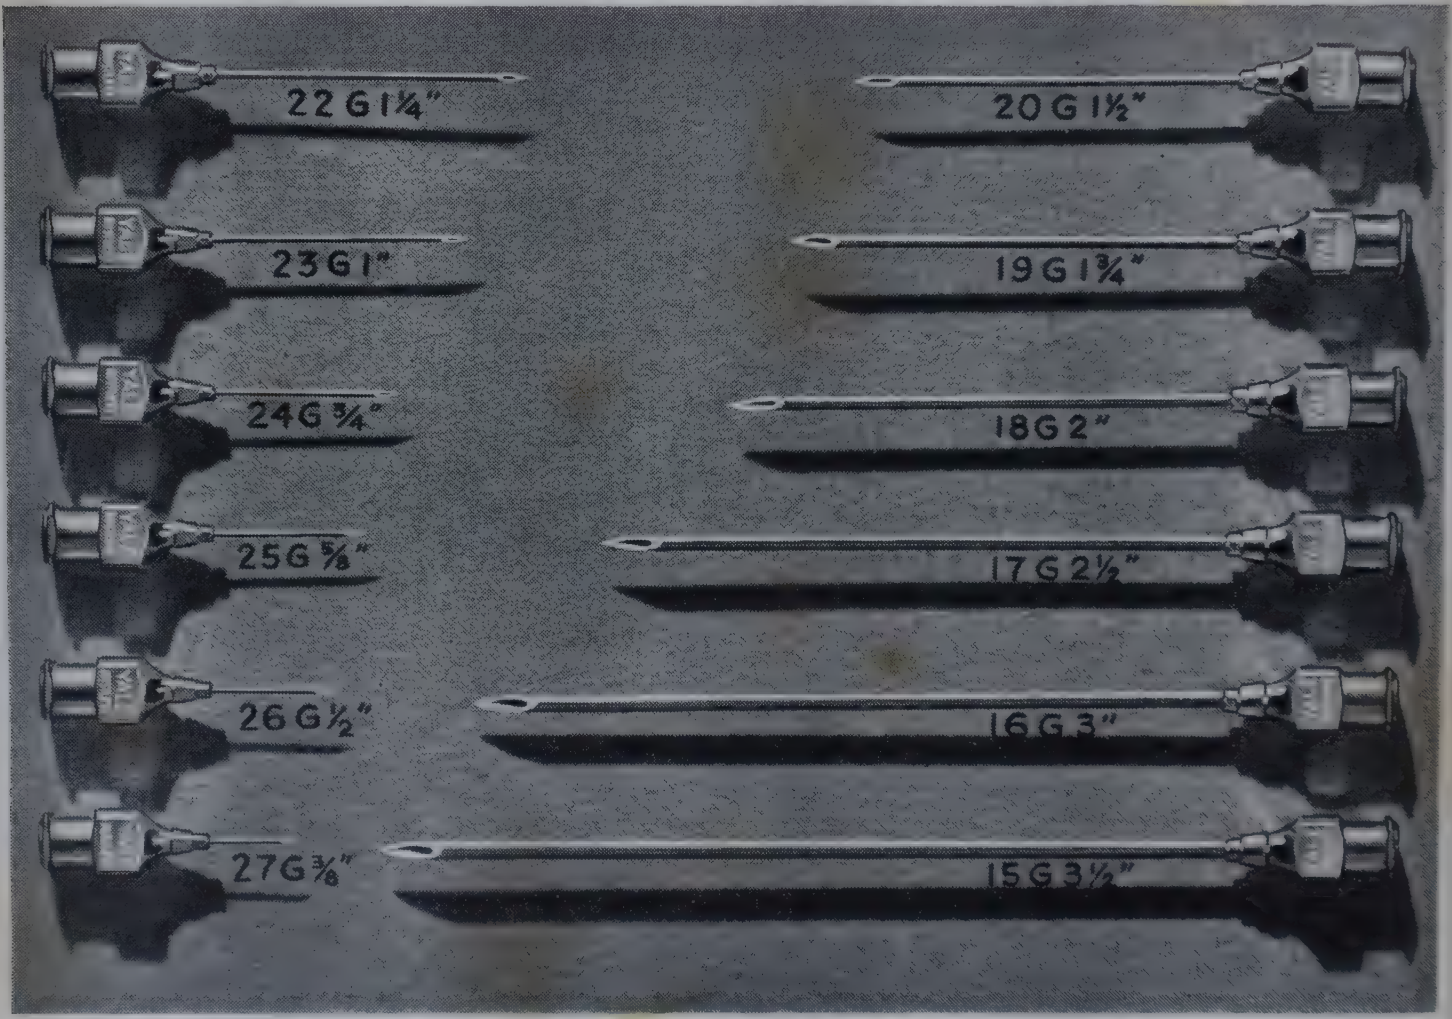

Fig. 326.—Actual size needles showing length and gauge. (Courtesy Becton-Dickinson & Co.)

Sterilizing, Cleaning, and Care of Needles

After use, all needles should be immediately washed and then rinsed with alcohol or ether. This is readily done by attaching the needle to a syringe and drawing alcohol or ether through the needle several times.

Thoroughly dry the bore of the needle with compressed air or by the use of the Brunet-Flagge Needle Drier.

Before putting away carbon steel needles (such as the Yale), dip the needle wire or stylet in oil or liquid petrolatum and insert. This prevents rust and corrosion and greatly increases the life of the needle. Erusto and Medical Center needles should not be oiled.

The points should now be carefully inspected and if blunt or scratchy, sharpened on a fine oilstone.

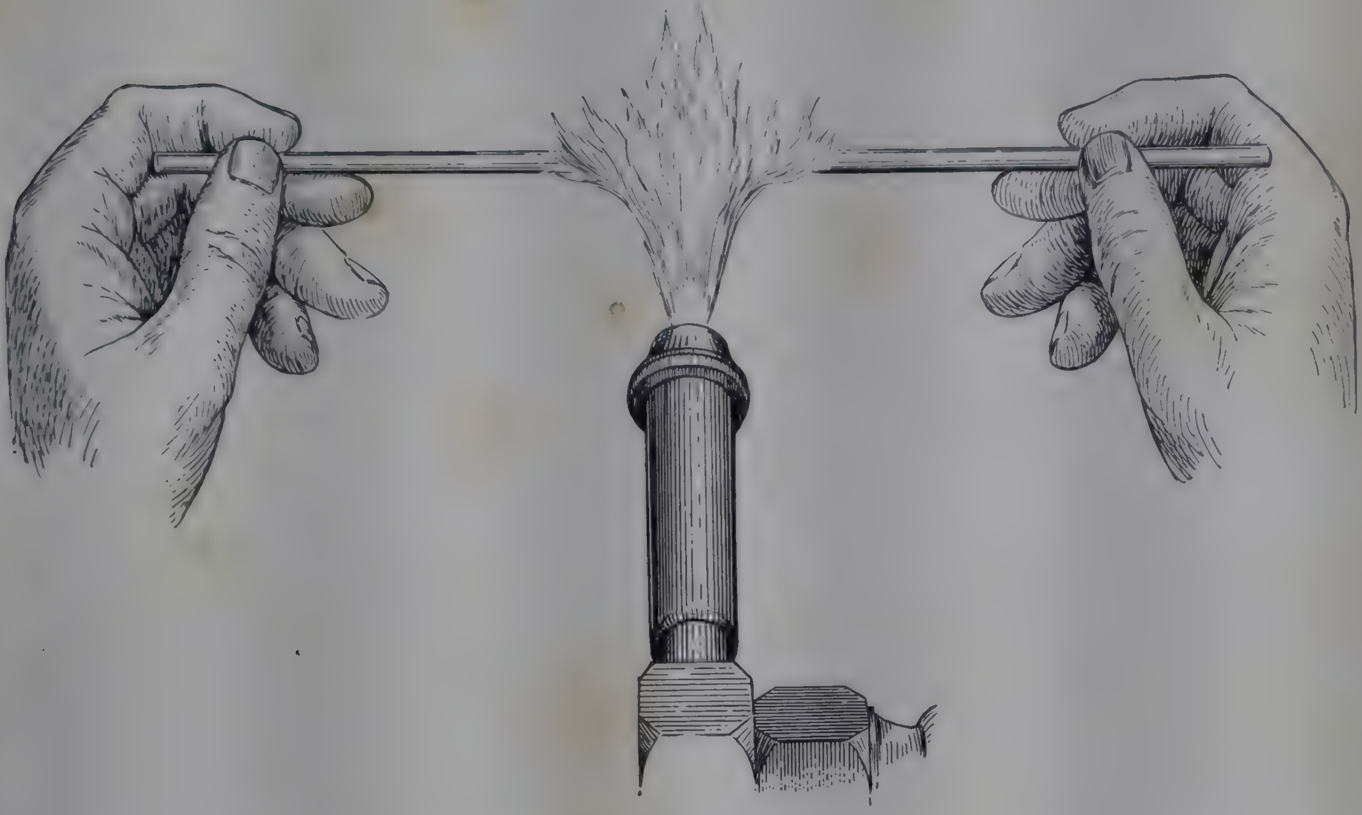

Fig. 327.—Heating glass tubing before drawing a capillary.

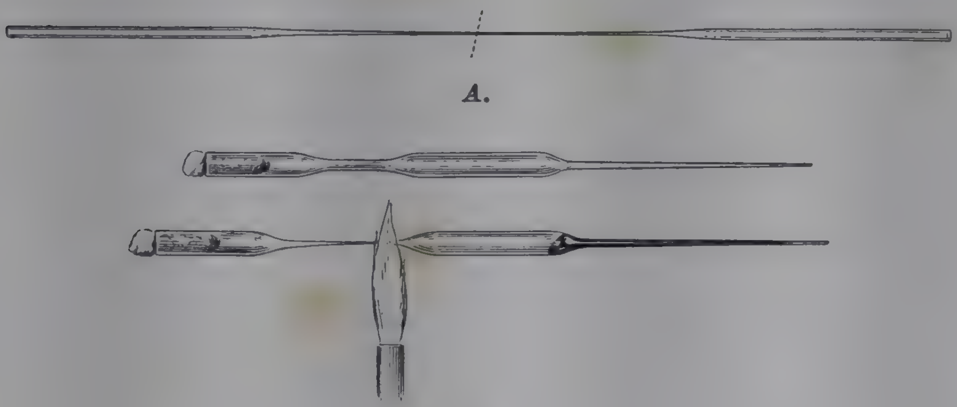

Fig. 328.—*A*, Cutting the capillary. *B*, Sealing the capillaries.

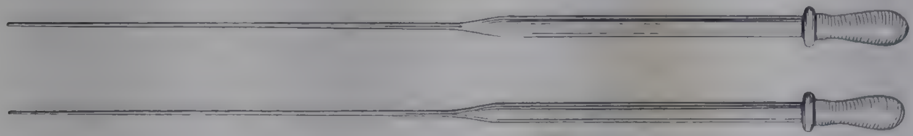

Fig. 329.—Completed capillaries.

The stylet should be kept in the needles. To insure protection of the point of the needle, it is well before sterilization to thrust a small piece of cork into the end of the needle.

Needles are governed by the law of deterioration as other material is. Repeated heating and use tend to weaken them. The newer the needle, the less danger of breakage. Test the temper of the large needle by bending it back and forth; short needles are best tested by pressing against the thumb.

The routine method of sterilization of needles is by dry heat for 2 hours at 170° C. The needles are placed in small test tubes, tightly stoppered, or they may be wrapped in paper which is thoroughly sealed. Objections to boiling are that sometimes infection has occurred from contamination of needles by spore-bearing organisms which are not killed by boiling.

Preparing Sterile Capillary Tubes

It is always well to have on hand in the laboratory pieces of glass tubing about 18 inches long, of 7 mm. caliber. These are prepared as follows: Cut a number of these tubes into 18 inch lengths. Stopper them at each end with a piece of cotton. Wrap them in separate bundles in paper and sterilize in the dry heat oven at 170° C. for two hours.

When a sterile capillary tube is required, open the package, remove one tube, heat it over a Bunsen burner (Fig. 327), and draw it out to the desired length and thickness. By turning the tube in the flame, a uniform degree of heat is obtained. When at least three inches are well heated, under rotation, the tube is taken out of the flame and rapidly pulled in a straight manner. It is then cut. These tubes can be made then into capillaries for drawing up blood or they can be used as sterile droppers.

Sterilizing in the Autoclave

One must learn to operate his own autoclave from operating directions and experience. Certain general rules, however, are of value. We shall describe the method of sterilizing in one type of steam pressure sterilizer:

The pop valves (safety valves at the top of the steam chamber) must be open at the beginning of sterilization. Fill the water tank below the sterilizer with water until the gauge is about two-thirds full. Be sure the water is turned off so that there is not a slow leak of water into the tank. Never fill the gauge completely. If the gauge is filled by mistake, the water can be drained from below the tank. Close all the valves on the sterilizer; that is, the chamber valve, the vacuum valve, and the valve on the door of the autoclave. Light the gas. Allow the pop valves to remain open until a good volume of steam comes from both of them. The steam should come in a steady stream, not in spurts. If it comes in spurts, there is air mixed with it. Now close the pop valves.

Allow the steam pressure to rise to 18 to 20 pounds in the jacket. If it goes above this, the safety valves will pop. When the pressure is 18 to 20 pounds in the jacket, open both the chamber and the vacuum valves simultaneously, using both hands. Allow a vacuum of 10 inches to register on the gauge above the autoclave, then immediately close the vacuum valve. Allow the pressure to rise in the steam chamber to 20 pounds. Both the chamber and jacket gauges should register the same pressure. Turn the gas low so as to maintain just 20 pounds pressure, and allow sterilization to proceed for thirty minutes. High pressure alone does not insure sterilization. The temperature must reach a proper degree. Good autoclaves are, therefore, equipped with thermometers. At 15 pounds pressure, e.g., the temperature should be 120° C.

Turn off the gas and allow the pressure to drop of its own accord to *O*. Never open any valves until there is no pressure in the autoclave.

Now open the door of the autoclave, and also open the pop valves. Always open the door while the sterilizer is still hot, but be careful not to be burned by the steam. Always leave all valves closed when through sterilizing.

After sterilization, drain the water out of the tank and refill two-thirds full of fresh water.

Place **tubes** in wire baskets to autoclave. When contaminated materials (used media) are sterilized, place the tubes and plates in deep trays or in buckets, so that the melted agar does not clog the pipelines.

Used tubes may be autoclaved in buckets, into which they are put upside down after removal of the plugs. The plugs should be destroyed by burning.

Protect the plugs of **bottles** by caps of wrapping paper which are fastened around the neck of the bottles with string. Cork and rubber plugs should not be used for glassware sterilized in the autoclave. Tubes which are to be closed with rubber stoppers must be sterilized with cotton in the autoclave. Sterilize the rubber stoppers separately in large test tubes, and exchange them for the cotton plugs under sterile precautions after autoclaving.

After emptying the autoclave, leave the sterile, unused tubes to solidify in the desired position. Immediately pour out the used media into proper containers (waste pails).

Petri dishes are best sterilized in buckets. The plates are opened, and the halves put into the bucket separately, upside down, so that the contents are liquefied by the heat and will flow to the bottom of the bucket. After autoclaving, the buckets are allowed to cool. The contents will solidify and can be easily removed.

Disposable plastic Petri dishes are available. These are sterilized by the manufacturer and do not have to be autoclaved if used only once.

Different **media** require differing pressures for various lengths of time. It is essential not to oversterilize, because the media suffer by prolonged or too intensive heating. The length of time necessary for sterilization also varies with the amount of media in the flasks. It is essential that baskets not be packed too tightly with tubes.

It is important, if **media containing fermentable substances** (commonly referred to as "sugars" or "carbohydrates") are to be sterilized before use, that the autoclave not be exhausted, but that the steam pressure be allowed to drop slowly. The best method is to shut off the steam immediately after sterilization and allow the autoclave to cool. The media are taken out when the temperature has dropped to 30° C. or lower, and the steam pressure in the chamber is equal to that outside.

Flowing steam is produced by leaving the door of the autoclave open. Careful watching of the thermometer is necessary to be certain that the inside of the autoclave reaches the proper temperature. The temperature may vary in different parts of the inner chamber, depending upon the location of the steam inlets.

Inspissation is the coagulation of media containing proteins (mostly serum or eggs). In order to obtain a smooth surface of the tubed media, great care must be exerted. Some laboratories use special inspissators, others perform this task in the autoclave. In the latter case, slant the tubes on a tray or rack and cover with newspaper. Then close the exhaust and the air outlet valve. Lock the door and let steam in slowly, to 15 pounds pressure. After 10 minutes slightly open the air outlet so that the pressure remains constant between 14.75 to 15.25 pounds. Sterilize for 20 minutes more, then shut off the steam and let the autoclave cool before opening the door.

Alli* suggested the following method: Fill a baking pan with fine sand to about 1 inch height. Cover the sand with a cloth and slant the tubes on the cloth. Place another cloth over the tubes and cover the first row with sand. Place more rows in the same manner. Open the steam valve and the air outlet until air is expelled. Slowly tighten the air valve until the pressure reaches 10 to 12 pounds, then close it. Maintain 15 to 17 pounds pressure for 30 minutes.

Sterilizing in the Dry Heat Oven

Never pack any sterilizer too tightly with material. Be sure the door is tightly closed before sterilization. Light the gas, keep the air outlet at the top of the oven open until the temperature registers 100° C., then close the outlet. Permit the temperature to rise to 170° C., and keep it at this point for two hours. After turning off the gas, be sure not to open the door until the contents have cooled to almost room temperature. Always time the sterilizer after the temperature reaches 170° C.

Pipettes and Petri dishes are best sterilized in appropriate metal boxes.

Recent investigations have been made concerning temperature levels in hot air ovens. These indications by Darmady and Brock[1] were made to assess, first, whether the heat actually penetrates to syringes to be sterilized in these hot air ovens; second, whether type of packing employed was satisfactory; and, third, at what position in the oven should the thermocouple of an automatic recording apparatus be placed. Usually to test an oven with thermocouples they are placed in glass tubes while the oven is empty. The efficiency of the oven is gauged by the degree of correlation of the temperature levels recorded throughout the oven. In England it is the custom to use a temperature of 160° C. for one hour as advocated by the Medical Research Council* on the sterilization of syringes. While Gradwohl advises 170° C. for two hours in a gas oven as being satisfactory, more recently Gerhards, using a fan oven, has shown that spores can be satisfactorily destroyed at 140° C. for one hour.

---

*Mil. Surg. 95: 235, 1944.

[1] Darmady, E. M., and Brock, R. B.: J. Clin. Path. 7: 290, 1954.

In the present investigation, two gas ovens which were used showed wide variations of temperature. Generally, the temperatures were considerably lower in the bottom shelf than in the top. Syringes tested near the back wall were consistently overheated. Tightly packed syringes did not reach the top degree and as much as 60° C. differences were noted. At the end of one hour, syringes on the lower shelf, except those placed in the back, had not reached 160° C. Even after one hour there was a variation of 40° C.

With the exception of fan ovens, the majority of ovens do not meet all the criteria necessary for perfect sterilization. Of course tight packing is to be avoided, and there must be a free flow of air all around articles to be sterilized; metal boxes or similar sealed containers may prevent the heat's penetrating to those syringes near the center. Overloading ovens seriously interferes with the heat distribution.

These investigators found that with an electric oven without a fan the over-all variation of temperature was not as great as with a gas oven. These two investigators claim that gas ovens showed such wide variations of temperature that these instruments were unsatisfactory for syringe service.

Experiments with four electric ovens without fans showed the main heat is taken up slowly and that, even though close correlations of temperature are obtained when the oven is empty, wide variations of temperature may occur. Loading ovens while still hot does not interfere with the transfer of heat to the articles to be treated. In fact, in the majority of instances it is to be preferred, but tight packing of syringes and needles is condemned as unreliable.

Method of Using the Arnold Steam Sterilizer

Place the material to be heated in the Arnold steam sterilizer, and close both doors.

There should be a thermometer in the top of the sterilizer.

Fill the basin under the sterilizer with water.

Light the gas burner under the sterilizer, and maintain a constant temperature of 100° C. by keeping the burner wide open.

The steam will rise from the boiling water in the basin into the sterilizer.

Do not begin timing the sterilizer until the temperature reaches 100° C.

After sterilization, allow the temperature to drop to the temperature of the room before opening the doors of the sterilizer.

Sterilizing by Filtration, and Care of the Filters

The filter candle, placed in its mantle, is inserted through the hole of the rubber stopper which is to be used in the filtering flask. Care is taken that the candle is screwed tightly in the stopper, and that the rubber plug which is part of the apparatus fits tightly, so that there is no air leak.

Place the filter candle and mantle assembled in the rubber stopper into the filtering flask, taking care that the rubber stopper fits the flask. Plug the arm of the flask with nonabsorbent cotton, and attach a piece of rubber tubing. Sterilize in the autoclave at 15 pounds pressure for thirty minutes.

When cool, pour the material to be filtered into the mantle.

Attach to the rubber tubing of the filter a piece of glass tubing having a stopcock in the center of the tube.

---

*Memorandum No. 15, 1945.

Attach to the suction pump.

Open the glass stopcock.

Start the suction, slowly at first, increasing gradually.

After filtration begins, alternately open and close the stopcock until the pressure is regulated in such way as to prevent foaming of the filtrate. When the pressure seems to be great enough for filtration to continue at a moderate rate, close the stopcock, and allow filtration to continue until the rate becomes considerably slower, then open the stopcock. After filtration, sterilize the Berkefeld filter as follows:

Autoclave at 15 pounds pressure for 30 minutes, then boil the filtering candle and mantle in a beaker or casserole before the fluid in the candle has been allowed to dry.

After boiling, remove with a pair of forceps, and dry in the incubator at 37° C.

After the candle has been dried, it is ready to be assembled, sterilized, and used for further filtration.

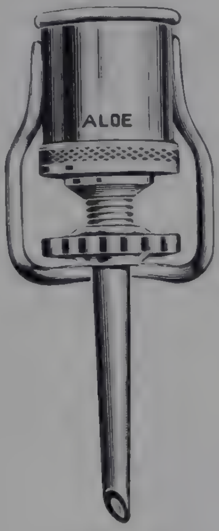

Fig. 330.

Fig. 331.

Fig. 330.—Seitz filter. (Courtesy A. S. Aloe Co., St. Louis, Mo.)
Fig. 331.—Berkefeld filter candle. (Courtesy A. S. Aloe Co., St. Louis, Mo.)

Filtration Through Seitz Filters

The Seitz filter makes use of asbestos pads instead of diatomaceous earth or unglazed porcelain for removal of bacteria from liquids during the filtration process. The asbestos filters are disk-shaped and vary in size and in grades of porosity. For bacterial work specify the E. K. grade of porosity when ordering the disks.

To use the Seitz filter assemble the apparatus by fitting the asbestos disk into the special metal container. Below the asbestos disk there should be placed a metal screen which comes with the apparatus. The screen and the disks are placed in the metal container and then tightened by means of set screws. The metal container with the asbestos in place is now covered with tinfoil then fitted tightly into the opening of a one hole rubber stopper which is placed in a Pyrex filtering flask. The arm of the filtering flask is plugged with nonabsorbent cotton and the whole apparatus is sterilized in the autoclave at 15 pounds pressure for 30 minutes. The apparatus as assembled is now attached to a vacuum pump in the same manner as the Berkefeld filter.

When filtration begins if there is foaming around the asbestos disk simply tighten the screws which hold it in the metal shield.

After use the disks are either burned or autoclaved and then discarded.

To Dispose of Contaminated Material

The best way to dispose of stools, sputa, etc., which are contained in paper or cardboard receptacles, and of contaminated wooden spatulas, swabs, etc., is to use an incinerator.

Place all other contaminated material in the autoclave preferably in deep trays or pails, to avoid overflow.

Sterilize at 15 to 20 pounds pressure for thirty to forty-five minutes (see pages 1394, 1395).

After sterilization has been completed, wash all glassware thoroughly with soap and water. If the glassware remains dirty, boil in a solution of Oakite,* one teaspoonful to a quart of water, and do not permit the water to dry on the glassware. Durlacque cleaner, which may be obtained at most grocery stores, is excellent for cleaning glassware. Any good detergent may be used.

Rinse thoroughly in tap water until all traces of the cleaning agent have been removed. It is very important to remove all the soap solution before sterilizing, or the glassware will become coated over with a white precipitate which is impossible to remove.

Immerse in a 1:1,000 nitric acid solution for several hours.

Rinse thoroughly in tap water to remove all traces of the acid.

Rinse in distilled water.

Wrap in the usual manner.

Sterilize in the dry heat oven at 170° C. for two hours.

Alternate Method.—Sterilize material as above. Pour out the hot contents into a waste pail. Discard plugs into incinerator pail. Place dishes and tubes in Charlab solution for 18 to 24 hours. Rinse with tap water, then proceed as above.

Care of the Incubator

To Regulate the Temperature at 37° C.

Attach incubator to the electric light socket, and turn the switch on. Allow the incubator to heat for twenty-four hours.

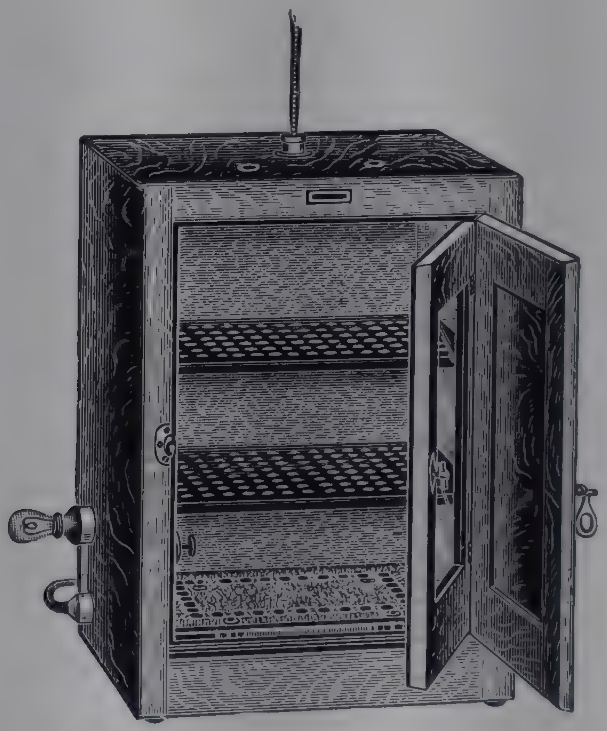

Fig. 332.—Electrically controlled incubator. (Courtesy E. H. Sargent & Co.)

If the temperature rises higher than 37° C., turn the thermostat wheel in the direction shown by the arrow next to the word "cold" until the light connected to the thermostat goes out.

Allow the door to remain closed until the light automatically turns on again, then read the thermometer. If the temperature at which the light turns on is higher than 37° C., turn the wheel again in the same direction, a slight turn, and proceed in this manner until the incubator maintains a temperature of 37° C.

If the temperature drops below 37° C., turn the wheel in the opposite direction.

Be careful to turn the thermostat wheel very slightly.

While the thermostat light is on, the incubator is heating.

When the light is off, the incubator is cooling. By watching this light, and the corresponding temperature changes, the incubator may be regulated fairly easily.

---

*Oakite Products, Inc., 826 Clark Ave., St. Louis Mo.

Keep the incubator in the laboratory in a place where it will not be agitated.

Be sure to keep a container of fresh, clean water in the incubator at all times to prevent the air from becoming dry. The size of the water container and the amount of water needed depend on the size of the incubator.

STAINING PROCEDURES[1]

General Principles

All bacterial dyes are aniline or coal-tar dyes, synthetic products. They are called either "acid" or "basic" dyes. This does not mean that the dye itself is necessarily either a free acid or a free alkali, but that they are salts of these free color acids or bases. Acid dyes owe their colored properties to the anion. basic dyes, to the cation. The actual reaction of a dye in solution depends on the relative proportions of the dye ion and cation or anion with which it is combined in the dye salt.

Basic dyes have a greater affinity for nuclei, while acid dyes have an affinity for cytoplasm. Since nuclear material of bacterial cells seems to be distributed throughout their bodies, basic dyes are usually used to stain them.

Preparation of Smears

Smears from pure cultures of bacteria are usually prepared by making an aqueous suspension of the organisms, drying a drop of this on a slide or cover glass, and fixing by gentle heat. Because of their extremely tiny size and their stiff walls, bacteria do not undergo the shrinkage and distortion such a method of fixation would cause were higher forms of life used. A small amount of the material is removed and suspended in a drop of distilled water on a slide, taking care not to make too thick a preparation. It should be of a faint turbidity, and solid masses of bacteria should be avoided. A drop of a broth culture is sometimes used to make smears, but solids from the culture material may interfere with the stain, and for this reason this method is not always satisfactory. If a smear shows no areas where the bacteria are separated from each other, more water should be added to dilute the smear.

Several smears may be made on the same slide. A slide with frosted edges is used. It is divided into the necessary number of fields by lines drawn with a wax pencil. A corresponding number of lines is drawn with a graphite pencil on the frosted part of the slide. The code numbers of the smears made on the slide are written on the frosted surface with the same pencil. Eight to twelve smears may be stained on the same slide.

Several methods of fixing are in use. Preferred method is to dry the smear, then pass it rapidly through a Bunsen flame two or three times; or to allow the smear to dry on a flat, moderately hot plate of nonrusting metal on a boiling water bath. Overheating (burning) may be prevented by careful checking of the temperature of the slide, by just touching the back of the slide to the back of the hand each time the slide has been passed through the flame. Staining without fixation after air-drying is not recommended. Special staining methods may call for special fixing methods, in which case the method will be given.

---

[1] Condensed from "Pure Culture Study of Bacteria" published by the Commission on Standardization of Biological Stains, May, 1944.

New slides must be used for acid-fast and flagella stains. It is essential that, after staining, the back surfaces of the slides be wiped clean with a piece of cloth or a paper towel.

Staining Formulas

Most of the staining technics given below are intended for use in study of pure cultures; various common staining formulas used in routine laboratory diagnosis of disease are also given. The literature contains many inaccuracies in staining methods. Few can be accepted in the light of present knowledge without some degree of interpretation to make them more explicit. In some cases the author's intentions are evident, while in others they must be inferred. Blind adherence to a staining technic is no guarantee for satisfactory results. *Always check a technic on known organisms for controls,* checking the solutions and water to make sure they are free from bacteria and spores.

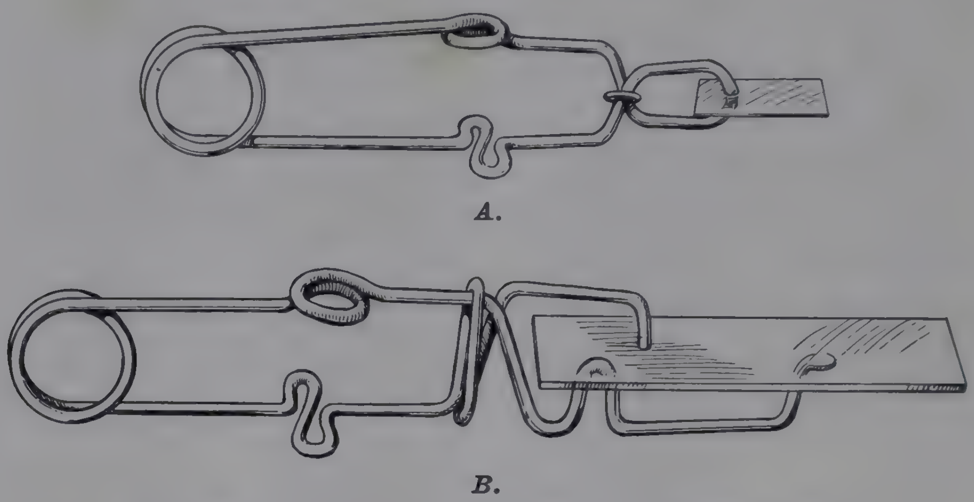

Fig. 333.—*A,* Cover glass holder. *B,* Slide holder.

STAINING TECHNIC*

Preparation and Fixation of Bacteriologic Smears

Slides should be fat-free, and free from lint or any other foreign substance.

Place a loopful of distilled water in the center of the slide.

Flame the platinum wire.

Remove the plug from the culture tube, or lift the cover of the Petri dish, or other container, flame the mouth of the container, hold the stopper between the third and fourth fingers.

With the cooled loop (which has been cooled inside of the tube or other container) pick up a portion of the material to be smeared.

Replace the stopper, flaming it, and flaming the mouth of the container.

Holding the slide in one hand, gently emulsify the material on the platinum loop in the water or saline on the slide.

Flame the loop.

The material on the slide should dry immediately.

Fix the smear by passing it three times through the flame, holding it in the upper portion of the flame a second at a time.

Allow to cool before staining.

If fixation by alcohol instead of dry heat is desired, the slide is placed in a Koplin jar of methyl alcohol for five minutes, or in ethyl alcohol for twenty minutes. Other fixatives, such as bichloride of mercury and acetic acid, may be used, the time varying according to the fixative.

---

*Some staining methods not included in this section may be found throughout the text. Consult the index for other stains.

Used slides are placed in Lysol or some other disinfectant solution. Boil them in tap water for one to two hours, then clean in the same manner as slides for hematologic work. See page 612. When possible, do not use a slide more than once.

Stains, Staining Solutions, and Staining Technic

Points to Be Considered in Making Staining Solutions

1. Stains used should preferably be those bearing the certification label of the Biological Stain Commission. This Commission does not manufacture nor sell stains, but tests and certifies those sent to it voluntarily by various manufacturers. This Commission was formed through the efforts of many investigators; its executive committee consists of representatives of a number of scientific societies.

2. All dyes should be weighed accurately on an analytical balance.
3. The dyes should be ground in a mortar with the diluent, adding a small amount of the diluent at a time until all has been added.
4. All staining solutions should be filtered before use, but not before standing for at least twenty-four hours.
5. No solutions should be used after precipitation has occurred. When precipitation occurs, discard the solutions from the bottom of the bottle after the rest of the stain has been used, or filter and use the filtrate.
6. Diluted solutions should be made in small quantities. The stock solutions keep for a much longer period of time than the diluted solutions, particularly those containing either carbolic acid or potassium hydroxide.
7. All solutions should show on their labels the concentration of the dye present and the date of preparation. Use stain-fast labels.
8. Keep all staining solutions out of direct sunlight.
9. Keep all staining solutions in glass-stoppered bottles.

BACTERIOLOGIC STAINS

Formula numbers are given at the left of each formula; namely, S-1, S-2, etc.

Stock Solutions for Making Bacteriologic Stains*

S-1. Saturated Alcoholic Solution of Gentian Violet.—

Gentian violet	5.0 gm.
95% alcohol	100 c.c.

Grind the gentian violet in a mortar, adding the alcohol slowly, until all the dye is in solution.

Place in a glass-stoppered bottle, and filter through filter paper after 24 hours.

S-2. Saturated Alcoholic Solution of Basic Fuchsin.—

Basic fuchsin	3.5 gm.
95% alcohol	100 c.c.

Carry out the technic above.

S-3. Saturated Alcoholic Solution of Methylene Blue.—

Methylene blue	1.5 gm.
95% alcohol	100 c.c.

Carry out the technic above.

S-4. Lugol's Stock Solution.—

This solution is 15 times the strength of Gram's iodine solution, and may be used as a stock from which Gram's iodine is made.

Iodine, resublimed	5.0 gm.
Potassium iodide, c. p.	10.0 gm.
Distilled water	100 c.c.

---

*This is not intended to be a complete catalogue of staining solutions. Other staining solutions are found throughout the text. Consult the index for special stains.

Rub up the iodine and the potassium iodide in a mortar until they are thoroughly mixed. Add the water, a small amount at a time, and grind it into the mixture, until all the water has been added. Allow to stand in a glass-stoppered bottle, and filter after twenty-four hours.

S-5. 10% Solution of Potassium Hydroxide.—

Dissolve 10 grams potassium hydroxide, c.p., sticks in about 50 c.c. distilled water in a stoppered Pyrex flask.

Cool under running water if the flask becomes hot.

Dilute to 100 c.c. with distilled water.

S-6. 5% Solution of Carbolic Acid.—

This may be made from the carbolic acid crystals or from liquid carbolic acid.

Liquid carbolic acid is made by adding 4 c.c. distilled water to each ounce of melted carbolic acid crystals.

If the crystals are used, they are melted, and 5 c.c. of the melted carbolic acid are used in 100 c.c. solution.

If the liquid carbolic acid is used, 5.74 c.c. of the liquid carbolic acid are used in 100 c.c. solution.

Place 50 c.c. distilled water in a 100 c.c. graduated cylinder.

Add either 5 c.c. *liquefied* carbolic acid crystals or 5.74 c.c. *liquid* carbolic acid.

Dilute to 100 c.c. with distilled water.

S-7. 1% Solution of Carbolic Acid.—

This may be made from the 5% solution by diluting one part of 5% carbolic acid solution to a total of 5 parts, using distilled water.

If made from the melted crystals, 1 c.c. of liquefied carbolic acid crystals is added to 50 c.c. distilled water in a 100 c.c. graduated cylinder, and then diluted to 100 c.c. with distilled water.

Diluted Stains

These dilutions are the stains actually used in staining bacteria. They are made from the above stock solutions.

Carbol Gentian Violet

S-8. Made From Stock Saturated Alcoholic Solution.—

Add 10 c.c. saturated alcoholic solution of gentian violet to 50 c.c. 1% carbolic acid solution in a 100 c.c. graduated cylinder.

Dilute to 100 c.c. with 1% carbolic acid solution.

Filter after twenty-four hours.

S-9. Made From Gentian Violet Crystals.—

Gentian violet	1 gm.
Carbolic acid crystals	2 gm.
Absolute alcohol	10 c.c.
Distilled water to make	100 c.c.

Rub up the gentian violet and the alcohol in a mortar.

Add the carbolic acid crystals, and mix.

Add two-thirds of the water, a small amount at a time, stirring constantly.

Pour the mixture into a bottle, and rinse the mortar with the remaining water, adding it to the mixture in the bottle.

Filter through filter paper after twenty-four hours.

S-10. Hucker and Conn.—

20% solution of crystal violet in 95% alcohol	100 c.c.
1% solution of ammonium oxalate, large crystals, in distilled water	100 c.c.

Mix just before use equal parts of the two solutions.

S-11. Kopeloff and Bermann.—

1% gentian violet *or* crystal violet *or* methyl violet 6B in distilled water	150 c.c.
5% solution of sodium bicarbonate in distilled water	50 c.c.

Just before use mix 15 c.c. of the violet solution with 4 c.c. of the bicarbonate solution.

S-12. Scudder.[*]—

1% solution of crystal violet in distilled water	90 c.c.
Phosphate buffer, pH 6.9 (see page 1407, S-49)	10 c.c.

Carbol Fuchsin

S-13. Made From Stock Saturated Alcoholic Solution.—

Add 10 c.c. saturated alcoholic solution of basic fuchsin to 50 c.c. 5% carbolic acid solution in a 100 c.c. graduated cylinder.

Dilute to 100 c.c. with 5% carbolic acid solution.

Filter after twenty-four hours.

S-14. Made From Basic Fuchsin Crystals.—

Basic fuchsin	1 gm.
Carbolic acid crystals	5 gm.
Absolute alcohol	10 c.c.
Distilled water to make	100 c.c.

Proceed as above as for carbol gentian violet.

S-15. Randolph and Mickell.[1]—

1% solution of basic fuchsin in propylene glycol	100 c.c.
5% solution of carbolic acid in distilled water	400 c.c.

Just before use, mix 10 c.c. of the fuchsin solution with 40 c.c. of the carbolic acid solution. Shake well.

S-16. Diluted Carbol Fuchsin.—

Dilute carbol fuchsin 1:10 with distilled water. Use the same day.

Methylene Blue

S-17. Loeffler's, Made From Stock Saturated Alcoholic Solution.—

Distilled water	100 c.c.
10% solution of potassium hydroxide	0.1 c.c.
Saturated alcoholic solution of methylene blue	30 c.c.

Filter through filter paper after 24 hours. When a "certified stain" is used, the addition of potassium hydroxide is optional.

S-18. Loeffler's, Made From Methylene Blue Crystals.—

Distilled water	100 c.c.
10% solution of potassium hydroxide	0.1 c.c.
Methylene blue, certified	0.3 gm.
95% alcohol	30.0 c.c.

Rub up the methylene blue with alcohol in a mortar. Transfer to a flask. Add the potassium hydroxide to the water and wash the mortar with the mixture. Pour the washings into the flask.

Filter through filter paper after 24 hours.

S-19. Manson's Methylene Blue.—

Methylene blue	2 gm.
Borax (sodium tetraborate crystals)	5 gm.
Distilled water	100 c.c.

Dissolve the borax in the distilled water.

Grind the methylene blue in the borax solution, a small amount at a time, and pour into a bottle.

Filter after one week.

---

[*] Stain Technol. **19**: 39, 1944.

[1] Am. Rev. Tuberc. **49**: 39, 1944.

S-20. Gabbett.—

Methylene blue	2 gm.
25% sulphuric acid	100 c.c.

Place the methylene blue in a bottle. Pour the acid over it. Filter after 24 hours.

Safranin

S-21. 1% Aqueous Solution of Safranin.—

Dissolve 1 gram of safranin in 100 c.c. distilled water by grinding it in a mortar, and adding the water, a small amount at a time, until all the dye has been dissolved.

Filter after 24 hours.

S-22. 0.25% Solution of Safranin.—

Safranin	0.25 gm.
95% alcohol	10 c.c.
Distilled water	90 c.c.

Rub up the safranin with the alcohol in a mortar. Pour into a flask. Wash the mortar repeatedly with small amounts of the distilled water. Pour washings into the flask. Filter through filter paper after 24 hours.

Neutral Red-Fuchsin, Meyrick and Harrison[1]

S-23. 1% solution of neutral red in distilled water	150 c.c.
Carbol-fuchsin	10 c.c.

Bismarck Brown, Neisser

S-24. Dissolve 0.2 gm. Bismarck brown Y in 100 c.c. of boiling distilled water. Filter through filter paper while still hot.

Gram's Iodine

S-25. Made From Stock Lugol's Solution.—

Add 10 c.c. Lugol's solution to about 100 c.c. distilled water in a graduated cylinder.

Dilute to 150 c.c. with distilled water, and mix.

Filter after 24 hours.

S-26. Made From Iodine Crystals.—

Iodine, resublimed	1 gm.
Potassium iodide, c.p.	2 gm.
Distilled water	300 c.c.

Proceed as for Lugol's solution, S-4, above.

S-27. Kopeloff and Bermann.—

Weigh 4 gm. sodium hydroxide into a 500 c.c. glass-stoppered flask.

Add 50 c.c. distilled water.

Shake until dissolved.

Add 10 gm. iodine, resublimed.

Shake until dissolved.

Dilute to 500 c.c. with distilled water.

Let stand in a dark place for 24 hours, then filter through filter paper into a brown glass-stoppered bottle.

Carbol Thionin, Nicolle

S-28. Thionin	1.0 gm.
Phenol	2.5 gm.
Distilled water	100.0 c.c.

Filter; dilute before use with an equal quantity of distilled water.

Pyronin Green

S-29. Pappenheim.—

Methyl green, certified	1.0 gm.
Pyronin Y, certified	0.25 gm.

---

[1] J. Path. & Bact. 54: 517, 1942.

Phenol	2.0 gm.
95% alcohol	5.0 c.c.
Glycerin	20.0 c.c.
Distilled water	100.0 c.c.

Mix the alcohol and phenol.
Dissolve the methyl green in alcohol-phenol.
Mix glycerin and distilled water.
Dissolve the pyronin in it.
Mix the two solutions.

S-30. Scudder.*—

Methyl green, ethylated	0.65 gm.
Pyronin, Y, certified	0.1 gm.
Distilled water	100.0 c.c.

Dissolve dyes in order.
Filter after 24 to 48 hours.

Nigrosin

S-31. Nigrosin Solution, Dorner.—

Nigrosin†	10 gm.
Distilled water	100 c.c.

Boil 30 minutes in an Erlenmeyer flask; then add as preservative:

Formalin (40%)	0.5 c.c.

Filter twice through double filter paper and store in serologic test tubes, about 5 c.c. to the tube. Stopper tubes with tinfoiled corks.

Neisser Stain

S-32. Solution I.—

Methylene blue	0.1 gm.
Absolute alcohol	2.0 c.c.
Glacial acetic acid	5.0 c.c.
Distilled water	95.0 c.c.

Dissolve the methylene blue in the absolute alcohol in a mortar.
Mix the acetic acid with the distilled water.
Add the acetic acid mixture to the solution of methylene blue a small amount at a time.
Filter after 24 hours.

S-33. Solution II.—

Crystal violet, certified	1.0 gm.
95% alcohol	10.0 c.c.
Distilled water	300.0 c.c.

Just before use mix 20 c.c. of Solution I and 10 c.c. of Solution II.

S-34. Solution III.—

Dissolve 2 gm. chrysoidin in 300 c.c. hot distilled water.
Filter while still hot.

Ljubinsky Stain

S-35.	Crystal violet, certified	0.25 gm.
	Glacial acetic acid	5.0 c.c.
	Distilled water	95.0 c.c.

Albert Stain

S-36.	Toluidine blue	0.15 gm.
	Glacial acetic acid	1.0 c.c.
	95% alcohol	2.0 c.c.
	Distilled water	100.0 c.c.

---

*Stain Technol. 19: 39, 1944.

†Nigrosin B Grubler recommended by Dorner; American nigrosins certified by Biological Stain Commission usually satisfactory.

Dissolve the toluidine blue in the alcohol.
Mix the acetic acid with the water.
Add the acetic acid solution to the dissolved dye.
After 24 hours filter through filter paper.

Wayson Stain

S-37.

Basic fuchsin	0.2	gm.
Methylene blue	0.75	gm.
Absolute alcohol	20.0	c.c.
Phenol crystals	10.0	gm.
Distilled water	200.0	c.c.

Dissolve the fuchsin and the methylene blue in the alcohol.
Dissolve the phenol in the distilled water.
Mix the two solutions.
After 48 hours filter through filter paper.

Richards and Miller Stain

S-38. Stain.—

Phenol, liquefied	3.0	c.c.
Distilled water	87.0	c.c.
Auramine 0	0.1	gm.
95% alcohol	10.0	c.c.

Mix the phenol and the water.
Dissolve the dye in the alcohol.
Add the phenol water to the dye solution.
Filter, if necessary.

S-39. Decolorizer.—

Sodium chloride	0.5	gm.
Concentrated hydrochloric acid c.p.	0.5	c.c.
70% alcohol	100.0	c.c.

Dissolve the salt in the acid.
Add the alcohol.

Pappenheim Differentiating Stain

S-40.

Corallin, yellow (rosolic acid)	1.0	gm.
Methylene blue	about 7.0	gm.
Absolute alcohol	100.0	c.c.
Glycerin	20.0	c.c.

Dissolve the corallin in the alcohol.
Filter after 48 hours.
Add the methylene blue.
Let stand for 4 days, shaking frequently.
Filter through filter paper.
Add the glycerin.
After 24 hours filter through filter paper.

Cooper's Solutions

S-41. Cooper Carbol Fuchsin.—

To 100 c.c. carbol fuchsin prepared according to formula S-13 or S-14, add 3 c.c. of a 10% solution of sodium chloride in distilled water. Keep in the refrigerator.

S-42. Alkaline Brilliant Green.—

To 100 c.c. of a 1% solution of brilliant green in distilled water add 1 c.c. of a 1% solution of sodium hydroxide in distilled water.

Marshall Stain[1]

S-43. Picric Acid Solution.—

Mix 10 c.c. of acetone with 50 c.c. of absolute alcohol.

Add picric acid to saturation. Filter through filter paper after 48 hours.

S-44. Auramine Green.—

Auramine O	0.09	gm.
Distilled water	90.0	c.c.
Malachite green	1.1	gm.
Distilled water	110.0	c.c.

Dissolve the auramine in 90 c.c. distilled water and mix.

Dissolve the malachite green in 110 c.c. distilled water and mix.

Mix the two solutions.

After 48 hours filter through filter paper.

Stains for Rickettsiae and Inclusion Bodies

Ordway-Machiavello[2]

S-45. Regaud's Fixative.—

3% potassium bichromate in distilled water	80 c.c.
Formalin	20 c.c.

Prepare fresh for use.

S-46. Stain.—

1% Poirer's blue, color index No. 707, in distilled water	10 c.c.	Mix.
0.45% eosin, bluish, color index No. 771, in distilled water	15 c.c.	Mix.

Mix the two solutions just before use.

Add 25 c.c. of distilled water slowly, with constant shaking.

Use within 24 hours. The dyes and the water used in this stain must be neutral.

Nyka[3]

S-47.

Basic fuchsin	5.0	gm.
90% alcohol	100	c.c.

Before use dilute 1.0 c.c. with 9.0 c.c. of distilled water.

S-48.

Methyl violet 7B	0.1	gm.
Distilled water	100	c.c.

Castañeda

S-49.

A. Buffer Solution.—

Dissolve 23.86 gm. disodium phosphate ($Na_2HPO_4.12H_2O$) in 1 liter of distilled water.

Dissolve 11.34 gm. anhydrous monosodium phosphate (NaH_2PO_4) in 1 liter of distilled water.

To 88 c.c. of the disodium phosphate solution add 12 c.c. of the monosodium phosphate solution, mix, and filter through a Berkefeld or Seitz filter.

Add 0.2 c.c. Formalin.

B. Methylene Blue Solution.—

Dissolve 21 gm. methylene blue in 300 c.c. of 95% alcohol.

Dissolve 0.1 gm. potassium hydroxide in 1 liter of distilled water.

Mix each solution, then after 24 hours add solution A to solution B and mix.

For further stains for Rickettsiae, see pages 1413, 1414; for Negri bodies, see page 1720.

---

[1] Brit. M. J. 2: 232, 1943.

[2] Lab. Digest 6: 2, 1942.

[3] J. Path. & Bact. 56: 264, 1944.

Capsule Stains

Hiss

S-50.	Saturated alcoholic solution of gentian violet	5 c.c.
	Distilled water	95 c.c.

MacNeal

S-51.	Eosin Y, certified	1.0 gm.
	Methylene blue, certified	1.0 gm.
	Azure A	0.6 gm.
	Methylene violet, Bernthsen	0.2 gm.
	Methyl alcohol, neutral, acetone-free	1,000.0 c.c.

Heat to 50° C for 30 minutes.

Keep at 37° C. for two days.

Filter through filter paper.

It is preferable to purchase the stain in dry form or in solution.

Gray*

S-52. Mordant.—

Saturated watery solution of mercuric chloride	10 c.c.
20% solution of tannic acid in distilled water	10 c.c.
Saturated watery solution of potassium alum	25 c.c.

S-53. Stain.—

Methyl alcohol	10 c.c.
1% solution of basic fuchsin in distilled water	10 c.c.

Mix.

Methyl alcohol	5 c.c.
1% solution of methylene blue in distilled water	5 c.c.

Mix.

Add fuchsin solution to methylene blue solution.

Lawson**

S-54. Mordant.—

5% solution of phosphomolybdic acid in distilled water.

S-55. Stain.—

Dilute 10 c.c. of Wright stain with 5 c.c. of glycerin just before use.

Flagella Stains

Gray

S-56.	Saturated solution of potassium alum in distilled water	5.0 c.c.
	20% solution of tannic acid in distilled water	2.0 c.c.
	Saturated aqueous solution of mercuric chloride	2.0 c.c.
	Saturated alcoholic solution of basic fuchsin	0.4 c.c.

Mix in order just before use.

Leifson

S-57.	5% solution of potassium alum in distilled water	10 c.c.
	2% solution of tannic acid in distilled water	10 c.c.
	1% solution of basic fuchsin in 95% alcohol	10 c.c.

Mix in order.

We have found it desirable to purchase the stain in powdered form from the Baltimore Biological Laboratory.

Dissolve 1.5 gm. of BBL Flagella stain in a mixture of 35 c.c. of 95% alcohol and 65 c.c. of distilled water.

Allow to stand for 10 minutes shaking several times.

The stain remains stable for several weeks if kept in a tightly stoppered bottle.

---

*J. Bact. 45: 301, 1943.

**J. Lab. & Clin. Med. 25: 435, 1940.

Decolorizing Agents

Distilled Water.—Distilled water is a decolorizing agent. If water is allowed to remain on slides after they have been stained, it will remove part of the stain. After staining and washing preparations, always stand them on end to dry if they cannot be blotted.

Absolute Alcohol.—Absolute alcohol is sometimes used as a decolorizing agent. For the Gram stain 95% alcohol is recommended.

Acid Alcohol.—Add 3 c.c. of concentrated hydrochloric acid, c.p., to enough 95% alcohol to make a total volume of 100 c.c.

Various acids and alkalies act as decolorizing agents. Where a special decolorizing solution must be used, it will be described with that staining technic.

STAINING METHODS

Simple Stains for Morphology

These stains serve to study the general morphology of the microorganisms. The slides are fixed over the flame before staining.

(I) Methylene Blue.—

Use methylene blue prepared according to directions under "methylene blue" (S-17) (S-18). For staining microorganisms in blood films, Manson's methylene blue (S-19) is used.

Flood the slide with methylene blue and stain for 1½ to 3 minutes.
Wash with distilled water.
Dry by draining, and examine.

(II) Dilute Carbol Fuchsin.—

Flood slides with diluted carbol fuchsin (formula S-16) for ½ to 1 minute.
Wash with distilled water.

(III) Carbol Thionin (formula S-28).—

Use as methylene blue.

Negative Demonstration of Bacteria

India ink, diluted with equal parts of distilled water or nigrosin (formula S-31) is used.

Mix a loopful of the bacterial suspension on the slide with the same amount of India ink or nigrosin solution. Make a very thin smear. Examine after drying.

Gram Stain

The Gram stain permits the differentiation of two groups of organisms, one of them called "gram-positive," the other "gram-negative." With most Gram staining methods, the gram-positive organisms stain purple, while gram-negative organisms stain red. While the Gram stain is the most commonly used bacterial stain, there is no uniformity in its technic. Because of the danger of overstaining or overdecolorizing, it is recommended that at least once a day known gram-negative and gram-positive organisms be stained at the same time as the cultures which are being examined. The following methods of Gram staining technic are commonly used:

(I) Original Gram Stain.—

Fix the slide in the flame and allow to cool.
Stain with carbol-gentian-violet (formula S-8 or S-9) ---------------------60 seconds
Wash with distilled water.
Stain with Gram iodine (formula S-25 or S-26) --------------------------30 seconds
Wash with distilled water.

Decolorize in 95% alcohol until no further violet comes away.

Wash thoroughly with distilled water.

Counterstain with 1% aqueous safranin (S-21) --------------------------2 minutes

Wash with distilled water.

Dry in the air, and examine.

Gram-positive organisms stain purple.

Gram-negative organisms stain red.

(II) Hucker Modification.—

Fix the slide in the flame and allow to cool.

Stain with Hucker crystal violet (formula S-10) ----------------------60 seconds

Wash with distilled water.

Stain with Gram iodine (formula S-25 or S-26)-------------------------60 seconds

Wash with distilled water.

Decolorize with 95% alcohol until no further violet comes away.

Wash thoroughly with distilled water.

Counterstain with 0.25% safranin (formula S-22)-----------------------10 seconds

Wash with distilled water.

Dry in air and examine.

(III) Kopeloff and Bermann Modification.—

This is an excellent stain for vaginal and urethral smears.

Fix the slide in the flame and allow to cool.

Stain with Kopeloff violet (formula S-11)-----------------------------5 minutes

Pour off stain.

Flood slide two or three times with Kopeloff iodine solution (formula S-27).

Decolorize with 100% acetone until no further violet comes away.

Dry in the air.

Counterstain with freshly prepared 1:1,000 watery basic fuchsin *or* neutral red-fuchsin Meyrick and Harrison (formula S-23)-----------------------------20 to 30 seconds

Wash with distilled water.

Dry in the air and examine.

No water should be used in this procedure before the application of fuchsin.

(IV) Scudder Modification.—

Fix the slide in the flame and allow to cool.

Stain with Scudder crystal violet (formula S-12)---------------------3 to 5 minutes

Pour off stain.

Apply Kopeloff iodine (formula S-27) two or three times.

Decolorize with 100% acetone until no further violet comes away.

Dry in air.

Counterstain with Scudder methyl green-pyronin (formula S-30)------1 to 2 minutes

Wash with distilled water.

Dry in the air and examine.

Scudder's modification of the Gram stain is used to study the cytologic elements present in pus.

(V) The Counterstain of Pappenheim.—

Stain as when carrying out any good Gram procedure. Preferred method is that of Kopeloff and Bermann (III).

Instead of fuchsin, counterstain with Pappenheim pyronin-methyl green (formula S-29) --1 minute

This method permits study of the cytology of smears from secretions and excretions.

Wash with distilled water.

Dry in air and examine.

(VI) Gram Stain for the Color-Blind.—

Stain with any accepted modification.

Instead of safranin, pyronin, or fuchsin, counterstain with Bismarck brown (formula S-24) --30 to 60 seconds

Gram-positive organisms are purple.

Gram-negative organisms are yellowish-brown.

Staining Acid-Fast Organisms

Acid-fast organisms are usually slow in taking stains but they do not lose them when treated with diluted acids and alcohol. When phenol is used as a mordant, heating is necessary to accomplish the staining. Instead of heating, however, cold staining for 24 hours may be substituted. Carbol fuchsin is the usual stain for the acid-fast organisms. With most staining methods the acid-fast organisms stain red.

(I) Ziehl-Neelsen Stain.—

Fix the slide in the flame.

Cover with carbol fuchsin (formula S-13 or S-14) and heat the slide gently from below with a Bunsen burner so that steam is visible (but not to boiling) ------------3 minutes

If the carbol fuchsin evaporates, add fresh solution.

Wash with distilled water.

Decolorize with 95% alcohol containing 3% hydrochloric acid until no further red comes away.

Wash with distilled water.

Either counterstain with methylene blue (formula S-17 or S-18)------1½ to 2 minutes *or* with 2% watery solution of malachite green *or* with brilliant green S-42--------2 minutes

Wash with distilled water.

Dry in the air and examine.

Acid-fast organisms are red.

Cells and other bacteria are blue (when methylene blue is used as a counterstain) or green (when malachite green is used as a counterstain).

(II) Cooper Modification.—

Fix the slide in the flame.

Stain with Cooper carbol fuchsin (formula S-41)----------------------3 to 5 minutes gently heating the slide so that steam develops.

Wash with distilled water.

Decolorize with 5% nitric acid in 95% alcohol.

Wash with distilled water.

Counterstain with Cooper brilliant green (formula S-42)----------30 seconds or longer

Wash with distilled water.

Dry and examine.

(III) Modification for Color-Blind Workers.—

Fix the slide as above.

Cover with carbol gentian violet (formula S-8 or S-9) and heat the slide to steam—5 minutes.

Wash with distilled water.

Decolorize with 95% alcohol containing 5% nitric acid until no further red comes away.

Counterstain with Bismarck brown (formula S-24)------------------------2 minutes

Wash with distilled water.

Dry in the air.

Acid-fast organisms are purple.

Cells and other bacteria are yellowish-brown.

(IV) Gabbett Modification.—

Fix the slide, stain with carbol fuchsin and wash with distilled water as above.

Decolorize and counterstain at the same time with Gabbett methylene blue solution (formula S-20) --20 to 30 seconds

Wash with distilled water.

Dry in the air and examine.

(V) Fluorescent Dye Method.—(See pages 1609 ff.)

Place a yellow filter in the ocular. The microscope lamp is equipped with a blue filter which transmits ultraviolet light. Use an aluminized mirror. Carry out the examination in a darkened room, using the 8 mm. objective and 20x oculars.

Stain the slide with Richards and Miller stain (formula S-38)--------2 to 3 minutes
Wash with tap water.
Decolorize with decolorizing solution (formula S-39) for 10 minutes or longer.
Wash with tap water.
No counterstain is used.
Dry in air and examine.

(VI) Pappenheim Method.—

Fix slide and stain with carbol-fuchsin as under Method I.
Do not wash.
Pour on Pappenheim differentiating stain (formula S-40) four or five times.
Wash with distilled water.

Dry in the air and examine. This method stains *Mycobacterium tuberculosis* but not the smegma bacillus. Tubercle bacilli are red, while smegma bacilli usually appear blue.

(VII) Randolph and Mickell Cold Method.—

Fix slide in flame.
Cover with Randolph and Mickell carbol fuchsin-propylene glycol (formula S-15)------------------4 minutes or longer
Wash with water.
Decolorize, counterstain and carry out the remainder of the procedure as under Method I.

(VIII) Simultaneous Gram and Acid-Fast Stain of Marshall.—

Fix slide over flame.
Stain with carbol fuchsin (formula S-13 or S-14)-------------------------5 minutes gently heating so that steam develops.
Wash with distilled water.
Apply picric acid solution (formula S-43) just to decolorize.
Wash with distilled water.
Stain with 0.25% crystal violet solution in distilled water---------------------1 minute
Wash with distilled water.
Cover with Lugol iodine (formula S-25 or S-26)---------------------------1 minute
Decolorize with 100% acetone.
Wash with distilled water.
Counterstain with auramine green (formula S-44)------------------15 to 30 seconds
Wash with distilled water.
Blot, examine.

Myco. tuberculosis stains crimson red with black granules; *Myco. smegmatis*, grayish green. Gram-positive organisms are purple-black; gram-negative organisms, grass-green.

Granule Stains

These stains serve for the study of bacterial morphology. They accentuate the granules in the bodies of *Corynebacterium diphtheriae* and are, therefore, most frequently used for studies of throat and nose smears.

Smears from the lesions or from cultures must be dried and fixed over the flame before the granule stain is applied.

(I) Methylene Blue.—

Apply methylene blue (formula S-17, S-18, or S-19)----------------1 to 2 minutes.
Wash with distilled water.
Dry in air and examine.
Granules are deep blue, bodies lighter.

(II) Gohar.*—

Stain with methylene blue (formula S-17)-------------------------------5 minutes.
Quickly decolorize with 1:1,000 sulphuric acid.
Rapidly wash with distilled water.

---

*J. Bact. 47: 575, 1944.

Stain with Lugol iodine (formula S-25 or S-26)----------10 seconds.
Wash with distilled water.
Counterstain with 1% eosin in distilled water----------30 seconds.
Wash with distilled water.
Dry in air and examine.
Granules are dark; bodies, yellowish.

(III) Neisser Technic No. I.—

Stain with Neisser solution I (formula S-32)----------30 to 60 seconds.
Wash with distilled water.
Stain with Bismarck brown (formula S-24)----------10 seconds.
Wash with distilled water.
Dry in air and examine.

(IV) Neisser Technic No. II.—

Stain with Neisser mixture (formula S-32 and S-33)----------10 seconds.
Wash with distilled water.
Counterstain with Neisser solution III (formula S-34)----------10 seconds.
Wash with distilled water.
Dry and examine.
Granules are dark; bodies, yellow.

(V) Ljubinsky.—

Stain with Ljubinsky stain (formula S-35)----------2 minutes.
Wash with distilled water.
Stain with Bismarck brown (formula S-24)----------30 seconds.
Wash with distilled water.
Dry and examine.
Granules are deep purple; bodies, brownish.

(VI) Albert.—

Stain with Albert stain (formula S-36)----------5 minutes.
Drain, do not wash.
Apply Lugol iodine solution (formula S-25 or S-26)----------30 seconds.
Wash briefly with distilled water.
Dry and examine.

Staining Rickettsiae and Inclusion Bodies

In many cases, staining with Giemsa or Wright solution carried out as with blood films, or the hematoxylin-eosin stain will yield good results. Special stains are used for Negri bodies (see page 1720). Out of the many dozens of suggested modifications, the following yielded good results in the hands of the editor:

(I) Ordway-Machiavello.—

Fix tissue in Regaud's fixative (formula S-45) 4 days, changing the fluid every day.
Wash in running water for 16 to 24 hours.
Transfer to 70% alcohol.
Carry through the routine histologic technic employing the paraffin method.
Cut sections not over 5 microns thick.
Deparaffinize.
Wash well in several changes of water.
Stain with Ordway-Machiavello stain (formula S-46)----------6 to 8 minutes.
Decolorize with 95% alcohol until pale bluish-pink.
Wash in absolute alcohol----------1 minute.
Transfer to two changes of xylol, slightly washing in the first.
Mount from second xylol.
Rickettsiae and inclusion bodies are bright red; nuclei and cytoplasm, sky blue.

(II) Nyka.—

Fix in Mueller fluid.
Carry through routine paraffin method.
Deparaffinize.
Keep in distilled water for 5 minutes.
Stain with Nyka first stain (formula S-47)------------------------5 to 10 minutes.
Rinse with tap water.
Differentiate with 90% alcohol ------------------------------------1 to 2 minutes.
Stain with Nyka second stain (formula S-48)----------------------1 to 3 minutes.
Rinse and differentiate with 1:1,500 acetic acid.
Dehydrate and mount.

(III) Castañeda.—

This is best for Rickettsiae.
Stain with Castañeda stain (formula S-49)-----------------------2 to 3 minutes.
Wash with running water---30 seconds.
Counterstain with safranin (formula S-21)----------------------1 to 2 minutes.
Drain and examine.

Capsule Stains

The capsules of bacteria are often detectable as unstained halos surrounding the bodies of the organisms. In many cases, however, special staining methods are necessary to ascertain the presence or absence of the capsules. The methods listed below give good results.

(I) Hiss.—

Mix material to be stained with an equal amount of serum. Make thin smear.
Allow to dry in air.
Fix either in the flame or in 1:10 diluted commercial Formalin.
Cover with Hiss stain (formula S-50) and heat to steaming for a few seconds.
Wash off the stain with a 20% watery solution of copper sulphate.
Dry in air and examine.
Bacterial bodies, cells, and background stain purple.
Capsules are colorless or pale lavender.

(II) MacNeal.—

Make thin smear.
Allow to dry in air.
Cover with MacNeal tetrachrome stain (formula S-51)----------------3 to 15 minutes.
Wash carefully with distilled water.
Dry in air and examine.
Capsules are colorless or pale.

(III) Lawson.[1]—

Prepare direct smear, without using a diluent, from the culture.
Dry in air.
Cover film with mordant (formula S-54)---------------------------------30 seconds.
Wash the slide with methyl alcohol.
Cover with 20 drops of stain (formula S-55)---------------------------2 minutes.
Add 30 drops of distilled water, mix stain on slide with the water and allow to act----
--------10 to 20 minutes.
Rinse with distilled water.
Drain slide and examine when dry.
Capsules are colorless or pale.

---

[1] J. Lab. & Clin. Med. 25: 435 1940.

Staining Flagella

General Method of Applying Flagella Stains

Very young and vigorous cultures must be procured. In general, twelve to twenty-four-hour growths on surface of agar are satisfactory. If stock cultures are used, make daily transplants for several days before studying, to restore vigor. Kulp* in 1926 suggested this method:

Use agar slants with plenty of water of condensation. Transfer a loopful of this water of condensation from a twenty-four hour culture to a second slant, then twenty-four hours later pour off one or two drops of condensation water aseptically into a tube of sterile distilled water of the same temperature as the culture. Incubate at optimum temperature of the organism for forty-eight to seventy-two hours. Johnston and Mack recommended a similar method. Others find that bacteria have a tendency to shed their flagella if left in water that long, one member of the Commission[2] obtaining excellent results when bacteria were in the water only seven hours.

Cover glass or slide must be scrupulously clean. Place in hot cleaning solution (page 192), clean in strong sodium or potassium hydroxide, rinse in weak hydrochloric acid, then in distilled water. Keep in alcohol until ready for use. Burn off alcohol from cover glasses just before use, holding cover glasses in the flame with forceps. Plimmer and Paine recommend baking slides on a wire gauze mat over a Bunsen burner just before using.

Greatly dilute the growth in distilled water, place tiny drops or streaks on the cover slip; discard those showing signs of grease. Preparations should be thin enough to dry immediately. Fixation of films by heat, although recommended by some authors, may destroy the flagella. Plimmer and Paine recommend scrupulously clean slides instead of cover slips, heated before use, and cooled to body temperature. Using a 3 mm. loop, place a drop of culture fluid on one end of the slide and tilt to allow the suspension to run down the slide. Slide should be warm enough to allow rapid drying. Gray placed a large loopful of the culture suspension on one end of a slide, and spread gently with a strip of unsized paper (e.g., typing paper).

Poor results are caused by greasy cover glasses or slides, old cultures, unsatisfactory medium, too slow drying of the smears, too thick suspensions of bacteria, insufficient or excessive mordanting, understaining, or overstaining. Most poor results come from improper handling of the culture, or from greasy slides or cover slips. The personal equation also enters into the picture. Best results seem to have been obtained with the Leifson and Gray methods, although success has been reported where other methods were used.

(I) Gray.—

Prepare film as directed in General Method and dry.
Apply Gray mordant (formula S-56)--------------------------------5 to 10 minutes.
Wash with distilled water.
Stain with carbol fuchsin (formula S-13 or S-14)-------------------5 to 10 minutes.
Wash with distilled water.
Drain and examine when dry.

(II) Leifson.[3]—

Prepare three slides.

With a wax pencil make a heavy continuous line along the edges of the slides, leaving about ¾ inch on one end free for handling. Place a large loopful of bacterial suspension on one end and tilt the slides so that the suspension runs down.

Dry in the air.

Add to each slide 0.8 to 1.0 c.c. of Leifson stain formula (S-57).
Stain first slide --8 minutes.
Second slide ---10 minutes.
Third slide --12 to 15 minutes.

---

*Stain Technology 1: 60, 1926.

[2] Biological Stain Commission.

[3] J. Bact. 36: 656, 1938.

Wash with tap water.
Drain and examine when dry.
If counterstain is necessary, stain with 1:1,000 methylene blue in a 1:2,000 aqueous solution of borax------10 minutes.

Staining Spores

If a special method is not used but the Gram or a simple bacterial stain applied, spores appear as unstained holes in the bacterial body. In order to visualize spores more clearly, special methods must be applied.

(I) Moeller.—

Make thin smears and fix in the flame.
Cover with chloroform ------2 minutes.
Wash with distilled water.
Cover with 5% chromic acid ------½ to 2 minutes.
Wash in water.
Steam with carbol fuchsin (formula S-13 or S-14)------3 to 5 minutes.
Decolorize with 5% sulphuric acid ------5 to 10 seconds.
Wash in water.
Stain with methylene blue (formula S-17, S-18, or S-19)------½ to 1 minute.
Wash in water.
Dry and examine.
Spores are red; bodies of bacteria, blue.

(II) Abbott.—

Make thin smears and fix in flame.
Cover with methylene blue (formula S-17, S-18, or S-19) and heat, bringing the stain to boiling several times but not continuously------1 minute.
Wash in distilled water.
Cover with a mixture of 1 part of saturated alcoholic eosin solution and 9 parts distilled water ------5 to 10 seconds.
Rinse with distilled water.
Blot.
Mount in balsam or clarite and examine.
Spores are blue; bodies of bacteria, pink.

(III) Wirtz-Conklin.—

Make thin smears and fix in the flame.
Cover with 5% aqueous malachite green and steam------3 to 6 minutes.
Wash with distilled water.
Stain *either* with ½% aqueous safranin *or* 5% aqueous Mercurochrome--30 to 60 seconds.
Wash with distilled water.
Dry and examine.
Spores are green; bodies of bacteria, pink.

CULTURE MEDIA

Culture media are divided into collecting, preserving, plating, and diagnostic media. With the exception of a few very selective media, all media must be sterile. Heat sterilization, however, may harm certain ingredients. It is of paramount importance, therefore, to adhere rigorously to the directions concerning sterilization. The glassware in which the media are stored or used must be chemically clean and sterile. No traces of the cleaning solution must remain on the glassware. Dichromate-sulphuric acid mixtures are not recommended for this reason. The tubing of media and the pouring of plates must be carried out in a dust-free room. Speaking and walking in the laboratory are to be avoided during these operations.

Most media are stored in the refrigerator or in the icebox. Proper plugging protects against contamination and, partly, against evaporation. Dried-out media cannot be used because a certain water content is essential for the growth of most organisms. Smaller laboratories often dispense rarely used media into large test tubes and store them in the refrigerator until used. Then a plate is poured with the contents of one of these tubes. *It is necessary to substitute the water lost by evaporation during storage.* In order to know how much water was lost, mark the upper level of the medium on each tube with a wax pencil when the tubes are taken out of the sterilizer. If a tube is taken out of storage and the contents melted, sterile distilled water must be added to fill the contents of the tube to the pencil mark. Seventeen to twenty c.c. are the proper amounts of medium per 100-mm. plate, if not directed otherwise.

Each tube or plate must be correctly labeled with a wax pencil, immediately after sterilization, to indicate its content.

Media should not be reheated or resterilized more often than allowed in the formula.

In addition to proper composition and sterilization, the pH of the medium and the final reaction are very important. This is checked by the use of indicators.

Small laboratories should purchase media ready-made, tubed, and sterilized. Baltimore Biological Laboratory, Difco, Inc., and the Gradwohl Laboratories supply such media.

Every bacteriologist, clinical pathologist, and laboratory technician should realize that proper media are the most essential tools in bacteriologic work. Proper preparation and proper keeping of the media are of such importance that this cannot be emphasized too strongly.

General Facts Concerning Culture Media

Culture media are divided into fluid, semifluid, semisolid, and solid media according to their consistency. Isolated colonies can be obtained only on solid media. The other media serve either as collecting, preserving, and enrichment fluids, or for the study of pure cultures. Solid media, except for certain coagulated media, are frequently used in plates. They may be poured into Petri dishes so that the material to be examined can be spread on the surface. Or the material to be examined may be mixed with the melted medium and this mixture poured into plates and allowed to solidify. In this way colonies may be isolated and selected for further study.

Present-day technic uses agar as the chief solidifying agent. When 0.05 to 0.2 per cent of agar is added to the medium, the medium will be semifluid. Such a solution supports the growth of Neisseriae, Clostridia, etc. Semisolid tubes contain 0.3 to 0.5 per cent agar. While high concentrations of agar (2 to 3 per cent) are commonly used in Europe, most American methods require only 1.5 to 1.7 per cent agar for a solid plate.

Media containing agar become liquid when heated to about 96° C. and solidify again when the temperature falls to about 45° C. Tubes are placed in a boiling water bath to liquefy the medium. Sometimes it is necessary to melt the agar in a flask over a Bunsen flame protecting the flask with a wire-and-abestos net, as for example, for dissolving dehydrated media when preparing them for use. In such cases, it is necessary to shake the flask frequently to prevent the ingredients from sticking to the bottom of the flask. If the agar burns, the culture medium must be discarded.

Gelatin is rarely used today because it melts at around 20° C. and therefore ''cold incubation'' is necessary if it is to be kept solid. It is still, however, the most reliable measure of bacterial proteolysis.

Distilled water should be used for the preparation of culture media.

All chemicals must be chemically pure.

Most media contain peptone in one form or another. While Bacto-peptone and BBL-polypeptone satisfy most requirements, many special peptones are used. Pancreatic digest of casein (Difco) has been used recently as an all-purpose peptone. Difco-tryptone and BBL-trypticase are recommended for indol production; Difco-proteose-peptone and BBL-thiotone for hydrogen sulphide production; Difco-neopeptone, proteose, and tryptose have their special indications. BBL-phytone is a papaic digest of plant material. Most media require 0.5 to 2 per cent peptone. It is essential that the proper peptone be used for each medium. Peptones are easily dissolved in distilled water.

Meat is essential for many media. Meat extract (Difco, BBL, Wilson, or others) is used routinely, but for more fastidious bacteria, infusions of heart, liver, brain, etc., are indicated. Some authors suggest ''hormone'' and tryptic digest broths which have growth supporting properties. These hormone media require special care, and for that reason the ready-made commercial products are used in many laboratories. Meat extracts, however, often give false positive fermentation reactions and are, therefore, by-passed whenever possible in such media.

Yeast extract, Bacto-Casamino acids, and supplements are required for a number of media. Yeast extract (Bacto) 0.3 to 1 per cent, strongly supports the growth of many microorganisms and may be substituted for a part or all of the meat extract when so indicated in the formula.

Fermentable substances—carbohydrates, alcohols, glucosides, and urea—are often destroyed by heat. They are, therefore, frequently added to the previously sterilized ''base'' after filtration through a Berkefeld or Seitz filter.

High quality Bacto (Difco) and BBL products may be easily substituted for ''hormone'' and other digest media described in European literature, as well as European brands of peptones.

Hemolysis must never be evaluated on plates containing fermentable substances, notably dextrose or sodium azide, since these materials cause false readings.

Negative indol tests will sometimes be observed when media containing carbohydrates are used for this reaction.

Many laboratories use dehydrated (desiccated) media. Such media are very convenient, simple to prepare, and very reliable. Excellent desiccated media are available from Difco, Inc.,[1] and the Baltimore Biological Laboratory (BBL).[2]

The intention of this edition of *Clinical Laboratory Methods and Diagnosis* is to recommend relatively fewer media than the former editions and to concentrate on those which are easily prepared or readily purchased on the market.

A few points in the technic of media making should be clarified.

(A) Making Solutions.—

Peptones, agar, and gelatin often adhere to the walls or to the bottom of the flask, and burn when the flask is heated. This spoils the medium. Particles adhering to the neck of culture tubes may cause sticking of the cotton plug. To avoid the adhesion of these materials to the glass surfaces, observe the following precautions:

Pour a small amount of water in the flask before adding the ingredients. If, for example, the medium is to be made up by dissolving the ingredients in 1000 c.c. of water, first pour about 500 c.c. of the water into the flask, then add the ingredients. Finally, pour the rest of the water into the flask to wash the inside of the neck of the flask. This washes into the contents of the flask any powder adhering to the neck.

The capacity of the flask should be double the amount of the medium to be made. Erlenmeyer flasks with wide necks and without pour-outs are preferred.

(B) Sterilization.—

The autoclave must not be packed too tightly or sterilization will not take place. Cover the plugs of the flasks with wrapping paper tied with a string around the necks of the flasks. Sterilize test tubes standing in racks with the exception of media containing eggs or serum or other coagulable substances. These must be slanted during sterilization.

(C) Pouring Plates.—

Plates must be poured under sterile conditions. Repeatedly flame the necks of the flasks between pouring the plates. Hold the plug of the flask in such a position that it does not become contaminated.

The media should not be warmer than 60° C. when poured. This will reduce the formation of water of condensation.

With the exception of Brewer's anaerobic agar, it is best to leave the plates on the laboratory table until the media have solidified, then store the plates upside down in the refrigerator. Store Brewer's agar right side up.

Each plate must be marked to indicate its contents.

Never use dried-out plates or plates showing growth of contaminants.

If the surface of the plate is moist, put the plate, with partly removed lid, in a dust-free incubator until the surface is dry. Do not open the incubator during this procedure except to take out the drying plates.

Some very selective media, such as those used for stool work, may be dried on the laboratory table with partly removed lids.

(D) Tubing Media.—

(1) Media which are sterilized after they have been tubed.—

Attach a piece of rubber tubing to a short-stemmed 4 to 6 inch glass funnel. (Fig. 334.) The size of the funnel varies according to the amount of the medium. Insert an eye dropper into the other end of the rubber tubing so that the pointed end of the eye dropper is free. Place this tubing apparatus in a ring stand high enough that space remains to operate the outlet. Put a Moore or Cenco clamp on the rubber tubing to allow interruption of the flow, and close the clamp. Fill the funnel with the medium. To fill the tubes, place the eye dropper well into the tubes so that the medium will flow into the tubes without soiling the upper parts which come in contact with the plug.

Plug the tubes and sterilize them.

---

[1] 720 Henry St., Detroit 1, Mich.

[2] 1640 Gorsuch Ave., Baltimore 18, Md.

(2) Media which are tubed under sterile conditions.—

The safest procedure is to use sterile pipettes and distribute the medium into sterile test tubes. It is best to have an assistant to flame the necks of the tubes and insert the plugs.

Another method is to prepare a tubing apparatus using a 500 c.c. (or larger) bottle, Pyrex glass, with a tube at the bottom. Adjust the rubber tubing and the eye dropper as they were adjusted to the funnel (1, above). Wrap the entire apparatus in paper and sterilize.

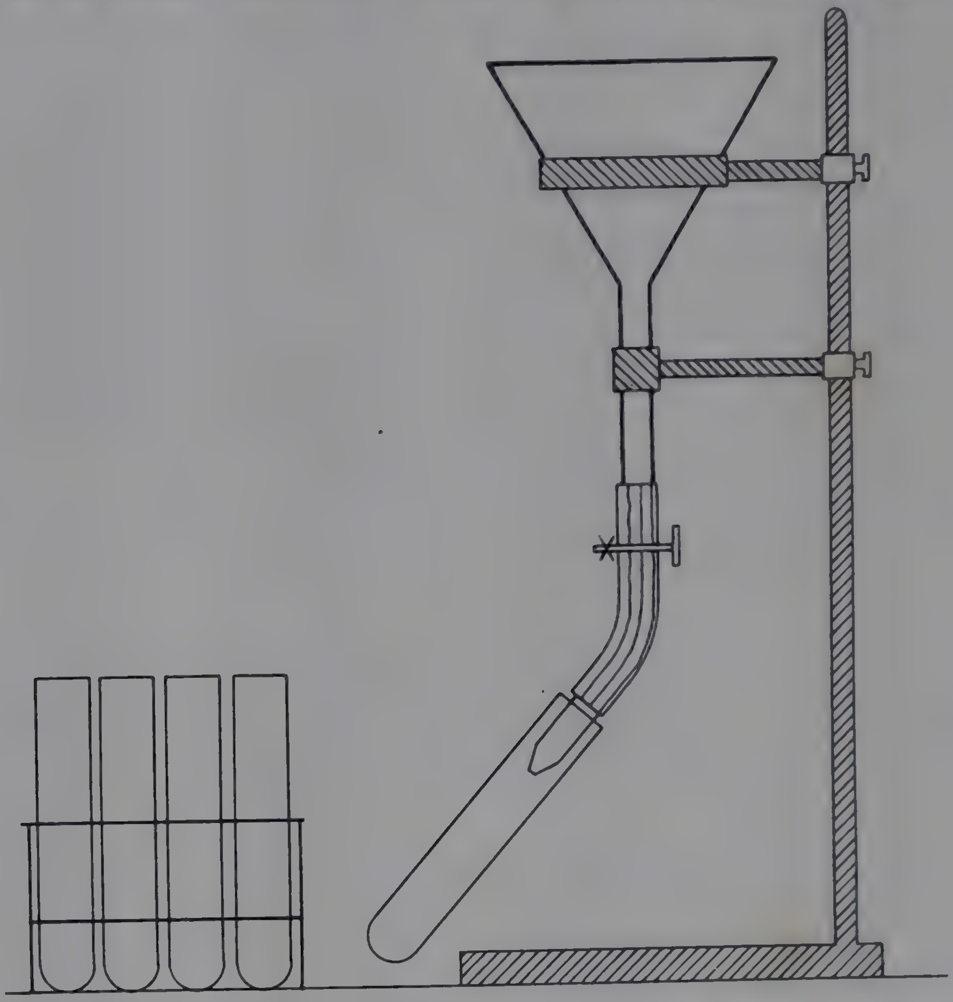

Fig. 334.—Apparatus for tubing culture media. (Courtesy Dr. Oscar Felsenfeld.)

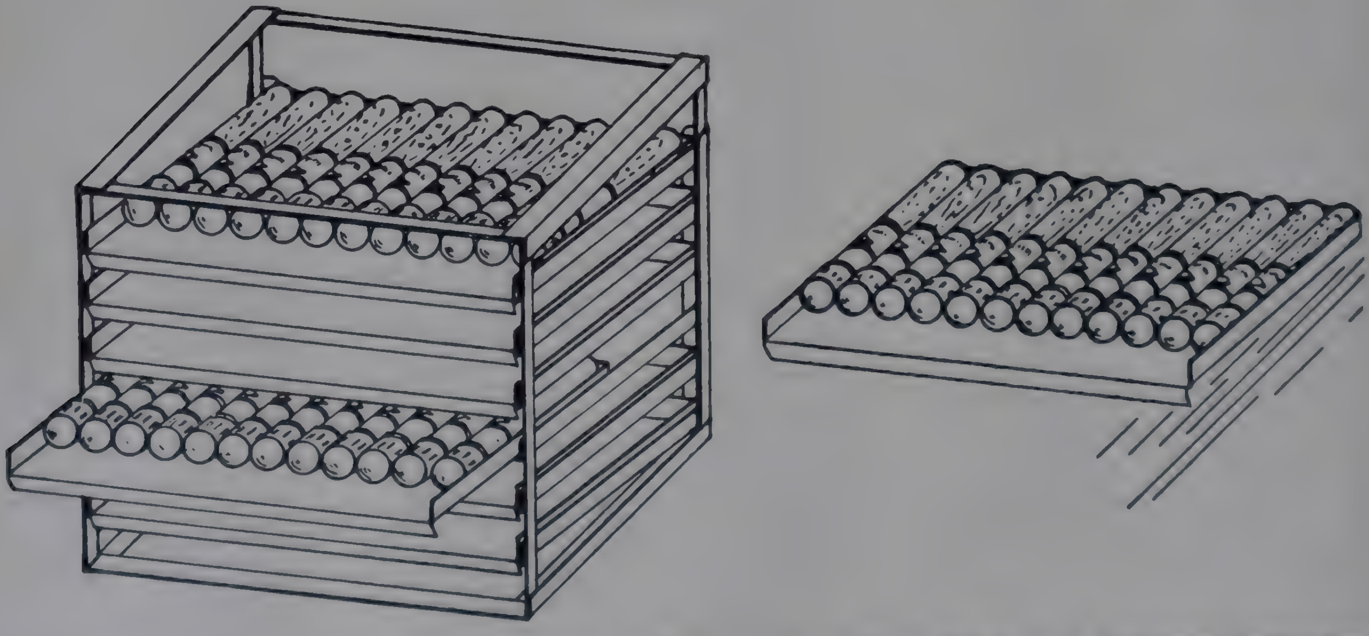

Fig. 335.—Bacteriologic tube cabinet, which retains culture tubes at a 5 degree angle for storage or incubation of slant surfaces in a horizontal plane. It may also be used for incubating fluid cultures when maximum surface contact is desired. (Courtesy Baltimore Biological Laboratory, Inc., Baltimore, Md.)

Protect the outlet of the apparatus against contamination during the operation by covering it with a sterile test tube between fillings.

All media tubed after sterilization must be checked for sterility by incubation at 37° C. for 24 to 72 hours, according to the medium.

(E) Preparation of Eggs.—

(1) Whole eggs.—

Scrub fresh eggs with soap, then wash with water, and put into 70% alcohol for 30 minutes or longer.

Prepare a large, strong-walled bottle containing numerous glass beads; plug with nonabsorbent cotton and sterilize in the dry heat oven.

Take the eggs out of the alcohol and wrap them in a sterile towel. When they are dry, open them with a sterile knife, nicking both ends, and collect the contents under sterile conditions in the sterile bottle. Shake the bottle until the eggs are homogeneous.

Take care not to touch the ends of the eggs after taking them out of the alcohol.

(2) Egg yolks.—

Clean and sterilize the egg shells as for the collection of whole eggs (1, above).

It is best for the operator to wear sterile rubber gloves. If he does not, then he must scrub his hands clean before handling the eggs.

Open the eggs by breaking the shell in the middle and parting the halves. Separate the yolks and the whites. Pour the yolks into the sterile bottle, and save the egg whites for other purposes.

Special Indicators Added to Culture Media

Andrade Indicator

One c.c. of Andrade indicator is used for each 100 c.c. of culture medium.

The medium containing the Andrade indicator is pink when hot, but becomes colorless when cooled to room temperature, if it is neutral or alkaline. It changes to a red or a deep pink when acid.

The method of preparation is given on the bottle if the acid fuchsin is purchased from a reliable chemical house. If the National Aniline Company's dye is used, dissolve 200 mg. of the acid fuchsin in 100 c.c. of distilled water.

It is suggested that if no technic of making the indicator is given on the label of the dye the worker use 500 mg. of acid fuchsin.

This solution turns a magenta red.

Add N/1 sodium hydroxide a drop at a time, and stirring after the addition of each drop until the solution turns from red, through pink, then to reddish brown, then to yellow.

The change in color is gradual, and the addition of the N/1 sodium hydroxide should be made very slowly, waiting several minutes after each few drops.

It usually requires 17 c.c. N/1 sodium hydroxide to bring the change in the color.

Phthalein Indicators

Use only reliable indicators; the Difco products are excellent.

(a) **Brom Thymol Blue.—**

Dissolve 0.4 gm. brom thymol blue
in 12.8 c.c. of N/20 sodium hydroxide by grinding in a mortar.
Dilute to 100 c.c. with distilled water.
Use 2 to 4 c.c. for each 1000 c.c. of culture medium.

(b) **Brom Cresol Purple.—**

Dissolve 0.4 gm. of brom cresol purple
in 13.8 c.c. of N/20 sodium hydroxide by grinding in a mortar.
Dilute to 100 c.c. with distilled water.
Use 2 to 4 c.c. for each 1000 c.c. of culture medium.

(c) **Phenol Red.—**

Dissolve 0.4 gm. phenol red
in 23.5 c.c. of N/20 sodium hydroxide by grinding in a mortar.
Dilute to 100 c.c. with distilled water.
Use 2 to 4 c.c. for each 1000 c.c. of culture medium.

Methods of Adjusting the Reaction of Culture Media*

Note.—N/10 solutions are always used in the titration of culture media to insure accuracy of results. N/1 solutions are used to adjust the reaction in order not to interfere too much with the total volume of medium.

(1) Colorimetric or Hydrogen Ion Method of Adjusting the Reaction of Culture Media to pH 7.2 to 7.6.—

Materials needed.—

Buret containing N/10 sodium hydroxide, filled to mark *0*.
0.02% phenol red indicator (aqueous). (Page 32.)
0.02% cresol red indicator (aqueous). (Page 32.)
1 c.c. pipette graduated in 0.1 c.c.
10 c.c. pipette.
Measuring cylinder, 100 c.c. capacity, graduated in 1 c.c.
Buffer solutions of pH 7.0, 7.2, 7.4, 7.6, 7.8, or an indicator color chart such as that found in Lubs: *The Determination of Hydrogen Ions* or Plate XL.
5 c.c. pipette for measuring the buffer solutions.
Test tubes for buffer solutions, and for the medium after it is adjusted.
Casserole.
N/1 sodium hydroxide solution.
N/10 hydrochloric acid.
Stirring rod.

Technic.—

Place 5 c.c. of each buffer in its respective tube, each tube labeled with the pH value of the buffer, and the name of the indicator. Add 0.5 c.c. 0.02% phenol red indicator to each tube.

Prepare a similar set of tubes, using cresol red indicator.

If the indicator chart is used, the buffer solutions may be omitted.

Place 10 c.c. of the medium to be adjusted in a casserole.

Add 1 c.c. phenol red indicator. If the medium is acid, it will turn yellow; if it is neutral, it will turn the orange color of the standard of pH 7.0 with phenol red indicator; if it is alkaline, it will turn red.

If it is acid, add the N/10 sodium hydroxide from the buret, a drop at a time, stirring constantly, until the solution in the casserole changes from yellow through orange to the red of the standard of pH 7.2, 7.4, 7.6 with phenol red indicator.

This is the end point. It may be desirable to place the medium in the casserole into a test tube to compare it with the buffer or the chart. Read from the buret the number of c.c. of N/10 sodium hydroxide used.

Calculation.—

Calculate the number of c.c. of N/10 sodium hydroxide required to adjust the reaction of the total quantity of culture medium made.

Divide this number by 10 to obtain the number of c.c. of N/1 sodium hydroxide to be used.

Add the N/1 sodium hydroxide to the medium, and mix thoroughly. Test the adjusted medium.

Example.—

It required 0.8 c.c. N/10 sodium hydroxide to adjust the reaction of 10 c.c. of culture medium. It will take 100 times 0.8 c.c., or 80 c.c., N/10 sodium hydroxide to adjust the reaction of 1000 c.c. culture medium. 1/10 of this quantity, or 8 c.c. of N/1 sodium hydroxide, is required to adjust the reaction of the medium. Add the 8 c.c. N/1 sodium hydroxide to the medium, and mix. The medium must be tested after the addition of the sodium hydroxide.

---

*See hydrogen ion concentration, pp. 29 ff.

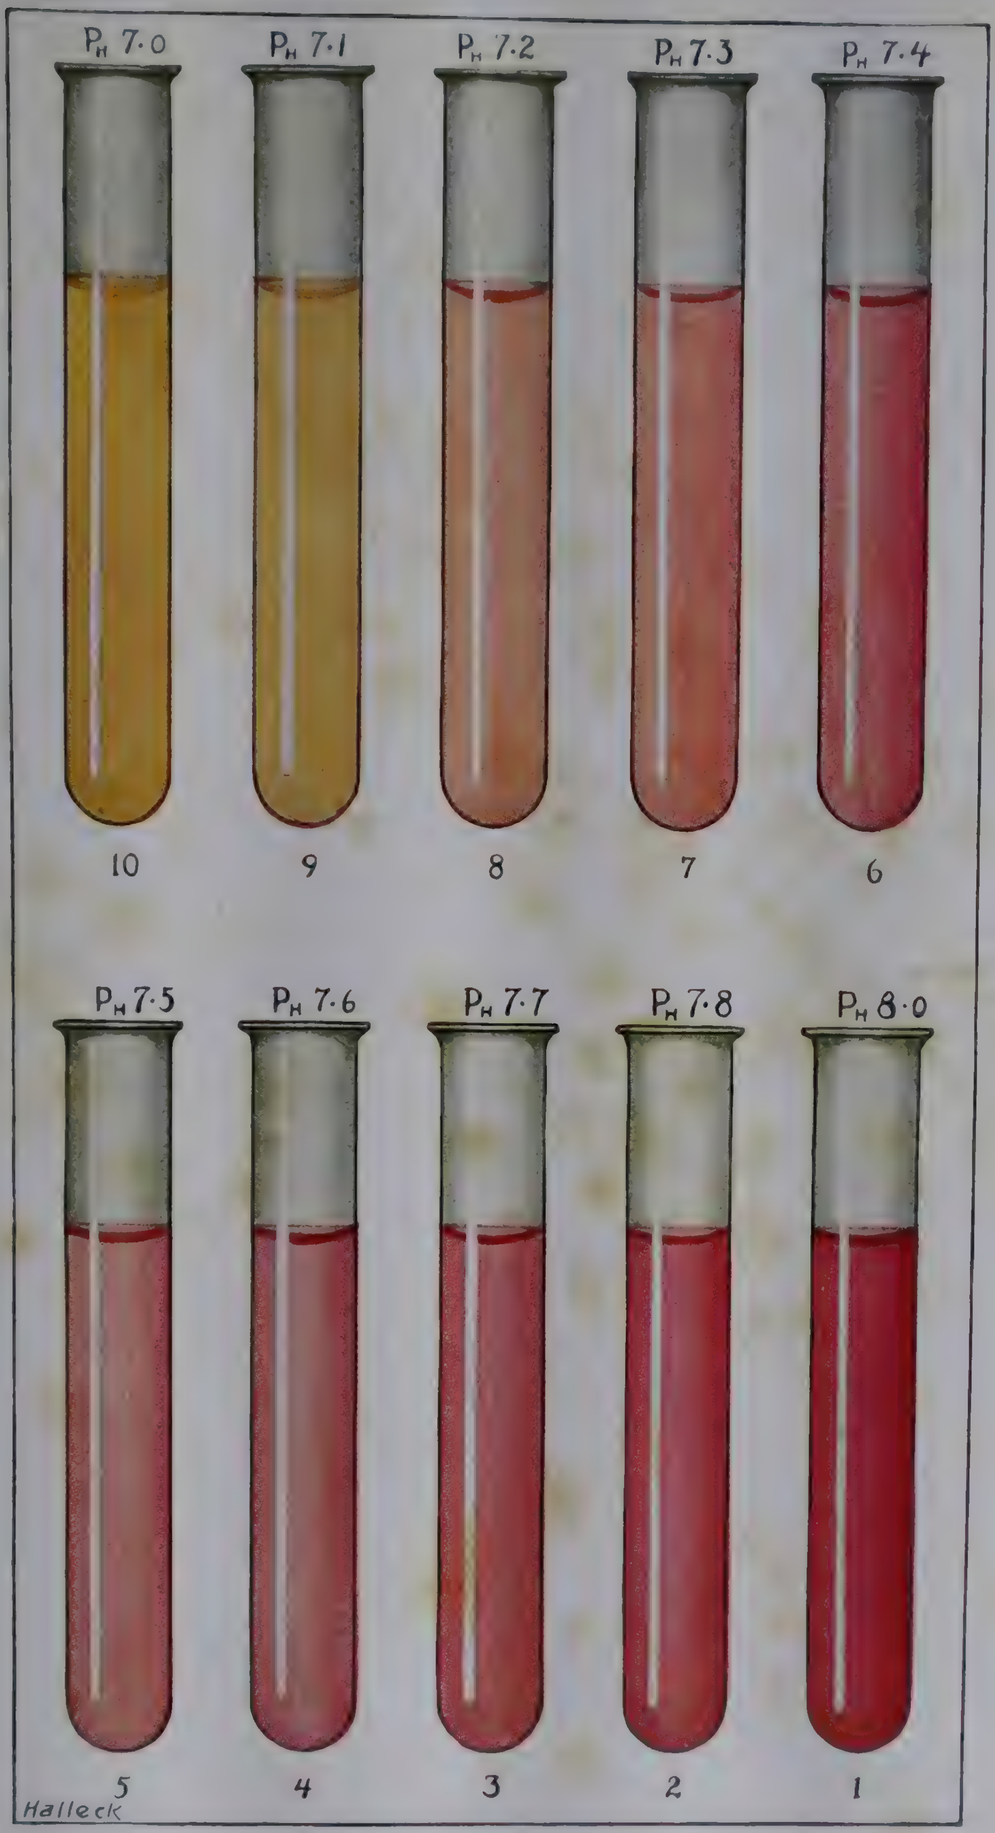

PLATE XL.—CHART SHOWING APPROXIMATELY THE TINTS PRODUCED BY ADDING PHENOLSULPHONEPHTHALEIN (PHENOL-RED) TO A SERIES OF PHOSPHATE SOLUTIONS OF THE H ION CONCENTRATIONS INDICATED IN EACH CASE BY pH.

(From Macleod: Physiology in Modern Medicine, The C. V. Mosby Co.)

Testing the Result.—

Place 5 c.c. of the adjusted medium in each of two test tubes.

To one of the tubes, add 0.5 c.c. of 0.02% phenol red indicator, and to the other, add 0.5 c.c. of 0.02% cresol red indicator.

Compare the colors of the two tubes with their respective standards. The tube containing the phenol red indicator should match the standard containing phenol red at the same point as the tube containing the cresol red indicator matches its standard. If this point is the desired end reaction, then the medium has been properly adjusted.

A solution at pH 7.6 reacts orange to phenol red and yellow to cresol red.

If too much sodium hydroxide has been added, titrate back to the desired pH, using hydrochloric acid in the buret.

(2) Colorimetric or Hydrogen Ion Method of Adjusting the Reaction of Culture Media to Other pH Values.—

The technic is the same as the above, but the end point is different. The sodium hydroxide is added to the medium in the casserole until it changes from yellow through orange to the red color of pH 8.0, as seen by matching with the color of the standard of that reaction.

After the medium has been adjusted, it reacts orange to cresol red, and red to phenol red.

If a medium of pH 7.0 is required, use phenol red as indicator because it changes color near this point. Alkalinize the fluid with N/10 sodium hydroxide until pink, then add N/10 hydrochloric acid until it turns just yellow.

(3) **Use of the potentiometer** is explained on pages 35 ff.

(4) **Use of indicator papers** is explained on pages 29 ff. and 43.

(5) **The pH of desiccated (dehydrated) commercially prepared media** is already adjusted. Any interference with it might spoil the medium.

Formulas of Culture Media

Formulas of culture media listed herein are numbered consecutively as M-1, M-2, etc., at the left of the medium.

M-1. Peptone Water.—

Peptone*	10 or 20 gm.
Sodium chloride	5 gm.
Distilled water	1000 c.c.

Dissolve the peptone and the salt in the water.

Filter through filter paper, if necessary.

Adjust the reaction to pH 7.4 to 7.6. For cholera work, pH 7.8 to 8.2 is favorable.

Distribute into test tubes or bottles.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

M-2. Meat Extract Broth.—

Peptone	10 gm.
Sodium chloride	5 gm.
Beef extract	3 gm.
Distilled water	1000 c.c.

Weigh the beef extract on a piece of wax paper.

Heat some of the water to 60° C. in a beaker. Drop the paper with the beef extract into the beaker.

Dissolve the salt and the peptone in some water.

Mix the beef extract solution and the salt-peptone solution.

Add the rest of the water. Filter through filter paper.

---

*Instead of peptone, tryptose, tryptone, thiotone, polypeptone, trypticase, or neopeptone may be used.

Adjust the reaction to pH 7.2 to 7.4

Distribute into test tubes or flasks.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

BBL extract broth, 18 gm. desiccated powder dissolved in 1000 c.c. distilled water, may be used instead of the above formula.

M-3. Trypticase Soy Broth, BBL.—

Trypticase	17	gm.
Phytone	3	gm.
Sodium chloride	5	gm.
Dipotassium phosphate	2.5	gm.
Dextrose	2.5	gm.

Suspend 30 gm. of the powder in 1000 c.c. of distilled water.

Mix thoroughly.

Warm gently until solution is complete.

Dispense and sterilize in the autoclave at not over 15 pounds pressure (121° C.) for 15 minutes.

If desired, 0.5 to 1.0 gm. of agar may be added per liter of broth before sterilization.

M-4. Infusion Broth—From Meat, Heart, Liver, or Brain.—

(a) Chop meat, heart, liver, or brain, and mix 500 gm. of it for "single strength" or 1000 gm. for ''double strength'' infusion with 1000 c.c. distilled water, in an enamel or stainless steel pot.

Let stand at 4° to 6° C. overnight, in the refrigerator.

Skim off the fat with a metal or enamel spoon.

Heat to 45° C. in a water-bath and keep at this temperature for one hour.

Boil without stirring for 30 minutes.

Filter through glass wool.

Dilute to 1000 c.c. with distilled water.

(b) Add tryptose or trypticase	10 gm.;	double strength	20 gm.
sodium chloride	5 gm.;	double strength	10 gm.

Adjust the reaction to pH 7.4 to 7.6. Heat to the boiling point, allow to cool, and adjust the reaction, if necessary.

Distribute in test tubes or flasks.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

Bacto-Heart Infusion Broth With Tryptose or BBL-Infusion Broth With Thiotone is prepared by dissolving 25 gm. of the desiccated powder in 1000 c.c. of distilled water.

M-5. Broth With Fermentable Substances.—

(a) Add to each 100 c.c. of peptone water (formula M-1) or extract broth (formula M-2) or cystine trypticase base (formula M-6), after the reaction is adjusted, 0.4 c.c. of a suitable indicator, such as 0.4% brom thymol blue, brom cresol purple, or phenol red.

Distribute 5 c.c. amounts into test tubes, preferably with screw caps.

Sterilize in an autoclave for 20 minutes at 15 pounds pressure.

Ready-made broth bases for fermentation studies are available as Bacto or BBL phenol red broth base and purple broth base. BBL phenol broth base with meat extract is also available.

(b) Sterilize 5 or 10% solutions of the carbohydrates, glucosides, or alcohols by filtration through a Seitz or Berkefeld filter.

(c) Add to each tube 0.5 c.c. of the 5% solution, or 0.25 c.c. of the 10% solution of the fermentable substance, with a sterile pipette, under sterile conditions.

M-6. Cystine Trypticase Agar Base.—

Cystine	0.5	gm.
Trypticase	20.0	gm.
Agar	3.5	gm.
Sodium chloride	5.0	gm.
Sodium sulph*ite*	0.5	gm.
Phenol red	0.017	gm.
Dissolve in distilled water	1000	c.c.

The final reaction will be pH 7.3±.

Suspend 29.5 gm. of the BBL powder in 1 liter of distilled water.

Add carbohydrate (0.5 or 1.0 per cent as preferred) if desired. Addition of more than 0.5% carbohydrate may necessitate adjustment of the pH, but with most carbohydrates there will be relatively little change in the reaction.

Mix thoroughly.

Heat gently with frequent agitation.

Boil for about 1 minute, or until solution is complete.

Tube and sterilize at 115° to 118° C., never over 12 pounds pressure, for 15 minutes.

Cool in an upright position and store at room temperature.

Do not refrigerate.

M-7. Serum and Ascitic Fluid Broth With Fermentable Substances.—

Proceed as above (a) to (c). After the fermentable substance has been added, add to each tube 0.5 c.c. of serum or ascitic fluid sterilized by filtration through a Seitz or Berkefeld filter.

Test all tubes for sterility by incubation at 37° C. for 48 hours.

M-8. Nitrate Broth.—

Dissolve 10 gm. tryptone
0.1 gm. potassium nitrate
in 1000 c.c. distilled water.

Adjust the reaction to pH 9.0 to 9.4.

Distribute in 3.5 c.c. amounts in test tubes.

Sterilize in the autoclave for 15 minutes at 15 pounds pressure.

M-9. Tryptose Blood Sodium Azide Broth, Pike.*—

To each 100 c.c. of beef heart infusion broth prepared according to formula M-4 but with 1% tryptose,
add 2 c.c. of 2% sterile solution of dextrose
and 5 c.c. of defibrinated rabbit blood.

Distribute into test tubes, 2 c.c. in each.

For use, add to each tube
0.15 c.c. of 1:1000 solution of sodium azide
0.10 c.c. of 1:25,000 solution of crystal violet.

M-10. Loeffler Blood Serum Medium.—

(a) **Preparation of the blood serum.**

Obtain beef blood in a sterilized, colorless wide-mouth quart bottle.

Allow coagulation to take place without agitation of the container or contents.

Place in the refrigerator until coagulation is complete.

Loosen the clot from the sides of the bottle by means of a sterile stirring rod.

Place in the refrigerator until the serum separates from the clot.

Remove the serum from the clot either with a transfer pipette or by pouring it into a glass container.

Centrifuge the serum in 50 c.c. centrifuge tubes at high speed for fifteen minutes under sterile precautions.

Decant the clear straw-colored supernatant serum, placing it is a glass container.

(b) **Preparation of the medium.**—

Dissolve 1 gm. dextrose
in 100 c.c. of meat infusion broth (formula M-4).

Add 300 c.c. fresh blood serum (cow, sheep, horse, or pig).

Distribute into sterile test tubes.

Slant in the autoclave.

Inspissate and sterilize as directed on page 1395.

Difco-Loeffler blood serum, 80 gm., dissolved in 1000 c.c. distilled water, and BBL-Loeffler's medium, 83 gm., dissolved in 1000 c.c. distilled water, may be used instead of the above medium.

---

*Proc. Soc. Exper. Biol. & Med. 57: 186, 1944.

M-11. Ulrich Milk.[*]—

Skim milk	100 c.c.
Methylene blue	0.005 gm.
Chlorphenol red	0.015 gm.
Distilled water	1000 c.c.

Final reaction is pH 6.5±.

Rehydrate BBL or Difco Ulrich milk by the addition of 100 gm. of the powder to a liter of distilled water, preferably preheated to 50° C.

Sterilize at 113° to 115° C. for 20 minutes, or by fractional steam sterilization for 30 minutes on 3 successive days. Avoid overheating and the consequent caramelization which readily occurs.

The uninoculated medium is bluish-gray. The color reactions in inoculated media vary with the amount of peptonization, degree of acidity, or reduction, and other changes produced by the growing organisms, but in general they are as follows:

Uninoculated medium	bluish-gray
Acid	pale yellow-green to yellowish-orange
Alkaline	pale bluish-purple to reddish-purple
Oxidation	bluish-green
Reduction	white
Alkaline, with peptonization	transparent reddish-purple

M-12. Chopped Meat Medium, Robertson.—

Beef heart, Difco	454 gm.
Proteose-peptone No. 3	20 gm.
Dextrose	2 gm.
Sodium chloride	5 gm.

This is **Bacto-Cooked Meat Medium.** Suspend 12.5 gm. of the desiccated product in 100 c.c. of cold distilled water.

After 15 minutes distribute, under constant shaking, into large test tubes, so that each tube will be filled to one-third with meat and to two-thirds with the supernatant fluid.

Sterilize in an autoclave for 15 minutes at 15 pounds pressure.

If the tubes are not used the same day, they should be heated in a boiling water bath for a few minutes shortly before use.

The final pH of the sterilized medium should be 7.2.

M-13. Meat Extract Agar.—

According to the concentration of agar desired, that is, 1.5%, or 2%, soak 15 or 20 gm. agar in 1000 c.c. extract broth (formula M-2) for 15 minutes.

Dissolve the agar *either* by careful heating over a flame *or* on an electric plate, *or* by autoclaving.

Adjust the reaction to pH 7.4 to 7.6

Dispense in tubes or bottles, as desired.

Sterilize for 25 minutes at 15 pounds pressure.

Difco or BBL nutrient agar, 31 gm. of the desiccated medium dissolved in 1000 c.c. of distilled water, is the same as the above formula.

For water analysis, use without sodium chloride.

M-14. Yeast Blood Agar, D'Anniello.—

(a) Yeast extract.—

Dissolve 10 gm. dehydrated yeast in 100 c.c. warm distilled water, stirring with a glass rod.

When dissolved, boil for 10 minutes, no longer.

Filter through gauze and cotton.

Place in a refrigerator for 48 hours.

Decant the supernatant fluid and sterilize by filtration through a Seitz filter.

Store in a refrigerator.

---

[*] Science 99: 352, 1944.

(b) **Agar Base.**—

Dissolve Difco blood agar base ---------- 40 gm.
Bacto agar ---------- 5 gm.
in 100 c.c. distilled water by heating.

Distribute into flasks, 500 c.c. to each flask.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

(c) **Medium.**—

Melt 500 c.c. agar base and cool to 45° C.

Add, with sterile precautions, 50 c.c. of yeast extract and 35 c.c. defibrinated blood.

Pour in plates.

M-15. Meat Infusion Agar.—

Infusion broth, double strength, formula M-4	500 c.c.
Agar	15 to 20 gm.
Distilled water	500 c.c.

Dissolve the agar in the distilled water by autoclaving *or* by careful heating. Mix the agar solution and infusion.

Readjust the reaction to pH 7.0.

Distribute into tubes or flasks.

Sterilize in the autoclave at 15 pounds pressure for 20 minutes.

M-16. Tryptose Agar, Difco.—

This contains 20 gm. tryptose, 1 gm. dextrose, 5 gm. sodium chloride, and 15 gm. Bacto-agar for each 1000 c.c.

Dissolve 41 gm. of the desiccated medium in 1000 c.c. of distilled water, distribute in tubes, and sterilize in the autoclave for 20 minutes at 15 pounds pressure.

M-17. Trypticase Agar (Eugonagar*).—

Trypticase	15.0 gm.
Phytone	5.0 gm.
Sodium chloride	4.0 gm.
Sodium citrate	1.0 gm.
Sodium sulphite	0.2 gm.
l-Cystine	0.2 gm.
Dextrose	5.0 gm.
Agar	15.0 gm.
Distilled water	1000 c.c.

Final reaction will be pH 7.0 ±.

Suspend 45.4 gm. BBL Eugonagar, dehydrated, in 1 liter of distilled water.

Allow the mixture to stand for about 5 minutes, and mix until the suspension is uniform.

Heat gently with occasional agitation, and boil for 1 or 2 minutes, or until solution has occurred.

Dispense and sterilize at 118° C. (12 pounds steam pressure) for 15 minutes.

M-18. Trypticase Soy Agar.—

Trypticase	15 gm.
Phytone	5 gm.
Sodium chloride	5 gm.
Agar	15 gm.

Final reaction should be pH 7.3 ±.

Suspend 40 gm. of the BBL powder in a liter of distilled water.

Allow to soak for 5 minutes and mix thoroughly.

Heat gently, with occasional agitation.

Boil for a minute or two or until solution is complete.

---

*Vera: J. Bact. 54: 14, 1947.

Dispense, and sterilize at 118° to 121° C. (15 pounds pressure) for 15 minutes when test tubes are used. If large volumes are used, the time but not the temperature may be increased.

For the preparation of blood plates for hemolysis studies, add 5% defibrinated blood to sterile trypticase soy agar which has previously been melted and cooled to about 45° C.

M-19. Dextrose Agar.—

(a) Sterilize 20% solution of dextrose by filtration.

(b) Melt sterile tryptose agar, M-16, or heart infusion agar, M-15.

(c) Add to 100 c.c. of melted agar, 0.5 c.c. dextrose solution (a), and mix. Pour in plates.

M-20. Penicillinase Media.—

To each 5 c.c. of trypticase soy broth (formula M-3), tryptose citrate broth (formula M-24), brain heart infusion broth (formula M-4), or other liquids used for blood cultures, add, with sterile precautions, just prior to inoculation, 0.1 c.c. of 1:100 solution of penicillinase Schenley or Difco. Do not reheat or store.

M-21. Sodium Azide Agar, Snyder and Lichtenstein.*—

Add to each 100 c.c. of blood agar (formulas M-28 or M-29), before pouring, 2 c.c. of 1% solution of sodium azide in distilled water.

Difco sodium azide blood agar base may be used.

M-22. Sodium Azide-Chloral Hydrate Blood Agar.—

(a) Prepare a 1% watery solution of sodium azide and sterilize by filtration through a Seitz filter.

(b) Prepare a 0.1% watery solution of chloral hydrate and sterilize by filtration.

(c) Prepare yeast blood agar as indicated under M-14, but just before pouring plates add to each 500 c.c.

10 c.c. of the sodium azide solution (a)
1 c.c. of the chloral hydrate solution (b).

(d) Pour plates.

M-23. Phenylethyl Alcohol Medium.—

Trypticase	15 gm.
Phytone	5 gm.
Sodium chloride	5 gm.
β-Phenylethyl alcohol	2.5 gm.
Agar	15 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.3 ±.

Suspend 42.5 gm. of the BBL dehydrated product in a liter of distilled water.

Allow to stand for 5 minutes and mix thoroughly.

Heat gently with occasional agitation.

Boil for 1 to 2 minutes or until solution is complete.

Dispense, and sterilize at 118° to 121° C. (12 to 15 pounds pressure) for 15 minutes.

To prepare blood plates, add 5% defibrinated blood to sterile phenylethyl alcohol medium which has been previously melted and cooled to about 45° C.

This medium is not to be depended upon for determination of hemolytic reactions, since atypical reactions may be observed. The usual blood agar plates may be made in parallel to determine the degree of inhibition provided by phenylethyl alcohol medium, and for determination of hemolysis.

A "brown-sugar" appearance is characteristic of the dehydrated product, and is not, therefore, an indication of deterioration.

M-24. Tryptose Citrate Broth, Huddleson.—

Dissolve 20 gm. tryptose
5 gm. sodium chloride
1 gm. dextrose
5 mg. thiamine
10 gm. sodium citrate crystals
in 1000 c.c. distilled water.

---

*J. Infect. Dis. 67: 113, 1940; 68: 113, 1941.

Adjust the reaction to pH 7.0.

Fill 20 c.c. amounts in 50 c.c. vaccine bottles.

Insert cotton plugs.

Sterilize in an autoclave for 20 minutes at 15 pounds pressure.

Exchange cotton plugs for sterile rubber diaphragm stoppers.

M-25. Castãneda Medium.*—

(a)	Tryptose	20 gm.
	Sodium chloride	5 gm.
	Sodium citrate	5 gm.
	Agar	30 gm.

Dissolve in 1000 c.c. distilled water by heating.

Put into 100 c.c. flat bottles, 15 c.c. per bottle.

Sterilize in an autoclave for 15 minutes at 15 pounds pressure.

Allow to solidify, laying the bottles on the flat side.

(b)	Tryptose	20 gm.
	Sodium citrate	20 gm.

Dissolve in 1000 c.c. distilled water.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

(c) When the surface of agar (a) is hard, cover it with about 10 c.c. of the tryptose-citrate solution (b).

(d) Exchange the cotton plugs of the bottles for sterile rubber caps and test for sterility after incubating for 24 hours at 37° C.

M-26. Liver Infusion Agar.—

Liver infusion, double strength, formula M-4	500 c.c.
Tryptose or trypticase	10 gm.
Agar	20 gm.
Distilled water	500 c.c.

Dissolve the ingredients in distilled water by heating.

Add the liver infusion.

Filter through glass wool.

Adjust the reaction to pH 7.0

Keep in boiling water bath for 20 minutes.

Filter again.

Adjust the reaction to pH 7.0

Distribute in flasks and sterilize in the autoclave for 30 minutes at 15 pounds pressure.

Bacto-liver infusion agar, 55 gm. per 1000 c.c., is an easily prepared substitute for the above formula.

M-26a. Liver Infusion Agar With Dyes, Huddleson.—

Prepare liver infusion agar (formula M-26), final pH 6.6 to 6.8.

(a) **Crystal Violet Plates.**—

Sterilize 1:700 solution of crystal violet in distilled water by steaming 1 hour.

To each 100 c.c. of the melted and sterile liver infusion agar and 0.1 c.c. of crystal violet solution. Pour in plates.

(b) **Basic Fuchsin Plates.**—

Weigh 1 gm. basic fuchsin and transfer to an Erlenmeyer flask.

Add 100 c.c. sterile distilled water.

Keep in boiling water bath for 20 minutes.

Add 0.4 c.c. of hot basic fuchsin solution to each 100 c.c. of the melted liver infusion agar.

Pour in Petri plates.

(c) **Thionin Plates.**—

Prepare 1% thionin solution just like the basic fuchsin solution above.

To each 100 c.c. of the melted liver infusion agar add 0.2 c.c. thionin solution.

Pour in plates.

---

*Proc. Soc. Exper. Biol. & Med. 64: 114, 1947.

M-27. Blood Agar Base.—

This medium is identical with the foregoing formula M-15 except that a peptone such as tryptose, thiotone, or trypticase, more favorable for the growth of fastidious organisms, is substituted for the simple peptone.

Difco-blood agar base with tryptose and BBL-blood agar base with thiotone, 40 gm. of the desiccated powder dissolved in 1000 c.c. distilled water, are excellent for this purpose.

M-28. Blood Agar. Method No. 1.—

Blood agar is a mixture of sterile blood in sterile blood agar base (formula M-27). As it cannot be sterilized after it is made, it is necessary to use the utmost care in preparing it.

For blood agar, rabbit's blood is preferable to human blood, as it does not inhibit the growth of pathogenic bacteria to the same extent as human blood. The blood must be taken in a sterile manner and must be kept sterile throughout the entire procedure. The agar to be used should be blood agar base (formula M-27) previously made and sterilized. It should be liquefied and kept at a temperature between 47° and 50° C. to prevent hemolysis of the blood cells that are to be added.

The medium may be made either in sterile Petri dishes or in sterile test tubes.

(a) Procuring the blood.

Assemble the following:

Rabbit and rabbit board.
Necessary equipment for ether anesthesia.
5 c.c. Luer syringe with a 21 gauge, 1½-inch needle previously sterilized in the dry heat sterilizer at 170° C. two hours.
A bottle, 100 c.c. wide mouth, to which have been added 10 drops of 20% solution of neutral potassium or sodium oxalate. The bottle and contents have been sterilized in the dry heat sterilizer at 170° C. for two hours. The sodium oxalate remains as a fine white powder in the bottom of the bottle.
Tincture of iodine.
Sterile sponges.
Alcohol to remove the iodine.
Bunsen burner.

Place the animal on the animal board.

Shave the skin over heart area.

Give the animal a light anesthetic.

Locate the heart by palpation.

Place a generous quantity of iodine on the skin over the area of the heart to sterilize the surface.

Plunge the needle attached to the syringe into the heart and withdraw 5 c.c. of blood.

Flame the mouth of the bottle containing the sodium oxalate.

Eject the contents of the syringe into the bottle, flaming the needle before ejecting the blood. Replace the cork.

Shake the bottle vigorously to oxalate the blood.

Remove the iodine from the animal's chest with alcohol, and release from board.

(b) Preparing the agar.

Sterile blood agar base (formula M-27) in tubes should be liquefied and kept at a temperature between 47° and 50° C. If blood agar is to be made in slants, there should be 5 c.c. agar in each tube; if it is to be made in 75 mm. Petri dishes, use tubes containing 10 c.c. agar; if using 100 mm. Petri dishes, use tubes containing 15 c.c. agar base.

(c) To make blood agar in Petri dishes.

Place in the center of a sterile Petri dish 0.5 c.c. of the oxalated blood, using a sterile pipette to measure the blood. If 100 mm. Petri dishes are used, use 0.75 c.c. of blood. Care should be taken to exclude all possibility of air contamination during this procedure.

Add to the Petri dish enough liquefied agar (temperature 47° to 50° C.) to fill the plate. Mix thoroughly by rotating the plate. Be sure that an even mixture is obtained. Bubbles are undesirable, because they obscure colony study.

Allow to solidify.

(d) **To make blood agar in test tubes.**

The blood agar base (formula M-27) should be in 5 c.c. quantities in test tubes. Liquefy and keep at a temperature of 47° to 50° C. in a water-bath. Using sterile precautions, add 0.25 c.c. of the oxalated blood to each test tube by means of a sterilized graduated 1 c.c. pipette.

Replace the cotton plug, and rotate the tube vigorously between the palms of the hands.

Slant immediately and allow to solidify.

Place in the incubator at 37° C. for three days for sterility test.

M-29. Blood Agar. Alternate Formula.—

Melt blood agar base (formula M-27), and when cooled to 45° C. add to each 100 c.c. of the medium 5 c.c. of sterile defibrinated human, rabbit, or horse blood.

If the base is kept in tubes each containing 15 c.c. agar, melt the agar by placing tubes in the water bath and add to each tube, when cooled to 45° C., 0.75 c.c. blood using a sterile syringe.

Pour into sterile Petri dishes.

Before solidification, flame the surface of the plates with a Bunsen burner, to free the plate of air bubbles.

M-30. Blood Dextrose Cystine Agar, Francis.—

Dissolve 0.1 gm. cystine and
1.0 gm. dextrose in
100 c.c. of agar (formula M-15) in flowing steam for 1 hour.

Cool to 45° C. and add 7 to 8 c.c. of defibrinated rabbit blood.

Keep in water bath at 60° C. for 2 hours.

Pour in plates or dispense under sterile conditions into sterile test tubes.

Place in incubator for 24 hours to test sterility.

Difco-cystine heart agar, 102 gm. dissolved in 1,000 c.c. distilled water, duplicates the above formula.

M-31. Chocolate Agar.—

Melt blood agar base (formula M-27) and when cooled to 45° C. add to each 100 c.c. of the medium 5 c.c. of sterile defibrinated blood.

If the base is kept in tubes each containing 15 c.c. agar, melt the agar by placing tubes in the water bath and add to each, when cooled to 45° C., 0.75 c.c. of blood, using a sterile syringe.

Put the flask or tubes in a container of warm water. Raise the temperature very slowly to 95° C.

Pour into sterile Petri dishes, or slant the tubes.

M-32. Hemoglobin Chocolate Agar.—

Proteose-peptone No. 3, Difco	20.0 gm.
Bacto-dextrose	0.5 gm.
Sodium chloride	5.0 gm.
Disodium phosphate	5.0 gm.
Bacto-agar	15.0 gm.

Suspend 9 gm. in 100 c.c. of cold distilled water. Dissolve by steaming for a few minutes. Mix well and place in the autoclave for 15 to 20 minutes at 15 pounds pressure.

Dissolve 2 gm. Bacto-hemoglobin in 100 c.c. distilled water at 50° C.

When solution is nearly complete, filter through coarse moistened cheesecloth to remove undissolved particles.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

Cool both this sterile double strength agar and sterile solution of Bacto-hemoglobin to 50 to 60° C.

Mix in equal quantities under sterile conditions, avoiding air bubbles, and pour in sterile Petri dishes.

A satisfactory chocolate agar may also be prepared by adding 5 c.c. of fresh sterile defibrinated blood to 100 c.c. of sterile single strength proteose No. 3 agar at 80° C.

The single strength medium, without enrichment, is prepared by suspending 45 gm. Bacto-proteose No. 3 agar in 1000 c.c. cold distilled water.

Dissolve the medium by boiling for a minute or two. Distribute as desired. Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

The final reaction of the medium without enrichment should be pH 7.3.

M-33. Chocolate Agar With Supplement.—

Supplement A is a yeast concentrate with 1:6,000 crystal violet.

Suspend 22.5 gm. of Bacto-proteose No. 3 agar in 250 c.c. distilled water. Dissolve by boiling or holding in a boiling water bath.

Sterilize in the autoclave for 15 to 20 minutes at 15 pounds pressure.

Suspend 5 gm. Bacto-hemoglobin in 2500 c.c. distilled water, below 50° C. Shake well to obtain an even suspension. Sterilize in the autoclave for 15 to 20 minutes at 15 pounds pressure (121° C.).

Cool the sterile double strength agar and 2% hemoglobin solution to 50 to 60° C.

Mix under sterile conditions.

Add with sterile precautions 5 c.c. of Bacto-supplement A, and mix well. Pour into Petri dishes.

M-34. Hirschberg Transport Medium.*—

Dissolve 4.5 gm. proteose No. 3 agar, Difco
4.0 gm. gelatin
0.6 c.c. of 0.04% Nile blue A
0.5 gm. agar
in 80.0 c.c. distilled water.

Adjust the reaction to pH 7.4.

Sterilize in the autoclave for 15 minutes at 15 pounds pressure.

Cool to 50° C. and add 20 c.c. of sterile defibrinated horse blood. Heat to 80 to 95° C. until chocolate agar is formed.

M-35. McLeod-Sanders-Hullinghorst Medium.†—

(a) Bacto-proteose No. 3 agar	45 gm.
Agar	5 gm.

Dissolve in 1000 c.c. distilled water by heating.

Sterilize in an autoclave at 15 pounds pressure for 20 minutes.

(b) 10% yeast extract (*see* Yeast Agar M-14).

(c) Before use, melt agar (a) and add to each 100 c.c.

Yeast extract (b)	10 c.c.
Human blood	7.5 c.c.

This medium may be heated to 80° C. and kept at that temperature until chocolatized.

(d) Pour plates.

M-36. Carpenter Medium No. II.‡—

(a) Proteose-peptone No. 3	15 gm.
Sodium chloride	5 gm.
Dipotassium phosphate (K_2HPO_4)	4 gm.
Monopotassium phosphate (KH_2PO_4)	1 gm.
Agar	20 gm.
Cornstarch	1 gm.

Dissolve in 1000 c.c. distilled water by heating.

This medium is available in desiccated form from Difco, Inc., under the name Bacto G.C. Medium.

Place in 100 c.c. quantities in 500 c.c. flasks, and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

(b) Agitate 10 gm. Bacto-hemoglobin in 500 c.c. distilled water for 10 minutes or longer, then filter through gauze to remove undissolved particles.

---

*South. M. J. 38: 493, 1945.

†Am. J. Pub. Health 41: 10, 1951.

‡Am. J. Syph. 33: 163, 1949.

Dispense in 100 c.c. amounts and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

(c) Before use, melt base (a), and add an equal amount of hemoglobin solution (b), and 1% Difco Supplement B.

(d) Pour plates.

M-37. Hormone-Brom Cresol Purple Agar, Gradwohl.—

(a) **Preparation of Ascitic Fluid for Use in Cultivation of the Gonococcus.**—Prepare a large (at least 2 quarts) colorless bottle, stoppered with a cork, by sterilizing it in the dry heat sterilizer.

Request the physician who is to collect the ascitic fluid not to place his finger over the end of the trocar, and to hold sterile paper or gauze over the bottle as the ascitic fluid is being collected. Use all aseptic precautions.

Place the ascitic fluid in the refrigerator until the sterility test has been completed.

Inoculate 3 tubes of M-47 and 3 of M-48, using the top of the fluid, fluid from the center, and from the bottom of the bottle. Place the ascitic fluid back in the refrigerator.

Place the 3 tubes in the incubator at 37° C. for 3 to 10 days. If no growth occurs in this time, the ascitic fluid is sterile and may be ampuled. If it is not sterile, it must be discarded.

If it is sterile, ampule, seal hermetically, and store in a refrigerator.

(b) **Preparation of the Base.**—Infuse 500 grams of lean chopped beef in 500 c.c. of distilled water in the refrigerator overnight.

The following morning, heat to 60° C.

Dissolve 20 grams agar in 500 c.c. distilled water by boiling.

Add the melted agar to the heated beef infusion, and bring to a vigorous boil.

Press through a wire gauze strainer. The filtrate will be very cloudy.

Add 20 grams Merck's peptone and 5 grams sodium chloride.

Heat to dissolve.

Adjust the reaction to pH 7.8-8.2.

Boil vigorously for about ten minutes to precipitate the phosphates.

Cool to 60° C. Dilute to volume with distilled water.

Stir in a mixture of one egg yolk in 10 c.c. distilled water.

Boil vigorously for fifteen minutes to coagulate the egg.

Allow to stand until flocculence of the egg has occurred.

Filter through glass or steel wool, carrying out the filtration in an Arnold steam sterilizer at a temperature just hot enough to keep the agar liquid. The filtrate should be crystal clear. Pour the filtrate back through the funnel if it is cloudy. This may have to be repeated several times.

To every 100 c.c. clarified agar add 1 gram levulose, c.p., and 2.5 c.c. 0.5% aqueous solution of brom cresol purple indicator.

Mix thoroughly.

Place in 10 c.c. quantities in test tubes.

Plug with nonabsorbent cotton.

Sterilize in the autoclave at 7 to 10 pounds pressure for forty-five minutes.

Place in the incubator for three days for sterility test before using.

Note.—If the medium is made in large quantities it keeps better in screw-cap vials than in cotton-plugged test tubes.

For use, melt a tube of the base (b) and cool to 45° C.

Place 2 to 3 c.c. ascitic fluid (a) in a sterile Petri dish, 75 mm. diameter.

Pour the base into the plate and mix by rotating the dish.

M-38. Glycerin Potato Veal Agar.—

Boil sliced potatoes with double volume of water. Filter through cotton.

To each 100 c.c. of filtrate add 40 c.c. glycerin.

Place in the autoclave for 30 minutes at 15 pounds pressure.

Melt 100 c.c. veal infusion nutrient agar (formula M-15).

Add 5 c.c. sterile potato glycerin mixture.

Pour into plates. Do not use plates for 24 hours after pouring.

M-39. Potato Glycerin Blood Agar, Bordet and Gengou.—

Potatoes, peeled and mashed	100	gm.
Glycerin	8	c.c.
Proteose-peptone	5	gm.
Sodium chloride	2.25	gm.
Agar	10	gm.
Distilled water	500	c.c.

Mix the potatoes and the glycerin with 200 c.c. distilled water. Boil, and when soft, dilute to volume with distilled water.

Strain through gauze.

Allow to settle.

Use the clear supernatant fluid.

To 100 c.c. of the supernatant fluid add the other ingredients, and the rest of the distilled water (300 c.c.).

Let soak for 15 minutes.

Dissolve by boiling.

Adjust the reaction to pH 6.4 to 6.6.

Distribute in flasks and sterilize in the autoclave for 25 minutes at 15 pounds pressure.

Before use, melt 100 c.c. of the base, let cool to 45° C., and add 20 c.c. of fresh human, rabbit, horse, or sheep blood.

Pour into plates.

The base may be purchased as Difco or BBL Bordet-Gengou Agar Base. Dissolve 40 gm. in 1000 c.c. of 1% glycerin in water as a substitute for the above formula.

M-40. Penicillin Agar, Bradford.*—

Add to medium M-39 (or to any other blood agar medium), just before pouring, 0.2 to 0.25 unit of penicillin for each c.c. of medium.

M-41. Tellurite Medium, Difco.—

Proteose-peptone No. 3	20	gm.
Bacto-dextrose	2	gm.
Sodium chloride	2	gm.
Agar	13	gm.

Suspend 40 gm. of Bacto-dextrose proteose No. 3 agar in 1000 c.c. cold distilled water. Boil for a minute or two to dissolve the medium, and distribute as desired. Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

Add 5 c.c. Bacto-tellurite blood solution to each 100 c.c. of sterile melted agar at 70 to 80° C. under sterile conditions.

Heat at 75 to 80° C. until it has the appearance of a ''chocolate'' agar and then cool to 50° C.

Distribute into sterile tubes or plates as desired.

Final reaction of the medium without enrichment is pH 7.4.

M-42. Tellurite Agar, BBL.—

Trypticase	20	gm.
Sodium chloride	5	gm.
Dextrose	2	gm.
Agar	20	gm.
Distilled water	1000	c.c.

The final reaction should be pH 7.5 ±.

Suspend 47 gm. of the BBL powder in a liter of distilled water.

Mix thoroughly until a uniform suspension is obtained.

Heat gently, with frequent agitation.

Boil for 1 or 2 minutes until solution is complete.

Sterilize at 118° to 121° C. (12 to 15 pounds pressure) for 15 minutes.

---

*Am. J. Pub. Health 36: 468, 1946.

To the sterile fluid agar, cooled to a temperature of about 50° C., add

Sterile serum (e.g., human)	50 c.c.
1% Tellurite, pH 9.0 to 9.5	5 or 10 c.c.

to each 1000 c.c. of medium.

Mix and pour into plates, using at least 20 c.c. of the complete medium in each plate. Plates so prepared should be usable for about 2 weeks if stored in a refrigerator.

If preferred, whole blood may be used instead of serum, and the tellurite concentration may be increased. However, colonial types may be less readily distinguished on the medium with blood, and inhibition of growth of some strains of Corynebacterium may occur when a higher tellurite content is employed.

M-43. Whitney-Damon Medium.*—

(a) Buffered water.—

M/15 disodium phosphate (Na_2HPO_4)	72 c.c.
M/15 monosodium phosphate (NaH_2PO_4)	28 c.c.
Distilled water	900 c.c.

Keep several bottles in stock.

(b) Tellurite solution.—

Grind 0.5 gm. potassium tellurite with 10 c.c. portions of buffer (a); pipette off and collect the supernatant fluid. A few drops of 10% potassium hydroxide may be added to facilitate solution. The final solution must be 0.5%. Sterilize by filtration through a Seitz filter.

(c) 10% watery solution of raffinose. Sterilize by Seitz filtration.

(d) Dissolve Difco-proteose No. 3 agar	45 gm.
in buffer solution (a)	1000 c.c.

Place in an autoclave at 15 pounds pressure for 15 minutes.

(e) Before use melt agar (d).

(f) Prepare a mixture of

Sterile human serum	60 c.c.
Raffinose solution (c)	48 c.c.
Tellurite solution (b)	12 c.c.

(g) Add 10 c.c. of mixture (f) to each 100 c.c. of base (d).

(h) Pour plates.

M-44. Elek, King, et al., Medium.†—

Proteose-peptone	20 gm.
Agar	15 gm.
Sodium chloride	2.5 gm.

Dissolve in 1000 c.c. distilled water.

Adjust the reaction to pH 7.8.

Place in 10 c.c. quantities in test tubes, and sterilize in an autoclave.

Before use, melt and add to each tube 2 c.c. of fresh, nonhemolytic rabbit or horse serum.

M-45. Phenol Red Mannitol Salt Medium, Chapman.—

Mannitol	10 gm.
Beef extract	1 gm.
Proteose-peptone No. 3, *or* Polypeptone	10 gm.
Sodium chloride	75 gm.
Agar	15 gm.
Phenol red	0.025 gm.

Suspend 111 gm. Difco or BBL phenol red mannitol salt agar in 1000 c.c. cold distilled water. Boil for 1 or 2 minutes to dissolve the medium.

Dispense, and sterilize in an autoclave for not more than 15 minutes at 15 pounds pressure.

The final reaction will be pH 7.4.

---

*Pub. Health Rep. **64**: 457, 1949.

†Am. J. Pub. Health **39**: 1314, 1949.

M-46. Chapman-Stone Medium.—

Yeast extract	2 to 2.5 gm.
Trypticase *or* Tryptone	10 gm.
Gelatin	30 gm.
d-Mannitol	10 gm.
Sodium chloride	55 gm.
Ammonium sulphate	75 gm.
Dipotassium phosphate	5 gm.
Agar	15 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.0 ±.

Suspend 20.2 gm. of the BBL or Difco dehydrated material in 100 c.c. of distilled water.

Allow to stand for 5 minutes.

Mix to obtain a uniform suspension.

Heat and boil for 1 or 2 minutes or until solution is complete.

Pour into plates while hot, being careful to avoid the formation of bubbles.

After solidification, the medium should be white and opaque.

If the medium cannot be used on the day of preparation, it should be dispensed and sterilized by autoclaving at 121° C. (15 pounds pressure) for 15 minutes.

M-47. Thioglycollate Medium, Brewer-Vera.—

To 750 c.c. of 2% polypeptone in water

Add 6 gm. dextrose
2.5 gm. sodium chloride
0.25 gm. l-cystine
0.1 gm. sodium sulph*ite*
0.5 gm. sodium thioglycollate
0.7 gm. agar dissolved in 250 c.c. distilled water.

Fill high columns of the liquid into large test tubes.

Sterilize in an autoclave for 20 minutes at 15 pounds pressure.

Store at room temperature.

Before use, heat to 80° C. for a few minutes and let cool.

This medium may be purchased in dehydrated form from Baltimore Biological Laboratories as thioglycollate medium. Dissolve 30 gm. in 1000 c.c. distilled water.

M-48. Fluid Thioglycollate Medium.—

Trypticase	15	gm.
l-Cystine	0.75	gm.
Dextrose	5	gm.
Yeast extract	5	gm.
Sodium chloride	2.5	gm.
Sodium thioglycollate	0.5	gm.
Resazurin	0.001	gm.
Agar	0.75	gm.

The Difco product contains casitone instead of trypticase and 0.3 c.c. thioglycollic acid instead of the sodium salt.

Suspend 29.5 gm. of the BBL or Difco powder in 1000 c.c. distilled water.

Allow to soak 5 to 10 minutes.

Mix thoroughly and then heat with occasional agitation of the medium.

Boil until solution is complete. The reaction must be pH 7.1.

Dispense in test tubes, filling them half full, using about 15 c.c. in 6 by ¾ inch tubes. If flasks are preferred, the ratio of surface to volume should be similar to that of tubes.

For maintenance of cultures, place a small quantity (approximately 0.1 gm.) of calcium carbonate ($CaCO_3$) in each tube before introducing the liquid.

Sterilize in the autoclave for 15 to 18 minutes at 15 pounds pressure.

Cool before use.

Store at room temperature, not in the refrigerator.

M-49. Thioglycollate Agar, Brewer.—

(a)	Polypeptone	20 gm.
	Sodium chloride	2.5 gm.
	Dextrose	10 gm.
	Agar	15 gm.
	l-Cystine	0.4 gm.
	Sodium thioglycollate	2 gm.
	Sodium formaldehydesulfoxylate	1 gm.
	Methylene blue, certified	0.002 gm.

Final reaction should be pH 7.2.

Preferably use the desiccated form produced by Baltimore Biological Laboratory. Use 51 gm. per 1000 c.c.

(b)	Trypticase	20 gm.
	Sodium chloride	5 gm.
	Agar	15 gm.
	Sodium thioglycollate	2 gm.
	Sodium formaldehydesulfoxylate	1 gm.

Final reaction should be pH 7.2.

Use 43 gm. per 1000 c.c.

After melting and sterilizing, add 1.5 to 5% blood.

Thioglycollate media should not be sterilized longer than 20 minutes at 15 pounds pressure.

M-50. Anaerobic Nitrate Broth, Reed and Orr.—

Dissolve 10 gm. tryptose
5 gm. sodium chloride
1 gm. potassium nitrate
1 gm. agar
3 gm. meat extract
1 gm. sodium thioglycollate
in 1000 c.c. distilled water, with heat. Filter while hot.

Adjust the reaction to pH 7.0.

Add 0.001 gm. Resazurin.

Distribute into test tubes and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Check for sterility.

Difco anaerobic nitrate broth and BBL indol nitrate broth, 25 gm. dissolved in 1000 c.c. distilled water, have similar formulas.

M-51. Iron Milk, Reed and Orr.—

Dissolve 100 gm. Difco skim milk with brom cresol purple
in 1000 c.c. distilled water.

Strain and distribute in 10 c.c. amounts in test tubes.

Add 1 gm. reduced iron* to each tube. Sterilize in the autoclave at 15 pounds pressure for 30 minutes.

Nails can be used and re-used after boiling in 50% hydrochloric acid and rinsing in tap water.

M-52. Iron-Gelatin for Anaerobes.—

Dissolve 120 gm. gelatin
8 gm. nutrient broth, desiccated, BBL or Difco
1 gm. dextrose
in 1000 c.c. distilled water.

Adjust the reaction to pH 7.0 to 7.2.

Distribute in test tubes.

Put 1 washed iron nail (see above) in each tube.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

---

*See formula M-52.

M-53. Motility Thioglycollate Medium.—

Thioglycollate broth, dehydrated, BBL or Difco	29.5 gm.
Agar	4.0 gm.

Dissolve in 1000 c.c. distilled water.

Tube and place in an autoclave at 15 pounds pressure for 15 minutes.

M-54. Thioglycollate Base.—

Trypticase	20 gm.
Sodium chloride	5 gm.
Dipotassium phosphate	2 gm.
Sodium thioglycollate	1 gm.
Agar	0.5 gm.
Distilled water	1000 c.c.

Final reaction should be pH 7.2 ±.

Suspend 28.5 gm. of the BBL powder in a liter of distilled water.

Allow to soak about 5 minutes.

Mix thoroughly.

When the suspension is uniform, heat gently, with occasional agitation, until the medium boils for 1 or 2 minutes and becomes clear.

Add 5 to 10 gm. of carbohydrate, if the medium is to be used for fermentation studies or for diagnostic work.

Dispense in test tubes, filling them half full, and using about 15 c.c. in 6 by ¾ inch tubes.

Sterilize by autoclaving at 118° to 121° C. (12 to 15 pounds pressure) for 15 minutes.

Add indicator after incubation, to detect decomposition of the added carbohydrate.

The medium should not be used until it has cooled to room temperature. The prepared medium should be stored in the dark at room temperature, *not in the refrigerator.* It may be used until not more than one-third of the column of liquid has been oxidized, as shown by the indicator. After prolonged storage, boil the medium for a few minutes and cool before use.

M-55. Thioglycollate Glycerol.—

10% yeast extract (*see* M-14)	50 c.c.
Proteose-peptone No. 4	15 gm.
Sodium chloride	2.5 gm.
d-l-Cystine	0.05 gm.
Sodium thioglycollate	0.5 gm.
Agar	0.75 gm.
Glycerol	20 gm.

Dissolve in 930 c.c. distilled water by heating.

Adjust the reaction to pH 7.4.

Add 0.1% brom cresol purple	7.5 c.c.

Dispense in screw-capped bottles.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

M-56. Trypticase Lactose Iron Agar, BBL.—

Trypticase	20 gm.
Agar	3.5 gm.
Lactose	10 gm.
Ferrous sulphate	0.2 gm.
Sodium sulph*ite*	0.4 gm.
Sodium thiosulphate	0.08 gm.
Phenol red	0.02 gm.

Use 34.2 gm. per liter of solution. Final reaction is pH 7.2. Sterilize in the autoclave for 25 minutes at 10 to 12 pounds pressure.

M-57. Nagler and McClung-Toabe Plate.*—

Proteose-peptone No. 2 or No. 3	40 gm.
Disodium phosphate	5 gm.

---

*J. Bact. 53: 2, 1947.

Monopotassium phosphate	1 gm.
Sodium chloride	2 gm.
Magnesium sulphate	0.1 gm.
Dextrose	2 gm.
Agar	25 gm.

Dissolve in 1000 c.c. distilled water by heating.

Adjust the reaction to pH 7.4.

Sterilize in an autoclave at 15 pounds pressure for 20 minutes.

Before use, melt, cool to 45° C., and add to each 90 c.c. of the medium 10 c.c. of sterile egg yolk.

Pour plates.

Sodium azide, 0.02%, may be added.

M-58. Petrik Medium.*—

All glassware and utensils coming in contact with the medium are sterilized in the autoclave for 30 minutes, at 15 pounds pressure.

Ingredients.—

Potato-Extract.—To 1,000 c.c. of 8.4 volume per cent glycerin water add 250 gm. of thinly sliced, freshly peeled potato with a minimum exposure to air. Autoclave with the glassware.

Eggs.—Wash fresh eggs in water, and immerse them in 70% alcohol for two hours.

Malachite-Green Oxalate.—Sterile 2% aqueous solution (2 gm. per 100 c.c. distilled water).

Loewenstein Solution.—

Asparagin	2.4 gm.
Primary potassium phosphate (KH_2PO_4)	1.6 gm.
Magnesium sulphate	0.16 gm.
Distilled water	50.0 c.c.

Autoclave with the glassware.

Potato-Egg Medium. Technic.—

Into a three quart pot, pour 500 c.c. of whole egg, and 100 c.c. of egg yolk.

Beat the mixture thoroughly.

Cool 350 c.c. of potato-extract to about 50° C., and add 12.5 c.c. of 2% aqueous malachite green solution, and the entire quantity (given above) of Loewenstein solution.

Beat thoroughly with an egg beater, and filter through several thicknesses of sterile gauze into the tubing funnel.

Place 10 to 12 c.c. in each tube, stopper the tube with a cotton plug, and slant in the inspissator or Arnold steam sterilizer.

Heat at 85° C. for exactly one-half hour. If the inspissator is used for heating the tubes, stopper them with cork stoppers to prevent loss of water from the medium during inspissation. If the Arnold is used, stopper the tubes soon after they are removed from the sterilizer. One heating is sufficient if sterile precautions are maintained during the preparation of the medium.

Incubate the tubes for three days to test for sterility.

After incubating for sterility, as an aid in keeping the moisture in the medium till ready for use and also to prevent drying out after planting and placing in the incubator, paraffin the stoppers of the tube with hot paraffin. Tubes can then be kept in the incubator for a longer period of time without the loss of a large amount of their moisture.

M-58a. Blood Agar Medium, Tarshis** **(for growth of tubercle bacillus).**—

Glycerin, analytical grade	3 gm.
Distilled water	219 c.c.

Dissolve the glycerin in the distilled water and add

Blood agar base, Difco, desiccated	9 gm.

Dissolve by heating in a boiling water bath.

Autoclave for 15 minutes at 15 pounds pressure.

Cool to 50° C.

---

*Ryley, John P.: Lab. Digest, July, 1941, p. 4, and personal communication.

J. Lab. & Clin. Med. **40: 628, 1952.

Add, under sterile precautions:

Human blood	75 c.c.
Penicillin solution, 75 U. per c.c.	3 c.c.

Mix well and keep in a 50° C. water bath while dispensing into sterile screw-capped tubes, about 6 c.c. per tube.

Allow to solidify with long slants.

Test for sterility after incubating for 48 hours.

M-58b. Charcoal Agar Medium, Whalen.*—

Dissolve with the aid of heat:

Proteose peptone No. 3, Difco	2 gm.
Asparagin	1 gm.
Disodium phosphate 12 H_2O	2.5 gm.
Monopotassium phosphate, anhydrous	1 gm.
Magnesium phosphate	0.5 gm.
5% aqueous solution of ferric ammonium citrate	10 c.c.
Sodium citrate	0.5 gm.
0.01% aqueous solution of cobaltous sulphate	1 c.c.
Savita yeast-vegetable extract	2 gm.
Dextrose	7.5 gm.
Glycerin	2.5 c.c.
1% solution of oleic acid in N/20 sodium hydroxide	8 c.c.
0.1% aqueous ethyl violet	3 c.c.
Agar	15.6 gm.

in 1 liter of distilled water.

Add, under thorough mixing, 4 gm. Nuchar C-190-N activater carbon.

Tube in approximately 6 c.c. quantities in screw-capped tubes, while stirring.

Autoclave at 15 pounds pressure for 15 minutes.

Allow to solidify with long slants.

M-58c. Egg Medium, Kauffmann.—

See page 1421 for preparation of whole eggs.

Weigh sterile thick-walled Erlenmeyer flasks containing beads.

Add 8 whole eggs.

Weigh the flask again and subtract the weight of the dry flask from the weight of the flask plus eggs. This gives the weight of eggs.

Add 0.85% sterile saline, the amount equivalent to one-third of the weight of the eggs.

Mix well and filter through sterile gauze. Distribute with sterile precautions into sterile tubes. Slant and inspissate for 1 hour at 80° C. on two consecutive days.

M-59. Egg Medium, Dorset.—

See page 1421 for the preparation of eggs.

Mix, in a sterile flask containing glass beads, 16 whole eggs and 100 c.c. of 0.85% sterile saline.

Mix and filter through sterile gauze.

Tube and sterilize as directed for egg medium M-58.

M-60. Loewenstein-Jensen-Holm Medium, Asparagin-Starch-Egg.—

(a) Asparagin solution.—

Dissolve 2.4 gm. potassium sulphate
0.24 gm. magnesium sulphate
0.6 gm. magnesium citrate
3.6 gm. asparagin
12.0 gm. glycerin
in enough distilled water to make 600 c.c. solution.

Sterilize in flowing steam for 2 hours.

---

*Bact. Proc. 55: 98, 1955.

(b) Add 30 gm. potato flour to solution (a).

Keep in water bath under constant stirring until sticky. Then allow to stand in the water bath for 1 hour at 56° C.

(c) Prepare whole eggs as described on page 1421.

Add 1000 c.c. of homogenized whole eggs to solution (b) and mix well.

Add 20 c.c. of 2% solution of malachite green previously sterilized in the autoclave at 15 pounds pressure for 15 minutes.

Mix well. Filter through gauze. Distribute into tubes.

Inspissate the first day ½ hour at 85° C.

Heat again the second day for ½ hour at 75° C.

M-61. Petragnani-Frobisher Medium.—

(a) Mix in an Erlenmeyer flask

Milk	225 c.c.
Potato starch	9 gm.
Peptone	1.5 gm.
Diced potatoes	150 gm.

Immerse the lower part of the flask in boiling water, shaking frequently, until the contents are sticky, then leave the flask in the water bath for 1 hour. Before use, cool to 60° C.

(b) Homogenize, preferably in a Waring blender,

Whole eggs	8
Glycerol	18 c.c.
2% watery malachite green	15 c.c.
(c) Dextrose	1.5 gm.
Asparagin	1.5 gm.

Dissolve in 50 c.c. distilled water by heating.

(d) Mix (a), (b), and (c).

Filter through gauze.

Tube and sterilize as directed for egg medium M-60.

M-62. Dubos Media.*—

Dubos broth base, with and without Tween 80; Dubos oleic agar base; Bacto-TB broth base, with and without Tween 80; Dubos serum; and Dubos albumin are best purchased from Difco, Inc.

For testing sensitivity of *Mycobacterium tuberculosis* to antibiotics and for the Dubos-Middlebrook neutral red virulence test of *M. tuberculosis,* the TB broth base without Tween 80 is recommended.

M-63. MacConkey Plate.—

Dissolve 20 gm. peptone (*or* 17 gm. peptone and 3 gm. proteose-peptone) in 1000 c.c. distilled water.

Add 5 gm. sodium chloride.

Add 5 gm. sodium glycocholate (*or* taurocholate *or* 1.5 gm. Bacto-bile salts No. 3) and 15 to 20 gm. granulated agar (20 is preferable).

Soak for 15 minutes, then dissolve by heating.

Adjust the reaction to pH 7.4.

Add 10 gm. lactose to the warm agar.

Sterilize in the autoclave at 15 pounds pressure for 20 minutes.

Add, with sterile precautions, 3 to 4 c.c. of 1% aqueous neutral red "certified." Boil the neutral red solution in a tube for five minutes before adding it to the medium.

When partly cooled, pour in Petri dishes, about 18 to 20 c.c. per dish. Allow to stand with slightly removed tops for one hour in a dust-free place at room temperature.

Store in the refrigerator.

There are numerous modifications of MacConkey's medium. Those made by BBL and by Difco are excellent; they contain one part of crystal violet for one million parts of the medium. This combination inhibits gram-positive microorganisms.

---

*J. Exper. Med. 83: 409. 1946; Am. Rev. Tuberc. 36: 334. 1942.

M-64. Desoxycholate Agar, Leifson.—

Soak 10 gm. peptone
5 gm. sodium chloride
10 gm. lactose
17 to 20 gm. agar
in 1000 c.c. distilled water for 15 minutes.
Dissolve by heating.
While still hot, add quickly and in the following order
2 gm. anhydrous dipotassium phosphate
2 gm. ferric ammonium citrate "green scales"
1 gm. sodium desoxycholate.
Adjust the reaction to pH 7.4.
Add 3 c.c. of 1% aqueous solution of neutral red.
Heat in steam for 15 minutes.
Pour plates in 17 to 20 c.c. quantities.
Allow to solidify with covers partially removed, for about 1 hour.
Store in the refrigerator.

BBL desoxycholate agar, 46 gm. dissolved in 1000 c.c. distilled water, duplicates the above formula.

M-65. Desoxycholate-Citrate Agar, Leifson.—

Infuse 1000 gm. ground lean pork meat
in 3000 c.c. distilled water at room temperature for 3 hours.
Add 10 c.c. of N/1 hydrochloric acid, and boil one minute.
Squeeze through gauze a small amount at a time, then filter through filter paper.
Add to the filtrate 10 c.c. of N/1 sodium hydroxide.
Boil 1 minute and dilute to 3000 c.c. with distilled water.
Add 30 gm. peptone (Thio or Wilson B).
Adjust the reaction to pH 7.5.
Boil for 5 minutes and filter through filter paper.
Add 60 gm. agar
and 15 c.c. N/1 sodium hydroxide.
Allow to soak at room temperature for 15 minutes.
Boil in steam for 20 minutes.
Place in Erlenmeyer flasks in 1000 c.c. quantities (or smaller amounts).
Add 10 gm. lactose
20.6 gm. crystalline sodium citrate
5 gm. sodium desoxycholate (optional 10 c.c. of 0.35% aqueous lead chloride solution)
to each 1000 c.c.
Adjust the reaction to pH 7.4.

Either store in the refrigerator immediately *or* add at once 2 gm. ferric ammonium citrate "green scales" and 3 c.c. of 1% aqueous solution of neutral red.

Pour in plates, 15 to 17 c.c. in each. Allow to dry with partially removed covers for 1½ hours. Store in refrigerator.

Small dewdrop-like crystals of sodium desoxycholate appear on the surface of the medium during storage. Their presence does not influence the quality of the medium. The "drops" disappear when the plate is incubated.

BBL desoxycholate-citrate agar with infusion, 73 gm. dissolved in 1000 c.c. distilled water, duplicates the above formula and saves much work.

M-66. Desoxycholate-Citrate Lactose Sucrose Agar, BBL.—

Sodium desoxycholate	2.5 gm.
Sodium citrate	10.5 gm.
Lactose	5.0 gm.
Sucrose	5.0 gm.
Polypeptone	7.0 gm.

Meat extract	3.0 gm.
Sodium thiosulphate	5.0 gm.
Neutral red	0.03 gm.
Agar	12.0 gm.

Suspend 50 gm. of the powder in 1000 c.c. distilled water. Mix thoroughly so that the suspension is uniform. Heat gently with occasional agitation of the medium. Boil for 1 or 2 minutes or until solution is complete. Cool the medium to about 50° C. and pour into Petri dishes. The plates may be used as soon as they have solidified, or they may be stored in the refrigerator for a few days.

If the surface of the agar appears to be wet, it is possible to dry it rapidly by inverting the plates and then tilting the bottom halves, containing the solid agar, on the edges of the lids.

M-67. S.S.* Agar.—

Beef extract	5 gm.
Proteose-peptone or Polypeptone	5 gm.
Lactose	10 gm.
Bile salts	8.5 gm.
Sodium citrate	8.5 gm.
Sodium thiosulphate	8.5 gm.
Ferric citrate	1 gm.
Agar	13.5 gm.
Brilliant green	0.33 mg.
Neutral red	0.025 gm.

Suspend 60 gm. of the Difco or BBL product in 1000 c.c. distilled water.

Boil for 1 or 2 minutes to dissolve completely.

Do not sterilize in the autoclave.

About 20 c.c. of the medium should be poured into standard Petri dishes 90 to 100 mm. in diameter.

It is very important that the surface of the plates be quite dry when inoculated. This is accomplished by allowing the medium to solidify and to stand for 2 hours with the covers partially removed.

Final reaction is pH 7.0.

M-68. D.E.C.† Agar, Panja and Ghosh.[1]—

Dissolve 5 gm. beef extract (Lemco or other)
5 gm. peptone, Difco
8.5 gm. sodium taurocholate
25 gm. agar
in 1000 c.c. distilled water.

Steam for 1 hour.

Adjust the reaction to pH 7.0.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

For use, melt, and add in order named:

Sodium citrate, crystals	8.0 gm.
Sodium thiosulphate, crystals	8.5 gm.
Disodium phosphate, crystals	7.5 gm.
Lactose	12.5 gm.
Ferric citrate "green scales"	3.0 gm.

Adjust the reaction, if necessary, to pH 7.4.

Add 15 c.c. of 0.25% solution of neutral red

and 5 c.c. of 2N sodium hydroxide.

Boil for 2 minutes.

Pour in plates.

---

*Salmonella-Shigella.

†Desoxycholate-Citrate.

[1] Indian. M. Gaz. 78: 55, 1943.

M-69. Bismuth Sulphite Agar, Hajna and Perry.—

(a) **Agar Base.—**

Agar	30 gm.
Beef extract	5 gm.
Peptone	10 gm.
Sodium chloride	5 gm.
Distilled water	1000 c.c.

Dissolve in the autoclave.

Adjust the reaction to pH 7.4 to 7.6.

Sterilize in the autoclave for 30 minutes at 15 pounds pressure and store in the refrigerator.

(b) **Hajna-Perry Reagent.—**

(1) Dissolve 80 gm. anhydrous sodium sulphite, Baker, in 400 c.c. boiling distilled water.

(2) Add 40 c.c. distilled water to 24 gm. bismuth citrate, c.p., mix to a paste, and add at once 10 c.c. pure ammonia (sp. gr. 0.897) and then drop by drop add more ammonia until the mixture is only fluorescent. Dilute to 200 c.c. with distilled water.

Mix the sodium sulphite and the bismuth solutions.

(3) Add 42 gm. of anhydrous dibasic sodium phosphate, Baker, to the above mixture and mix well until nearly dissolved.

(4) Dissolve 3.2 gm. crystalline ferrous sulphate, c.p., in 40 c.c. of distilled water.

Add 2 drops of concentrated hydrochloric acid, and add this solution to the above mixture. Cover the mixture with a beaker and boil carefully until the color turns slate gray. Store in dark, tightly stoppered bottle.

(c) **1% Aqueous Solution of Brilliant Green ''Certified for Media.''—**

(d) **For Use.—**

To 1000 c.c. melted, partly cooled base (a)
add 10 gm. glucose
70 c.c. Hajna-Perry reagent (b)
3 to 4 c.c. brilliant green solution (c).

Pour in plates as for the original Wilson-Blair medium.

M-70. Bismuth Sulphite Plate, Difco and BBL.—

Peptone	10 gm.
Beef extract	5 gm.
Dextrose	5 gm.
Disodium phosphate	4 gm.
Ferrous sulphate	0.3 gm.
Bismuth sulph*ite* indicator	8 gm.
Agar	20 gm.
Brilliant green	0.025 gm.

Suspend 5.2 gm. bismuth sulphite agar in 100 c.c. cold distilled water. Bring to a boil as rapidly as possible and allow it to simmer for 1 to 2 minutes.

If the medium is prepared several days before use, it should be poured into plates and stored in a cold moist atmosphere to prevent drying. The melted medium should never be allowed to solidify in flasks and be remelted.

Final reaction of the medium is pH 7.7.

M-71. Eosin Methylene Blue Agar, Holt-Harris and Teague.—

Use nutrient agar, 2%, made with 0.3% beef extract (3 gm. per 1000 c.c.), formula M-13.

To 1000 c.c. of melted agar base, add
50 c.c. 10% aqueous sterile solution of lactose
(optional: 10% sterile sucrose, 50 c.c.)
20 c.c. of 2% aqueous solution of eosin Y
and 20 c.c. of 0.5% to 0.65% aqueous methylene blue solution.

Pour in plates.

Dry with lids closed.
Store in the refrigerator in inverted position.
BBL and Difco desiccated products may be used, 36 gm. in 1000 c.c. distilled water.

M-72. Eosin Methylene Blue Agar, Levine.—

Dissolve 10 gm. Bacto-peptone
2 gm. dipotassium phosphate
10 gm. lactose
15 gm. agar
in 1000 c.c. distilled water.

Add in the order named 2 c.c. of 2% aqueous eosin Y solution. Mix well and add 0.5 c.c. of 2% aqueous solution of methylene blue. Mix well and sterilize in the autoclave at 15 pounds pressure for 15 minutes. Pour in plates.

This formula is duplicated by BBL and Difco eosin methylene blue agar of Levine, 37.5 gm. dissolved in 1000 c.c. distilled water.

M-73. Brilliant Green Agar, Kristensen-Kauffmann.—

Meat or yeast extract	3 to 5 gm.
Peptone	10 gm.
Sodium chloride	5 gm.
Lactose	10 gm.
Sucrose	10 gm.
Phenol red	0.08 gm.
Brilliant green	0.0125 gm.
Agar	20 gm.
Distilled water	1000 c.c.

Sterilize in an autoclave. The final reaction should be about pH 7.2.
BBL and Difco duplicate this formula.
Dissolve 58 gm. in 1000 c.c. distilled water.

M-74. Aronson Medium.—

(a) Prepare extract nutrient agar (formula M-13) with 3% agar content, pH 7.4 to 7.6.
(b) Saturated alcoholic solution of basic fuchsin.
(c) 10% solution of sodium carbonate, anhydrous.
(d) 20% solution of sucrose.
(e) 20% solution of dextrin.
(f) 10% solution of sodium sulph*ite*, anhydrous.

Melt the agar (a) and add, to each 100 c.c., 5 c.c. of the carbonate solution (c).
Sterilize in flowing steam for 15 minutes.
While still hot, add, in order
5 c.c. sucrose solution (d)
5 c.c. dextrin solution (e)
0.4 c.c. fuchsin solution (b)
2 c.c. sodium sulphite solution (f)
Boil for a few minutes, then pour in plates. Store in dark and use within 3 days.

M-75. Bismuth-Sucrose Mannitol Agar, Wilson and Reilly.—

(a) **Reagent.**—

(1) Dissolve 100 gm. sodium sulph*ite* in 500 c.c. of boiling distilled water.

Dissolve 30 gm. bismuth ammonium citrate "scales" in 250 c.c. boiling distilled water.

Mix the two solutions and boil for 2 minutes. Let cool.

(2) Dissolve 50 gm. sucrose
and 5 gm. mannitol in 250 c.c. distilled water.

Dissolve 15 gm. sodium bicarbonate, anhydrous, in 400 c.c. distilled water. Mix the two solutions.

Add solution (2) to solution (1). Keep in a dark well-stoppered bottle.

(b) **Sodium Carbonate Solution.—**

Dissolve 53 gm. sodium carbonate, anhydrous,
in 400 c.c. distilled water.

(c) **Base.—**

Dissolve 10 gm. peptone
5 gm. sodium chloride
20 gm. agar
in 1000 c.c. distilled water.
Add 10 c.c. sodium carbonate solution (b)

Sterilize in the auotclave for 20 minutes at 15 pounds pressure. If necessary, adjust the reaction to pH 8.6.

(d) **Medium.—**

Melt 100 c.c. of the base (c), cool to 60° C., and
add 20 c.c. bismuth reagent (a)
2 c.c. 1:1000 phenol red solution
2 c.c. absolute alcohol.
Mix and pour in plates. Store in the dark. Use within 4 days.

M-76. Tetrathionate Broth, Mueller.—

(a) **Iodine Solution.—**

Dissolve 20 gm. of potassium iodide in 100 c.c. of distilled water by grinding in a mortar.

Add slowly and with constant grinding 25 gm. iodide. Keep in a dark glass-stoppered bottle.

(b) **Broth.—**

Peptone	10 gm.
Beef extract	3 gm.
Distilled water	1000 c.c.

Dissolve by heating. Adjust the reaction to pH 7.4.
Sterilize in the autoclave at 15 pounds pressure for 20 minutes.

(c) **Sodium Thiosulphate Solution.—**

Dissolve 50 gm. sodium thiosulphate
in 100 c.c. of distilled water by heating.

(d) **Pulverized Calcium Carbonate, U.S.P.—**

Method.—

Add the thiosulphate solution (c) to 900 c.c. of the broth (b).

Place in 10 c.c. quantities in test tubes.

Add to each tube about 0.5 gm. of calcium carbonate on the tip of a tongue depressor, and boil for 5 minutes.

Cool to room temperature and add 0.2 c.c. of the iodine solution (a) to each tube.

Do not sterilize.

BBL and Difco desiccated tetrathionate broth base may be used.

M-77. Tetrathionate Broth With Brilliant Green, Kauffmann.—

For each 1000 c.c. of the broth described in formula M-76 (b) add
10 c.c. of 1:1,000 aqueous solution of brilliant green "certified,"
and 25 gm. dried oxgall Difco.
Adjust the reaction again.
Prepare the medium in the same manner as that of Mueller, formula M-76.

M-78. Selenite F Medium, Leifson.—

Peptone	5 gm.
Lactose	4 gm.
Anhydrous sodium hydro-selenite	4 gm.
Combination of mono- and disodium phosphate	10 gm.
Distilled water	1000 c.c.

Adjust the reaction to pH 7.0 to 7.1.

Place 8 to 10 c.c. quantities in large test tubes, so that the column of the fluid is 5 to 7 cm. high.

Plug and sterilize by steam sterilization for 30 minutes.

Difficulties are frequently encountered in managing the correct proportions of phosphates and selenite. It is suggested, therefore, that the medium be obtained in its dehydrated form from the Baltimore Biological Laboratory, Baltimore, Md. The dehydrated powder is highly hygroscopic. Excess heating during sterilization may prove detrimental to the medium. If it is tubed and sterilized properly, it keeps well, either at refrigerator or room temperature. If the fluid turns red, or if a large red sediment occurs, decomposition of the medium has set in, and the medium has lost its usefulness.

M-79. Double Sugar Iron Agar, Kligler.—

To each 100 c.c. of melted extract nutrient agar (formula M-13), pH 7.4,
add 1 gm. lactose
0.05 gm. ferric ammonium citrate
0.05 gm. sodium thiosulphate
0.1 gm. dextrose
and 0.5 c.c. of a 0.5% watery solution of phenol red.

Tube and sterilize for 20 minutes at 15 pounds pressure in an autoclave.

Slant with long butts and short slants.

This medium may be purchased from Difco or Baltimore Biological Laboratory. Dissolve 52 gm. of the powder in 1000 c.c. distilled water.

M-80. Triple Sugar Iron Medium (T.S.I.), Hajna.—

Polypeptone	20 gm.
Lactose	10 gm.
Sucrose	10 gm.
Dextrose	1 gm.
Sodium chloride	5 gm.
Ferrous ammonium sulphate	0.2 gm.
Sodium thiosulphate	0.2 gm.
Agar	13 gm.
Phenol red	0.025 gm.

The medium may be purchased in dehydrated form from Baltimore Biological Laboratory or from Difco. Use 59.4 gm. per liter.

M-81. Braun Media, Modified.*—

(a) **Basic Solution.**—

Proteose-peptone No. 3 *or* Trypticase	20 gm.
Meat extract	1 gm.
Sodium chloride	2 gm.
Disodium phosphate, c.p.	2.254 gm.
Monopotassium phosphate, c.p.	0.09 gm.
Magnesium sulphate, c.p.	0.02 gm.

Dissolve in 1000 c.c. distilled water.

(b) **Sterile 3% solution of agar** in distilled water.

(c) Add to each 100 c.c. of basic solution (a)

Tryptophan	0.02 gm.
Cystine	0.004 gm.
Lactose	1 gm.
Sucrose	1 gm.
Sodium or ammonium lactate	1 c.c.

Adjust the reaction to pH 7.6.

Add 0.4% brom thymol blue ---------- 1 c.c.

(d) Mix equal parts of melted agar (b) and solution (c).

---

*Schweiz. Ztschr. allg. Path. 8: 13, 1941.

(e) Tube, sterilize in autoclave at 15 pounds pressure for 15 minutes, and allow to solidify with long slants. This is **"Tube A."**

(f) Add to each 100 c.c. of basic solution (a)

Mannitol	2 gm.
Sodium thiosulphate, c.p.	0.1 gm.
Sodium or ammonium lactate	1 c.c.

Adjust the reaction to pH 7.6.

Add 0.4% brom thymol blue ---------- 1 c.c.

(g) Proceed as under (d) and (e), but allow the medium to solidify in a vertical position. This is **"Tube B."**

M-82. Motility Medium, Tittsler and Sandholzer.*—

Tryptose	5 gm.
Beef extract	3 gm.
Agar	5 gm.

Dissolve in 1000 c.c. distilled water.

Adjust the reaction to pH 7.4.

Tube and place in an autoclave at 15 pounds pressure for 15 minutes.

M-83. ''H''-Broth, Hajna and Damon.—**

Thiotone *or* Tryptone	10 gm.
Beef extract	3 gm.
Dextrose	1 gm.
Sodium chloride	5 gm.
Dipotassium phosphate	2.5 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.2 ±.

Suspend 21.5 gm. of the BBL or Difco powder in a liter of distilled water.

Mix thoroughly.

Warm slightly, if necessary to obtain solution.

Dispense in 5 or 6 c.c. amounts in 16 by 100 mm. test tubes, or in 3 c.c. amounts in 13 by 100 mm. tubes.

Sterilize by autoclaving at 121° C. (15 pounds pressure) for 15 minutes.

M-84. Semisolid Enteric Medium.†—

Thiotone	10 gm.
Beef extract	3 gm.
Sodium chloride	5 gm.
Agar	4 gm.
Gelatin	80 gm.
Sodium citrate	2 gm.
l-Cystine	0.2 gm.
Ferrous ammonium sulphate	0.2 gm.
Distilled water	1000 c.c.

The final reaction should be pH 6.9 ±.

Add 104.4 gm. of the dehydrated medium, BBL, to a liter of water preheated to about 50° C.

Heat over boiling water until the gelatin dissolves.

Boil for about 2 minutes.

Dispense the medium in 13 by 100 mm. test tubes. Regular 16 or 18 mm. test tubes may be used.

Sterilize in an autoclave at 118° C. for 15 minutes.

The medium should be inoculated by stabbing the center to one-third or one-half the depth of the medium.

It is recommended that cultures be incubated at 30° C. for 2 days or more.

---

*J. Bact. 31: 575, 1936.

**Pub. Health Rep. 65: 116, 1950.

†Edwards and Bruner: U. Kentucky, Circ. 54: 1942; and Hajna: Pub. Health Lab. 8: 36, 1950.

M-85. Lactose Indicator Broth.—

Thiotone	10 gm.
Trypticase	10 gm.
Beef extract	3 gm.
Sodium chloride	5 gm.
Sodium citrate	2 gm.
l-Cystine	0.2 gm.
Lactose	20 gm.

Dissolve in 1000 c.c. distilled water.
Adjust the reaction to pH 7.4.

Add *either* 0.4% brom thymol blue	5 c.c.
or 0.4% brom cresol purple	5 c.c.

Distribute into Kolmer tubes, about 1 or 1.5 c.c. per tube.
Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

M-86. Triple Sugar Motility Medium, Felsenfeld and Young.—

Dissolve

Proteose-peptone No. 3 or Trypticase	10 gm.
Sodium chloride	3 gm.
Lactose	10 gm.
Sucrose	10 gm.
Salicin	5 gm.
Agar	3 to 3.5 gm.

in 1000 c.c. distilled water by boiling for a few minutes.
Adjust the reaction to pH 7.4 to 7.6.
Add 2 c.c. of 0.4% brom thymol blue
and 10 c.c. of Andrade indicator.
Tube with long butts and short slants.

Sterilize in the autoclave for 20 minutes at 10 to 12 pounds pressure. Test for sterility by incubating for 24 hours and observing for growth of bacteria.

Inoculate by deep stab.

M-87. Fulton Broth.*—

Dissolve 5 gm. adonitol
5 gm. aesculin
5 gm. salicin
5 gm. sucrose
0.05 gm. ferric ammonium citrate ''brown scales''
in 1000 c.c. of Difco-purple broth base.
Tube and sterilize in the autoclave for 15 minutes at 12 pounds pressure.

M-88. Semisolid Mannitol, Felsenfeld.—

Dissolve 10 gm. proteose-peptone No. 3 *or* trypticase
5 gm. sodium chloride
10 gm. mannitol
3 to 3.5 gm. agar
in 1000 c.c. distilled water by boiling.
Adjust the reaction to pH 7.4 to 7.6.
Add 4 c.c. of 0.4% brom cresol purple.
Tube with long butts.
Sterilize for 25 minutes at 15 pounds pressure in the autoclave.

In a recent modification, 0.05 gm. each of ferric ammonium citrate and sodium thiosulphate are added to each 100 c.c. of the medium.

M-89. Semisolid Mannitol With Hydrogen Sulphide Indicator.—

Thiotone	20 gm.
Yeast extract (*see* M-14)	3 gm.

---

*Chilton and Fulton: J. Lab. & Clin. Med. **31**: 824, 1946.

Sodium chloride	5 gm.
Mannitol	10 gm.
Agar	4 to 5 gm.
Sodium thiosulphate	0.2 gm.
Ferric ammonium citrate	0.2 gm.

Dissolve in 1000 c.c. distilled water by heating.

Adjust the reaction to pH 7.4.

Add 0.4% brom thymol blue ---------- 5 c.c.

Tube in Kolmer tubes.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Inoculate by stabbing.

Take unusual care that the medium is not allowed to dry.

M-90. Urease Broth, Rustigian and Stuart.*—

Urea	20 gm.
Monopotassium phosphate	9.1 gm.
Disodium phosphate	9.5 gm.
Yeast extract	0.1 gm.
Phenol red	0.01 gm.

Use 3.87 gm. of the BBL or Difco powder per 100 c.c. of distilled water.

When the powder has dissolved, filter the medium through a sterile bacteriologic filter, either a Seitz or a candle filter.

Distribute the broth in 1 or 2 c.c. amounts in small sterile tubes.

M-91. Urease Broth With Lactose.—

Before sterilization by filtration, to each 100 c.c. of medium M-90 add 2 gm. of lactose.

M-92. Methyl-Red Voges-Proskauer Medium.—

Peptone *or* Polypeptone	5 gm.
Dipotassium phosphate, anhydrous	5 gm.
Dextrose	5 gm.
Distilled water	1000 c.c.

Dissolve the peptone and the phosphate by gentle heating. Adjust the reaction to pH 7.0 to 7.2.

Add the dextrose.

Distribute in 5 c.c. amounts into tubes.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Baltimore Biological Laboratory and Difco desiccated products marked "M.R.—V.P. Medium" are good substitutes for the above formula. Dissolve 17 gm. in 1000 c.c. distilled water.

M-93. Simmons Citrate Agar.—

Dissolve 1 gm. monoammonium phosphate
1 gm. dipotassium phosphate
0.2 gm. magnesium sulphate
2 gm. sodium citrate
5 gm. sodium chloride
in 1000 c.c. distilled water.
Add 20 gm. agar.

Soak for 15 minutes. Dissolve by heating, and adjust the reaction to pH 6.8.

Add 5 c.c. of 0.4% aqueous solution of brom thymol blue.

Tube and sterilize in the autoclave at 15 pounds pressure for 20 minutes.

Slant with long butts. Inoculate only the slants.

BBL and Difco desiccated powder, 24.2 gm. to 1000 c.c. distilled water, may be used.

M-94. Hippurate Broth.—

Dissolve 1 gm. sodium hippurate
in 100 c.c. beef infusion broth (formula M-4).

---

*Proc. Soc. Exper. Biol. & Med. 47: 108, 1941.

Sterilize by filtration through a Seitz or Berkefeld filter.

Place, with sterile precautions, into sterile test tubes, 3 c.c. in each tube

M-95. Micromedium, Bertacchini, Modified.—

Dissolve 20 gm. peptone
3 gm. yeast extract
5 gm. sodium chloride
5 gm. agar
in 1000 c.c. distilled water.

Adjust the reaction to pH 7.2 to 7.4.

Add 10 c.c. Andrade indicator (page 1421)

and 2 c.c. of 0.4% brom thymol blue solution.

Distribute in 10 c.c. quantities in test tubes.

Sterilize for 20 minutes at 15 pounds pressure in the autoclave.

For use, melt and add to each tube 2 c.c. of 10% sterile solution of carbohydrate.

Mix well. Cool to 50° C., and add to each tube 0.5 c.c. of the culture to be tested.

Mix well.

Use a different sterile pipette for each tube. Place 0.3 c.c. quantities of each mixture into sterile Petri dishes. A number of different culture specimens may be put in the bottom of each dish provided that each 0.3 c.c. quantity is distinctly separated from the others, and each quantity is properly labeled.

Incubate at 37° C. and observe after 2, 4, 6 (and 8) hours for acid and gas formation, using the microscope.

M-96. Buffered Glycerol, Teague and Clurman.—

Sodium chloride, U.S.P.	4.5 gm.
Anhydrous dipotassium phosphate	3.1 gm.
Anhydrous monopotassium phosphate	1.0 gm.
Glycerol, U.S.P.	300.0 c.c.
Distilled water	700.0 c.c.

Dissolve the sodium chloride and the phosphates in the water, add the glycerol, adjust to pH 7.2 using phenol red as indicator.

Place in specimen bottles, filling the bottles less than one-half full with the fluid. Sterilize for 30 minutes at 15 pounds pressure.

M-97. Buffered Glycerol Water.—

Sodium chloride	4.5 gm.
Dipotassium phosphate, anhydrous	3.1 gm.
Monopotassium phosphate	1.0 gm.
p-Aminobenzoic acid	0.05 gm.
Cysteine hydrochloride	0.05 gm.
Glycerol	300.0 c.c.
Distilled water	700.0 c.c.

Dissolve the ingredients in the distilled water and adjust the reaction to pH 7.2.

Distribute and sterilize in the same manner as M-96.

M-98. Alkaline Sea-Salt Water, Venkatraman and Ramakrishnan.[*]—

(a) Dissolve 27 gm. sodium chloride
1 gm. potassium chloride
3 gm. magnesium chloride $(MgCl_2 \cdot 6H_2O)$
in 100 c.c. distilled water.

(b) Dissolve 12.405 gm. boric acid
14.912 gm. potassium chloride
in 800 c.c. hot distilled water, then dilute to 1000 c.c. with distilled water.

(c) 8% aqueous solution of sodium hydroxide.

For use, mix 20 c.c. sea salt solution (a)
250 c.c. boric buffer (b)
135.5 c.c. sodium hydroxide solution (c)

---

[*] Indian J. M. Res. 29: 681, 1941.

in enough distilled water to make 1000 c.c.

Distribute in 10 c.c. quantities in screw-capped bottles of 30 c.c. capacity.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

M-99. Potato Dextrose Agar.—

Mix: Infusion from 200 gm. potatoes with
20 gm. dextrose and
15 gm. agar.

Suspend 39 gm. of BBL or Bacto potato dextrose agar in 1000 c.c. of cold distilled water.

Boil for 1 or 2 minutes to dissolve. Sterilize in the autoclave for 20 minutes at 15 pounds pressure. Final reaction is pH 5.6.

The label of each package of Bacto potato dextrose agar specifies the quantity of sterile tartaric acid (10% solution) that is to be added to each 100 c.c. of the sterile melted medium to adjust the reaction to pH 3.5.

Add the tartaric acid to the medium, mix well, and pour plates.

The medium should never be heated after the acid has been added, since heating in the acid state will hydrolyze the agar, and destroy its ability to solidify.

M-100. Malt Extract Agar.—

Dissolve 20 gm. agar in 800 c.c. distilled water by boiling.

Dissolve 25 gm. malt extract in 200 c.c. of distilled water.

Mix the two solutions. Distribute into bottles or tubes.

Sterilize in the autoclave for 30 minutes at 15 pounds pressure.

Difco malt agar, 45 gm. dissolved in 1000 c.c. distilled water, is the same as this medium.

M-101. Wort Agar.—

Maltose, technical	12.75 gm.
Malt extract, Difco	15.00 gm.
Dextrin, Difco	2.75 gm.
Glycerol	2.35 gm.
Dipotassium phosphate	1 gm.
Ammonium chloride	1 gm.
Bacto-peptone	0.78 gm.
Bacto-agar	15 gm.

Suspend 50 gm. of Bacto wort agar in 1000 c.c. cold distilled water.

Boil for a few minutes to dissolve.

Distribute into tubes or flasks as desired and sterilize in the autoclave for 15 minutes at 15 pounds pressure.

Final reaction is pH 4.8.

Due to the high acidity of the medium the heating process should be completed in as short a period of time as possible. Excessive heating of this acid medium causes a breaking down of the agar, resulting in inability to solidify properly when cool. Normally medium prepared from Bacto wort agar is soft and is ideal for planting purposes. However, if a medium of solidity satisfactory for streaking is desired, it can be prepared by using 60 gm. of Bacto wort agar per 1000 c.c. of water.

M-102. Sabouraud Agar I.—

Dissolve 20 gm. agar
in 1000 c.c. distilled water by heating.

While hot, add 10 gm. peptone and 40 gm. maltose.

Boil until dissolved. Adjust the reaction to pH 6.0 to 6.2.

Distribute into bottles or tubes.

Sterilize in the autoclave for 30 minutes at 15 pounds pressure.

Difco and BBL Sabouraud maltose agar, 65 gm. dissolved in 1000 c.c. distilled water, are reliable desiccated products.

M-103. Sabouraud Agar II.—

This differs from formula M-102 in that it contains dextrose instead of maltose.

M-104. Emerson Agar.[*]—

Beef extract	4 gm.
Gelysate	4 gm.
Sodium chloride	2.5 gm.
Yeast extract	1 gm.
Dextrose	10 gm.
Agar	20 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.0 ±.

Suspend 41.5 gm. of the BBL powder in a liter of distilled water.

Allow to stand for 5 minutes, and mix thoroughly.

Heat, with occasional agitation, and boil for 2 minutes to insure solution.

Dispense and sterilize at 118° to 121° C. for 15 minutes.

M-105. Littman Medium.[†]—

Oxgall	15 gm.
Gelysate and Polypeptone	10 gm.
Dextrose	10 gm.
Agar	16 gm.
Crystal violet	0.01 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.0 ±.

Suspend 51 gm. of the BBL powder in a liter of distilled water.

Allow to stand for 5 minutes.

Mix until a uniform suspension is obtained.

Heat with occasional agitation.

Boil for 2 minutes.

Dispense, and sterilize by autoclaving at 118° C. (12 pounds pressure) for 15 minutes.

Cool to 46° C.

Add 30 units of streptomycin per c.c. of medium (see *note*).

For best results, isolation plates should be made with about 30 c.c. of medium per plate. Plates should be allowed to stand, preferably for about 6 hours, before using.

NOTE: Littman medium should be used *without* streptomycin when the presence of *Nocardia asteroides* or any other organisms having sensitivity to streptomycin is suspected.

M-106. Mycophil Agar.—

Phytone	10 gm.
Dextrose	10 gm.
Agar	16 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.0 ±.

Suspend 36 gm. of the BBL dehydrated medium in a liter of distilled water. Allow to stand for 5 minutes and mix thoroughly.

When the suspension is uniform, heat with occasional agitation, and boil for about 2 minutes.

Dispense, and sterilize at 118° C. (12 pounds pressure) for 15 minutes.

M-107. Cornmeal Agar.—

Heat 40 gm. yellow cornmeal in 500 c.c. distilled water for 1 hour at 65° C.

Dissolve 15 gm. agar in 500 c.c. distilled water by boiling.

Mix the two solutions. Dispense into tubes or flasks.

Sterilize in the autoclave for 25 minutes at 15 pounds pressure.

BBL cornmeal agar without dextrose, 21 gm. dissolved in 1000 c.c. distilled water, may be used.

Difco cornmeal agar with dextrose, 19 gm. dissolved in 1000 c.c. distilled water, may be used instead of the above formula.

---

[*] Emerson, Whiffen, Bohonos, and DeBoer: J. Bact. 52: 357, 1946.

[†] Science 106: 109, 1947.

M-108. Brilliant Green Lactose Broth.—

Dissolve 10 gm. peptone
10 gm. lactose
200 c.c. ox-bile
in enough distilled water to make 975 c.c.

Adjust the reaction to pH 7.2 to 7.4.

Add 13.3 c.c. of 0.1% solution of brilliant green, certified.

Place in 10 or 20 c.c. quantities in test tubes containing inverted fermentation vials.

Sterilize in the autoclave for 20 minutes at 12 pounds pressure.

A suitable dehydrated medium is made by Difco and BBL (brilliant green bile broth, 2%). Dissolve 40 gm. of this medium in 1000 c.c. distilled water and tube in 10 c.c. quantities when 1 c.c. or less of inoculum is to be used.

Dissolve 60 gm. in 1000 c.c. distilled water and tube in 20 c.c. quantities when the inoculum is to be 10 c.c.

M-109. Lauryl Sulphate Broth, Mallman and Darby.—

Dissolve 20 gm. tryptose *or* trypticase
5 gm. lactose
2.75 gm. dipotassium phosphate
2.75 gm. monopotassium phosphate
5.00 gm. sodium chloride
0.10 gm. sodium lauryl sulphate
in 1000 c.c. distilled water.

Adjust the reaction to pH 7.2.

Distribute in 10 to 20 c.c. quantities in test tubes. Place inverted fermentation vials in the tubes.

Sterilize for 15 minutes at 15 pounds pressure in the autoclave.

To use the dehydrated BBL or Difco product, lauryl sulphate tryptose broth, dissolve 35.6 gm. in 1000 c.c. distilled water, to test samples of 1 c.c. or less in 10 c.c. medium.

M-110. Dextrose Meat Extract Agar.—

To 100 c.c. of extract agar (formula M-13) with 1.5% agar, pH 7.2, add before sterilization 0.1 gm. dextrose.

Tube and sterilize as usual.

Difco proteose tryptone agar, and BBL dextrose extract agar, 34 gm. dissolved in 1,000 c.c. distilled water, may be used for this formula.

M-111. Dextrose Meat Extract Milk Agar.—

(a) Prepare extract agar with dextrose according to formula M-110.

(b) Dissolve 10 gm. Difco or BBL skim milk in 100 c.c. distilled water.

Before sterilizing agar (a), add to each 100 c.c. 1 c.c. of skim milk (b).

Tube and sterilize as usual.

M-112. S.F.* Medium, Hajna and Perry.—

Dissolve 20 gm. tryptone *or* trypticase
5 gm. sodium chloride
5 gm. dextrose
4 gm. dipotassium phosphate
1.5 gm. monopotassium phosphate
0.5 gm. sodium azide
8 c.c. of 0.4% brom cresol purple solution
in 1000 c.c. distilled water.

Place in 10 c.c. quantities in test tubes and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

The desiccated BBL and Difco products are used by dissolving 36 gm. in 1000 c.c. of distilled water.

---

*Fecal streptococci.

M-113. Yeast Peptone Glucose Extract Agar, Jamieson.*—

To 100 c.c. of Difco tryptone glucose extract agar (formula M-110) add before sterilization

0.4 gm. yeast extract, Difco
1.0 gm. skimmed milk
1.0 gm. agar.

Heat to dissolve. Place in 4.5 c.c. quantities in flat 1-ounce bottles with screw caps.

Sterilize in the autoclave at 15 pounds pressure for 30 minutes.

Store in the refrigerator.

M-114. L Agar, Vera.[1]—

Lactalysate	20 gm.
Sodium chloride	2 gm.
Sodium citrate	3 gm.
Dextrose	9.5 gm.
Agar	13.5 gm.
Distilled water	1000 c.c.

The final reaction should be pH 7.0 ±.

Suspend 48 gm. of the BBL powder in a liter of distilled water.

Allow to stand for 5 minutes, and mix until a uniform suspension is obtained.

Heat gently with occasional agitation.

Boil for 1 or 2 minutes, or until solution is complete.

Dispense, and autoclave at 118° C. (12 pounds pressure) for 15 minutes. DO NOT OVERHEAT.

M-115. Stock Culture Agar, Difco.—

Beef heart infusion	500 gm.
Difco proteose peptone	10 gm.
Bacto gelatin	10 gm.
Bacto dextrose	0.5 gm.
Bacto isoelectric casein	5 gm.
Disodium phosphate	4 gm.
Sodium citrate	3 gm.
Bacto agar	7.5 gm.

Dissolve 50 gm. of the desiccated product in 1000 c.c. distilled water.

Tube and sterilize in the autoclave for 20 minutes at 15 pounds pressure.

Final reaction will be pH 7.5.

Cystine trypticase base, BBL (M-6), serves the same purpose.

M-116. Pleuropneumonia Medium, Norman and Kuhn.*—

(a) Trypticase	20 gm.
Agar	3.5 gm.
Sodium chloride	5 gm.
Sodium sulph*ite*	0.5 gm.
Cystine	0.5 gm.

Dissolve in 1000 c.c. distilled water by heating.

Add yeast extract	5 gm.

Dissolve by heating.

Adjust the reaction to pH 8.0.

Dispense into tubes, 4 c.c. per tube.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Before use, melt, and add to each tube 1 c.c. of sterile rabbit serum, which has been inactivated by heating at 52° to 56° C. for 30 minutes.

(b) Same as medium (a), but with 2% agar, is used for plates.

---

*Canad. Pub. Health J. 37: 90, 1946.

[1] J. Bact. 54: 14, 1947.

[2] J. Bact. 58: 270, 1949.

M-117. Pleuropneumonia Media, Difco.—

PPLO Enrichment Broth, PPLO Agar, and Bacto-PPLO Serum Fraction are commercially available.

M-118. Dextrose Starch, Serum Agar, Brown and Nunemaker.*—

(a) Dissolve 65 gm. of Difco dextrose starch agar in 1000 c.c. distilled water by heating.

Adjust the reaction to pH 7.6.

Distribute in flasks in 100 c.c. amounts.

Sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Before use, melt and add 10 to 15 c.c. of serum or ascitic fluid to each flask.

(b) To prepare a solid medium, add 0.5 gm. of agar to each flask before sterilization.

M-119. Penicillin Assay Agar Base.—

Beef extract	1.5 gm.
Yeast extract	3 gm.
Peptone	6 gm.
Agar	15 gm.

Dissolve in 1000 c.c. distilled water by heating.

Adjust the reaction to pH 6.8; for streptomycin assay, to 8.0.

Distribute, and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Difco Penassay base agar and Mycin assay agar, and BBL base agar are superior to the homemade media.

M-120. Penicillin Assay Broth.—

Beef extract	1.5 gm.
Yeast extract	1.5 gm.
Peptone	5 gm.
Dextrose	1 gm.
Sodium chloride	3.5 gm.
Dipotassium phosphate	3.68 gm.
Monopotassium phosphate	1.32 gm.

Dissolve in 1000 c.c. distilled water by gentle heating.

Adjust the reaction to pH 7.2; for streptomycin assay, to 8.0.

Distribute and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Difco Penassay broth and Mycin assay broth, and BBL antibiotic assay broth are superior to the homemade media.

M-121. Penicillin Seed Agar.—

Beef extract	1.5 gm.
Yeast extract	3 gm.
Peptone	6 gm.
Pancreatic digest of casein	4 gm.
Dextrose	1 gm.
Agar	15 gm.

Dissolve in 1000 c.c. distilled water by heating.

Adjust the reaction to pH 6.8.

Distribute and sterilize in an autoclave at 15 pounds pressure for 15 minutes.

Difco Penassay seed agar and BBL seed agar are superior to the homemade media.

M-122. Yeast Beef Agar.—

This medium differs from medium M-121 in that it contains 0.1% dextrose. It is commercially available from Difco and BBL.

---

*Bull. Johns Hopkins Hosp. 70: 201, 1942.

REAGENTS AND REACTIONS

Throughout this section, reagents and reactions are numbered as R-1, R-2, etc.

R-1. Motility

Motility of bacteria and other organisms may be determined by examining hanging drop preparations of broth cultures of the organisms. (See page 1467 for technic.)

Another very reliable method for testing for motility is to inoculate semisolid media by stabbing with a deep stab down to the bottom of the tube. Use formulas M-53, M-82, M-84, M-88, or any other semisolid medium containing 0.3% to 0.5% agar. Nonmotile organisms grow only along the stab line. Motile organisms spread out into the medium.

R-2. Decomposition of Fermentable Substances

Decomposition of fermentable substances (carbohydrates, alcohols, glucosides, etc.) is usually indicated by change in color of the indicator present in the culture medium. Such media as M-5, M-6, M-7, M-84, M-95, etc., contain indicators which are added during preparation. Clostridia are tested in media to which the indicators are often added after incubation, since they might reduce them.

One may observe for the formation of acid or of acid and gas. Acid formation in liquid media is indicated by a change in the color of the medium. Acid formation in solid media is indicated by a change in the color of that portion of the medium immediately surrounding the bacterial colonies. At times the acid formation is profuse and the entire plate or tube assumes the acid color.

Gas formation may be observed in liquid media, in semisolid media, or in solid media. In semisolid media, gas formation is indicated by formation of bubbles. This method of testing is preferred.

To determine gas formation in liquid media, place an inverted vial in each tube of the medium before sterilization. During sterilization this inverted tube fills up with medium. Gas formation during fermentation collects in the sealed end (top) of the inverted tube. The quantity of gas can be measured if desired.

In solid media gas formation is detected by the formation of bubbles in the media. In some cases gas formation is so profuse that the entire tube of medium is blown up, sometimes out of the tube.

It is important to remember that gas cannot be produced without acid formation. The color of the indicator, therefore, is always changed to the acid color when gas bubbles are present. If gas bubbles are observed without color change, either the vial, in the liquid medium, is too large and did not fill up during sterilization, or the solid medium broke for some other reason, such as drying. At all events, such bubbles are the result of some technical error and are not due to gas formation by the bacteria.

For practical purposes, it is enough to test gas formation in dextrose only. If an organism, especially Enterobacteriacea, forms gas from this carbohydrate, it may be considered a gas-former. This permits simplification of laboratory procedures, especially when fermentation vials are employed instead of the more convenient semisolid media which show gas formation by the development of bubbles. Vials are difficult to clean and often get lost during the cleaning procedures. Should vials be used, they must be put in dextrose only; the other carbohydrate media are tubed without them. An exception is, naturally, work with water and milk.

R-3. Hemolysis

It is often necessary to test the ability of bacteria to hemolyze blood. To test aerobic organisms, streak blood agar plates formula M-28 or M-29. To test anaerobic organisms, streak yeast blood agar formula M-14. Incubate the plates for 24 and 48 hours.

Hemolysis occurs as a clear (dissolved) zone surrounding the bacterial colonies. For a detailed description of types of hemolysis, refer to pages 1487 ff.

Poured plates give the most reliable results. Add the bacterial suspension or liquid culture to the blood agar while it is still liquid (temperature must be as low as possible) and pour plates. Allow to solidify and incubate for 24 and 48 hours, then observe for hemolysis.

If a quantitative estimation of hemolysis is desired, use the tube method. Mix equal parts of bacterial suspensions or broth cultures with suspensions of red blood cells. Incubate at 37° C. in a water bath.

The concentration and source of red blood cells used in the test will vary with different organisms. The routine procedure is to mix 0.5 c.c. of the culture with 0.5 c.c. of 5% rabbit red blood cells and incubate for 4 hours.

One must never test for hemolysis in media containing carbohydrates.

R-4. Coagulase Formation

Preparation of the Culture.—

(a) Use a 24-hour broth culture of the staphylococci to be tested; *or*

(b) Transfer the typical opaque, round, white or golden orange colony from the original plate where the isolation was made to an agar slant, and incubate for 12 hours, or slightly longer.

Test for Coagulase.—If the broth culture is used, add 0.5 c.c. of the 24-hour culture to 0.5 c.c. of citrated human blood plasma.*

If the agar slant is used, transfer one loopful of the growth to 0.5 to 1 c.c. of plasma in a small (75 by 10 mm.) tube.

Place in a water bath at 37° C. and observe frequently over a period of three hours, observing for coagulation. If the 37° C. water bath is not available a hot air incubator is satisfactory, but the test must be carried out for a six-hour period. A second reading is made in six to eight hours in the water bath, and in twelve to eighteen hours in the incubator.

Formation of a clot indicates a positive test. The size of the clot is not important. It is desirable that the clot form in three hours. Antibiotic treatment may result in loss of coagulase. Levine uses two different concentrations of plasma—undiluted whole plasma and plasma, one volume, diluted with two volumes of saline. Bacto-coagulase plasma solution is a reliable product.

R-5. Fibrinolysin Test

Fibrinolysin is an active substance, produced by some bacteria, notably streptococci pathogenic for man, which dissolves human fibrin.

Inoculate a nutrient agar plate (M-15) containing 10% plasma, heated for 10 minutes at 56° C.

Incubate for 48 hours at 37° C. and observe for zones of clearing surrounding the colonies. This indicates formation of fibrinolysis.

R-6. Reaction in Milk

Inoculate Ulrich milk M-11 or anaerobic iron milk M-51.

Record the formation of acid, gas, clotting, and peptonization.

R-7. Liquefaction of Gelatin

The classic procedure was to inoculate gelatin, incubate at 18° to 20° C. and observe for liquefaction.

A satisfactory method is to inoculate gelatin formula M-84 in screw-capped tubes and incubate at 37° C. After 48 hours, one week, two weeks, and three weeks, put the tubes in the refrigerator for 30 minutes. If the gelatin does not solidify it has been decomposed.

Another method is to streak the organisms on Chapman-Stone agar, formula M-46, and incubate for 24 hours.

Observe for cleared zones around the colonies which indicate liquefaction of the gelatin.

R-8. Reduction of Nitrates

Sulphanilic Acid-Naphthylamine Reaction.—

Reagents.—

1. Nitrate broth, formula M-8, and anaerobic nitrate broth, M-50.
2. Dissolve 0.8 gm. of sulphanilic acid in
   100 c.c. of 5 N acetic acid, sp. gr. 1.041.

---

*Dehydrated plasma for the coagulase test is now available from Warner-Chilcott, 9 East 62nd St., New York 21, N. Y., and from Difco Laboratories, Detroit, Mich.

3. Dissolve 0.5 gm. alpha-naphthylamine
in 100 c.c. of 5 N acetic acid, sp. gr. 1.041.

Technic.—

Inoculate tubes of nitrate broth and incubate for 3 days.

To the growth add 0.1 c.c. of the sulphanilic acid solution (2).

Then add, drop by drop, alpha-naphthylamine solution (3) until a red or maroon color appears. This is a positive reaction.

R-9. Hydrogen Sulphide Formation

Hydrogen sulphide formation is detected by black discoloration of a proper indicator, such as, lead acetate, ferric citrate, bismuth citrate, etc. These substances are added to the medium (M-51, M-52, M-56, M-79, M-80, M-84, etc.).

Some workers prefer to use *lead acetate papers.—*

Dissolve 10 gm. lead acetate, neutral, in 50 c.c. boiling distilled water.

Immerse strips of filter paper, about 2½ by ¼ inches, in this solution.

Dry in the incubator and store in well-stoppered bottles.

Inoculate broth cultures or slants containing a peptone favorable to the production of hydrogen sulphide, such as thiopeptone or proteose-peptone No. 3.

Incubate and then insert a strip of the lead paper between the plug and the neck so that it reaches into the tube but does not touch the medium.

Observe the paper for 48 hours for evidences of blackening or browning which indicate H_2S formation.

R-10. Bile Solubility Test

Inoculate neopeptone extract broth M-2 or trypticase soy broth M-3, or M-6, with the organisms to be tested.

Preparation of Bile for Use in the Bile Solubility Test.—

The bile may be obtained from the abattoir. It is collected in a sterile bottle.

Filter through sterile filter paper.

Place in 5 c.c. quantities in sterile ampules.

Seal in the flame.

Sterilize in the autoclave at 15 pounds pressure for thirty minutes.

If a precipitate forms after a time, it can be removed by centrifuging the bile, and decanting the supernatant fluid.

Filter about 5 c.c. of the original culture through sterile filter paper, or make a suspension of one of the colonies in 5 c.c. sterile saline.

Add 0.5 c.c. of sterile bile. Incubate for 10 minutes to one-half hour at 37° C.

Examine by means of the hanging drop.

Pneumococci dissolve.

Sodium Taurocholate or Sodium Desoxycholate Solutions for the Bile Solubility Test.—Solutions of pure bile salts are preferable to ox bile because they may be sterilized and the concentration better controlled. Note that heat-killed pneumococci are not bile-soluble. Sodium taurocholate or sodium desoxycholate is used in 10% solution for the bile solubility test.

Leifson Technic.[1]—Make up a 10% sodium desoxycholate solution with 1:50,000 Merthiolate as preservative. Add 2 drops of this solution to 1 c.c. of a 24-hour broth culture or saline suspension of the test organism. Make up a control of 1 c.c. of the culture and 2 drops of sterile saline solution. If the organism is a pneumococcus, the solution clears or the organisms are dissolved at once. Examine, however, for at least 10 minutes before calling the test negative.

Lauryl Sulphate Test, Bayliss.[2]—

To 0.9 c.c. of the culture add 0.1 c.c. of 2% sodium lauryl sulphate.

Incubate for 30 minutes at 37° C.

Pneumococci will dissolve in this time.

---

[1] J. A. M. A. **104**: 213, 1935.

[2] J. Lab. & Clin. Med. 28: 748, 1943.

R-11. Hippurate Test

Inoculate hippurate medium formula M-94 and incubate for 24 hours.

Add an equal amount of the reagent:

2 c.c. concentrated hydrochloric acid
98 c.c. distilled water
12 gm. ferric chloride ($FeCl_3 \cdot 6H_2O$)

Observe for a 15-minute period for precipitation.

R-12. Indol Formation

Inoculate broth or semifluid agar containing no carbohydrates, but a peptone favorable for indol production, such as, tryptone or trypticase formula M-1 or M-50.

Incubate 16 to 24 hours (or longer) and test by one of the following methods:

(a) Kovacs.—

Dissolve 5 gm. *p*-dimethyl amino benzaldehyde
in 75 c.c. of amyl *or* butyl alcohol in a water bath at 55 to 60° C. When solution is complete
add 25 c.c. of concentrated hydrochloric acid.

Add 0.5 to 1.0 c.c. of this reagent to the culture and shake well.

A red ring forms within 5 minutes if the reaction is positive.

(b) Jacobs and Pincus.[1]**—**

Reagent.—

Dissolve 10 gm. trichloroacetic acid
in 30 c.c. chloroform.
Add 2 gm. *p*-dimethyl amino benzaldehyde.
Transfer to a separatory funnel.
Saturate by shaking with concentrated hydrochloric acid.

Technic.—

Shake the culture with 1/5 its volume of chloroform.
Separate the chloroform layer.
Add 1 drop of the reagent to each c.c. of this layer.
Keep at 50° C. for 30 seconds.
A pink or rose color indicates indol formation.

(c) Goré.—

Prepare test tubes with absorbent cotton plugs, and inoculate these culture tubes with the organism to be tested.

Moisten the plugs with a few drops of saturated solution of potassium persulphate.

Moisten the plugs with Ehrlich reagent (method b).

Push the plugs down to about 1 inch above the surface of the medium.

Place tubes in boiling water bath for 15 minutes.

A red color on the plugs indicates the presence of indol.

(d) Gnezda.—

Saturate a strip of filter paper with oxalic acid by dipping it into a warm saturated aqueous solution of oxalic acid.

Inoculate the culture medium, and when replacing the plug, insert the strip of paper between the plug and the neck of the tube.

Incubate the culture and observe after 24 and 48 hours for pink discoloration of the paper, which represents indol formation.

R-13. Methyl Red Test

Inoculate tubes of methyl red Voges-Proskauer medium formula M-92 and incubate for 3 days.

To each 5 c.c. of the medium add 2 drops of freshly prepared 0.04% solution of methyl red.

A yellow color indicates a positive reaction.

---

[1] Science 102: 204, 1945.

R-14. Voges-Proskauer Test

Inoculate tubes of methyl red Voges-Proskauer medium formula M-92 and incubate for at least 48 hours. Then carry out one of the methods below.—

(a) Leifson.—

Reagent.—

Dissolve 1 gm. copper sulphate in 40 c.c. ammonia water
and add 10% sodium hydroxide, enough to make 1000 c.c. solution.

Technic.—

Add an equal volume of the reagent to the medium.
Let stand for 30 minutes without the plug.
If the reaction is positive an eosin color will develop.

(b) Barritt.—

Reagents.—

1. 5 % alcoholic solution of alpha-naphthol
2. 40% solution of potassium hydroxide

Technic.—

Transfer 0.6 c.c. of alpha-naphthol (1) to a test tube.
Add 1.0 c.c. of culture in methyl red Voges-Proskauer medium.
Add 0.2 c.c. of potassium hydroxide (2).

Shake. Observe for a 4-hour period. A pink or red color indicates a positive reaction.

(c) O'Meara.—

To the growth in the culture medium, add that amount of creatine which can be picked up on a knife point.
Add 5 c.c. 40% sodium hydroxide.
Shake for 2 to 5 minutes.
A pink color indicates a positive reaction.

(d) Rapid Method, Coblentz.[1]—

Reagents.—

1. Methyl red Voges-Proskauer medium formula M-92 tubed in 2 c.c. quantities.
2. 5% solution of alpha-naphthol in 95% ethyl alcohol.
3. Dissolve 40 gm. potassium hydroxide
   in 100 c.c. distilled water.
   Add 0.3 gm. creatine.
   Dissolve by shaking.

Technic.—

Make a heavy inoculation in the culture medium (1) from an agar slant and incubate at 30° C. for 6 hours.

Add 0.6 c.c. of alpha-naphthol solution (2) to each tube.

Add 0.2 c.c. of alkaline creatine (3).

Shake vigorously for 1 minute. Observe after 10 minutes for a red or pink color, which indicates a positive reaction.

R-15. Urease Test

(A) **Method of Rustigian and Stuart.[2]—**

Inoculate urease test medium formula M-90 and incubate not longer than 24 hours. A red color indicates urea decomposition.

(B) **Rapid Method of Anderson.[3]—**

Make a heavy inoculation of urease test medium formula M-90 tubed in 0.1 c.c. quantities by transferring the inoculum from a slant culture.

Incubate for 30 minutes and observe for pink to red color, which indicates urea decomposition.

---

[1] Am. J. Pub. Health 33: 815, 1943.
[2] Proc. Soc. Exper. Biol. & Med. 47: 108, 1941.
[3] Science **101**: 470. 1945.

R-16. Cholera Red Test

Grow organisms in tryptone nitrate broth formula M-8 for 24 hours.

Add 0.3 c.c. concentrated sulphuric acid.

A red color indicates a positive reaction.

R-17. Citrate Utilization

Inoculate Simmon citrate agar formula M-93 by streaking the surface.

Incubate and observe for 3 days. The indicator turns blue when citrate is utilized.

R-18. Oxidase Test

Culture organisms on blood plates containing dextrose (M-28, M-29).

Reagent.—

Dissolve 0.1 gm. dimethyl-para-phenylenediamine hydrochloride or oxalate
in 10 c.c. distilled water.

Preserve in a glass stoppered bottle. Use within one week.

Technic.—

Flood the plate with about 2 c.c. of the reagent.

Oxidase-positive organisms, such as, *N. gonorrhoeae, N. intracellularis,* many bacilli, etc., give a lavender color, which turns purple, and, finally black.

Tetramethyl-para-phenylenediamine hydrochloride is less toxic for Neisseriae but more expensive. Dimethyl-para-phenylenediamine oxalate is more stable.

R-19. Acrolein Reaction

Schiff Reagent.—

Dissolve 0.125 gm. basic fuchsin
in 100 c.c. distilled water by gentle warming.
Cool to room temperature and decant.
Add to the fluid 50 c.c. freshly prepared 4% sodium sulphite
and 4 c.c. concentrated hydrochloric acid
and enough water to make a total volume of 250 c.c.
After 5 minutes at room temperature, filter rapidly through filter paper.
Store in a dark bottle at room temperature.

This reagent will keep for one month.

Technic.—

Grow organisms in thioglycollate glycerol broth M-55.

Transfer 0.5 c.c. of this growth to 2.5 c.c. thioglycollate broth in a Kolmer tube.

Incubate at 37° C. until decolorized, but not longer than 24 hours.

Add to a separate tube 0.9 c.c. of this culture and 0.1 c.c. of fresh Schiff reagent.

A magenta color within 15 minutes at room temperature denotes a positive reaction.

R-20. Lecithinase Reaction

Grow organisms anaerobically on Nagler's plate or its modification M-57.

Observe after 48 and 60 hours for precipitation around the colonies.

CULTURE METHODS

With the exception of body fluids, material collected from cases or carriers is rarely inoculated directly into tubed fluid media for diagnostic purposes. Stools, pus, and swabs (except when investigating diphtheria, tuberculosis, and protozoan infections) are plated on media in Petri dishes. In many cases, however, an enrichment fluid, such as tetrathionate broth, is inoculated first; then, after sufficient incubation, plates are streaked from this fluid. In other cases, a preservative, such as that of Hirschberg for *N. gonorrhoeae* or buffered glycerol saline for bacillary incitants of diarrhea, is used, chiefly for the transportation of the specimens. Thus, the bacteriologic investigation becomes a planned procedure. Best results are attained when a proper scientific selection of methods is combined with reliable, sterile technic, and rapid work.

Preserving Fluids must be inoculated with a proper amount of material. Too much material impairs the efficacy of the preservative, while too little may cause false negative results. The technic of the use of preservatives for transportation of material is described in detail in the section dealing with diagnostic methods.

Enrichment Fluids must be handled in a manner similar to that used for preserving fluids. In addition to the proper amount of inoculum, temperature and length of incubation are of paramount importance in order to prevent the overgrowth of "contaminating" microorganisms.

Plating Media must be prepared and kept under conditions prescribed for the respective medium. Plating is the only reliable technic for isolation of bacteria in pure culture. It is usually done by streaking the material on the surface of media in Petri dishes.

POINTS IN IDENTIFYING BACTERIA

Make a survey examination in a hanging drop preparation to determine morphology and grouping. Then make a Gram stain to study staining characteristics.

Transplant to various culture media, preferably in Petri dishes to study colonies. When various characteristics of the bacteria are learned, use other culture media for further study, or transfer to sugar-containing broths or special media for fermentation reactions.

Note characteristic pigments, odors, effect on blood, effect on blood serum, egg, whether gelatin is liquefied. Observe whether growths are slight, moderate, or abundant; transparent or opaque; adherent; whether they emulsify easily or with difficulty, whether colonies are confluent or discrete.

If necessary, inoculate animals, make bile solubility tests, or agglutination tests.

Always try to place an organism in its genus, then proceed to identify the species.

Streaking Plates

Only proper streaking can insure isolated colonies. It is a sheer waste of time and material to simply smear a specimen over a plate or a section thereof, expecting to make a bacteriologic diagnosis. The art of streaking a plate is not inborn in bacteriologists, but has to be learned by hard daily practice.

If the streaks "did not come out" so that no isolated colonies were obtained, a fresh specimen must be requested. An honest laboratory worker will avoid issuing a negative report when distinctly isolated colonies have not been seen on the plates.

Re-plating may help in an emergency but should not be practiced.

Method I. "Streak" Method

Have on hand a Petri dish containing the culture medium on which the organism to be isolated grows characteristically.

Pick up a loopful of material to be planted, and streak out over the upper part of the culture medium across from one side to the other. Be careful to touch the surface of the medium, but do not dig into the agar.

Flame the platinum wire.

Streak out at right angles to the original line of inoculation making the streaks about ½ inch distant from each other.

Flame the platinum wire.

Turn the plate, and streak at right angles to the parallel lines just made, so that the result is a series of lines forming small squares over the surface of the medium.

Flame the platinum wire.

Throughout the procedure, use precautions to eliminate contamination with air bacteria.

Turn the plate **upside down** and place in the incubator for twenty-four hours or longer at 37° C., until a good growth has been obtained.

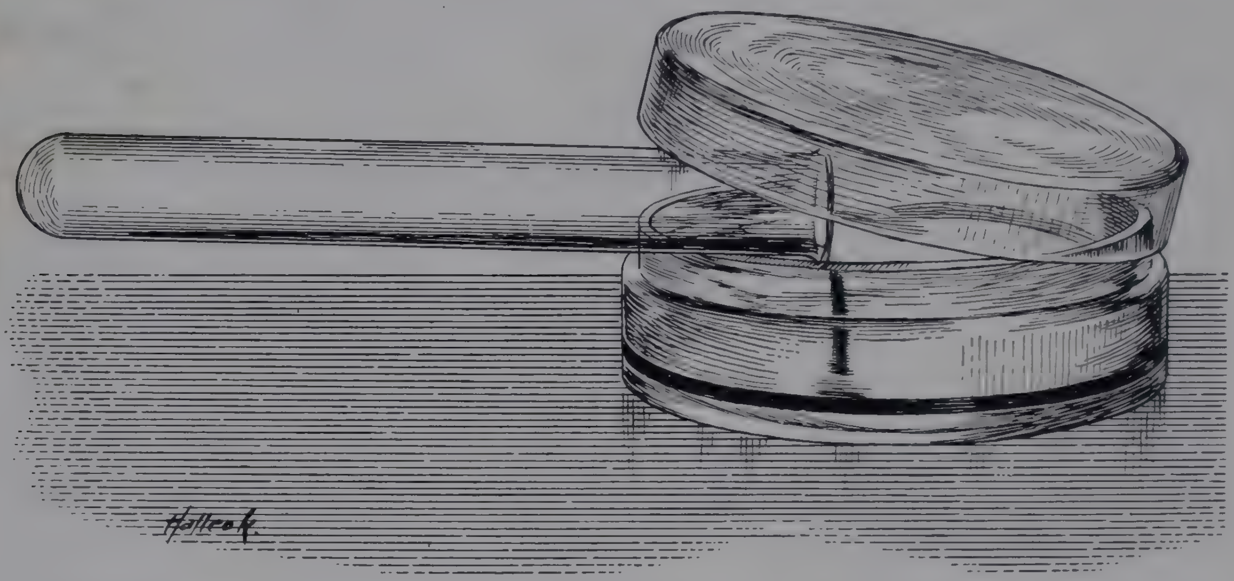

Fig. 336.—Pouring melted agar into a Petri dish.

By fishing out a typical colony under the microscope, and inoculating on a slant or another Petri dish of the same medium as that used in the isolation process, a pure culture is obtained.

The amount of material taken in the original loopful must be gauged by the possible number of bacteria in the specimen. There should be few enough bacteria so that at the ends of the streaks distinct colonies appear.

If there is a growth of bacteria in the centers of the squares formed by the streaking process, these, obviously, are contaminants.

If the medium is very moist, the water of condensation will carry the bacteria over the surface of the plate, and render it unfit for isolation purposes. Care should be taken, therefore, to eliminate as much of the water as possible.

Method II. "Clock Streak"

Pick up a loopful of the material to be plated and streak out over the upper ⅕ of the plate.

Flame the loop and cool it by stabbing it once or twice into the medium in some place which was not streaked.

Turn the plate about 70 degrees.

Take some of the material from the streaked area by drawing the loop through it in a straight line, and streak out over the next ⅕ of the plate. Return the loop to the streaked portion, draw a line through it, and streak the material out.

Flame the loop and cool it by stabbing it once or twice into the medium in some place which was not streaked.

Turn the plate about 70 degrees.

Take some material from the part last streaked and streak out as before.

Repeat this procedure once more. See Fig. 337.

Proceed in the manner described in **Method I.**

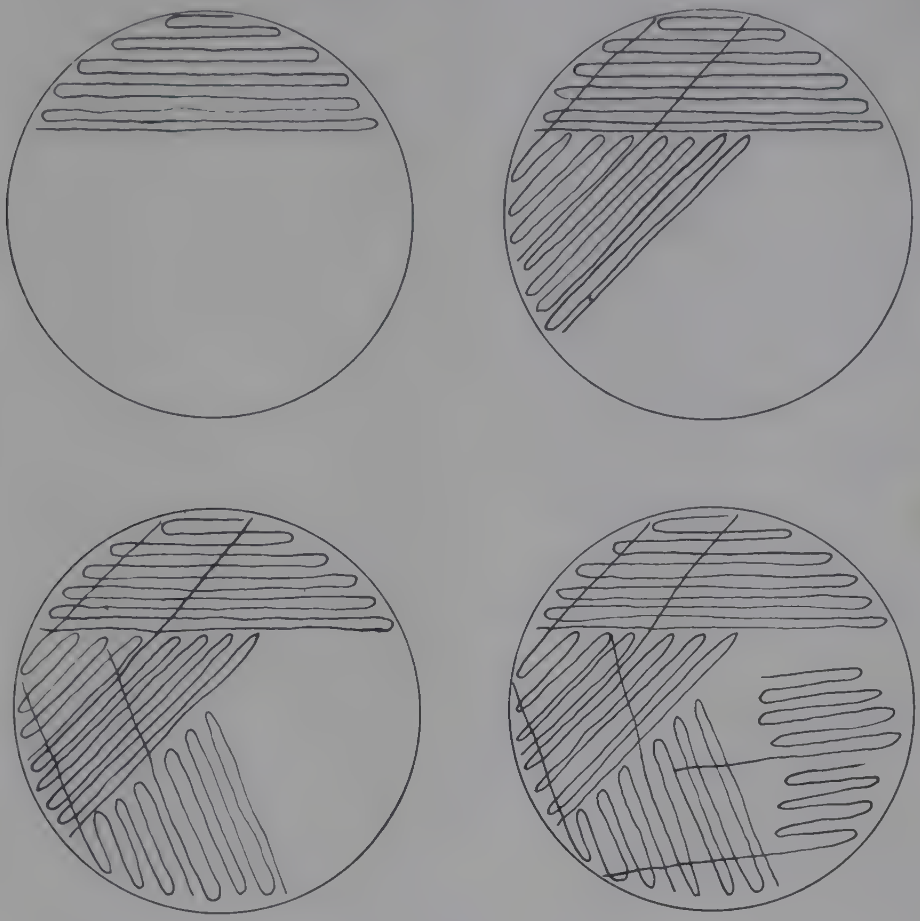

Fig. 337.—Steps used in performing the clock streak. (Courtesy Dr. Oscar Felsenfeld.)

Method III. "Z" Method

Prepare a Petri dish of the desired culture medium, and allow it to solidify.

Pick up a loopful of the material to be planted, and streak over the surface of the agar in such way that a letter "Z" is formed and covers the surface of the plate. Flame the loop.

Streak out from the initial line of inoculation; flame the loop; streak out from another point on the line; flame the loop; continue this process until many streaks have been made, flaming the loop between each streak. Flame the loop.

Turn the plate upside down in the incubator at 37° C. for twenty-four hours or longer, and proceed in the manner described under **Method I.**

Method IV. "Compass" Method

Prepare a Petri dish of the desired medium, and allow it to solidify.

Along the radius of the circle (Petri dish) place three small loopfuls of the material to be isolated.

Prepare a piece of capillary glass by heating glass tubing in the flame, pulling it out to a capillary, then, while still hot, bending it to a 45 degree angle. (These capillaries may be prepared, wrapped, and sterilized, ready for use.)

Using the capillary as a compass, describe a circle over the surface of the medium in such way that the three loopfuls of material are spread in a thin layer over the entire surface.

Burn the capillary in the flame.

Turn the plate upside down in the incubator at 37° C. for twenty-four hours or longer, then proceed in the manner described in **Method I.**

Method V. Spreading With a Glass Rod

Prepare glass rods by bending them at a 90 degree angle. The short end of the rod should be about ⅓ of the diameter of the plates used, the longer arm about 5 inches long.

Wrap each rod in paper and sterilize in the dry heat sterilizer.

Place a drop of the material to be examined on the plate of culture medium.

Rub it in with the sterile glass rod.

Without taking fresh material, rub the same glass rod over the surface of a second plate.

Proceed as directed in **Method I.**

Method VI. ''Spreading'' Method

This method is useful when the material to be isolated is in a liquid.

Pour a plate of the desired medium, and allow to solidify.

Place 0.05 c.c. (1 drop) of the material to be isolated on the surface of the agar. A sterilized 1 c.c. pipette graduated in 0.01 c.c. may be used for measuring the drop.

Allow the drop of material to spread over the surface of the agar in such way that it entirely covers the medium.

Turn the plate upside down, and incubate at 37° C. for twenty-four hours or longer.

Proceed in the manner described under **Method I.**

This method can be used only if few bacteria are present.

Some Precautions in Plating

The surface of the plate must be dry but not dried-out.

To avoid contamination, do not keep the plates open too long. Lay the lid on the laboratory table upside down. Hold the bottom of the Petri dish (the part which contains the medium) in a vertical position, with the medium turned toward the worker, to prevent settling of organisms from the air.

When plates are examined or inoculated, it is imperative that the worker does not speak. Contaminated fishings are sometimes due to the selection of colonies which are too near the others. Contamination during the ''fishing'' process is often due to conversation while the covers are removed. Cultures are exposed during this time, and precautions must be taken not to contaminate them.

Do not cut the medium with the inoculating loop. If this should occur on soft media, interrupt the streak and take fresh material from another part of the surface of the plate for continuance of the streak.

Always keep Petri dishes upside down except when streaking them or during inspection or ''fishing.''

''Fishing'' or ''Picking'' Colonies

For most purposes, the colony to be transferred from the plate to a differentiating medium is selected macroscopically. Use daylight coming in through the window, and not direct sunshine. Using a wax pencil, draw a circle on the bottom of the Petri dish around the colony to be fished.

Flame a platinum or nichrome wire.

Raise the bottom of the Petri dish to eye level, holding it in a vertical position.

Cool the needle by touching it once or twice to the medium in an area which was not streaked and on which there is no growth. Or, better, allow it to cool in the air.

Pick up the colony taking care not to touch another colony in so doing. If using selective media which retard the growth of contaminants but do not kill them, pick up only the center of the colony.

Replace the Petri dish in its cover.

Holding the needle between the index finger and the thumb, and using the same hand, pull out the plug of the tube containing the differentiating medium held in the other hand. To accomplish this, use the little finger of the hand, bending it against the palm, with the top of the cotton plug between the finger and the palm of the hand.

Flame the neck of the tube.

Inoculate the medium in the tube.

Again flame the neck of the tube and replace the plug.

Flame the needle.

If the hands of the worker are unsteady, it is best to rest the elbows on the table while picking colonies. It is also possible to lean the hand holding the plate against the hand holding the needle by touching the proximal parts of both antithenars.

When "fishing" with the aid of a microscope is indicated, the following procedure is recommended.

Focus the colony on the Petri dish with lid open using the 16 mm. objective of the microscope. Leave the Abbé condenser in the microscope. Keep the edge of the colony in sharp focus.

Flame a platinum or nichrome loop.

Steady the arm on the table.

Holding the platinum loop between the first and second fingers, to make it easy to manipulate, and guiding it with the thumb, place the hand on the stage of the microscope with the little finger resting on the stage. Place the wire over the area of the colony. Look into the microscope at the colony and introduce the wire until it appears in the field of vision.

Remember that an invert image is presented, and that a loop introduced from the right side appears on the left side of the microscopic field.

Pick up the colony that has been selected.

Withdraw the wire, taking care that it does not touch any spot on the medium.

With a little practice this can be accomplished with a great deal of ease.

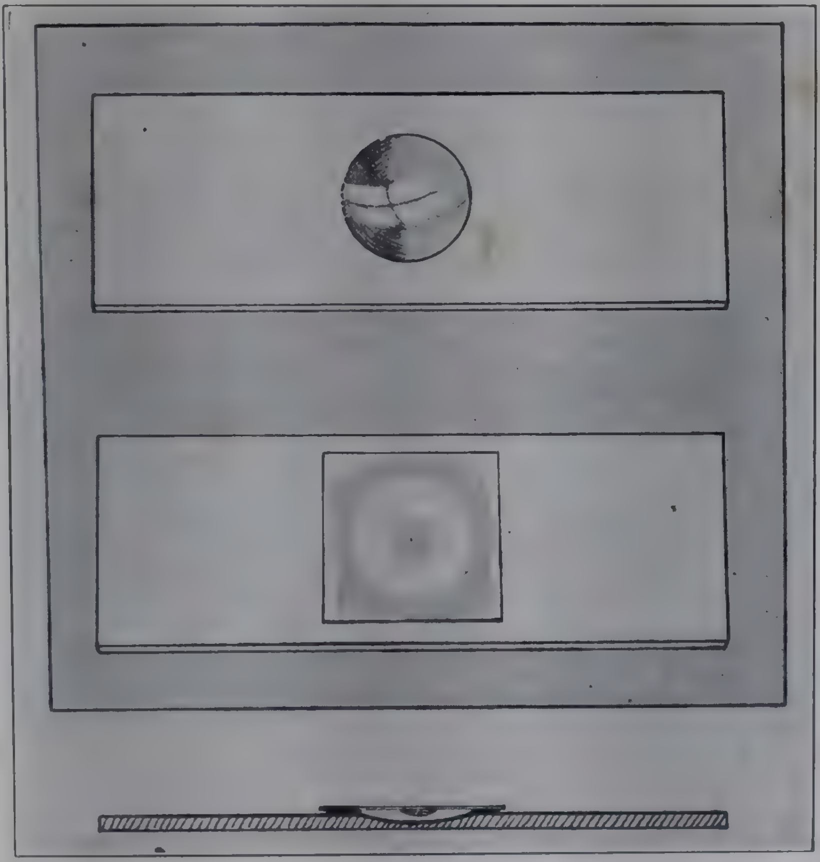

Fig. 338.—Preparing a hanging-drop specimen.

Making and Examining Hanging-Drop Preparations

The hanging-drop slide should be fat-free, and free of lint. Clean a ⅞ inch cover glass, taking care not to touch the glass with the fingers.

Place a small quantity of petrolatum around the edge of the cover glass.

Pick up a loopful of material to be examined, and place it in the center of the cover glass. Take care not to take too large a loopful, as it will touch the hanging-drop slide, and give a false appearance when examined.

Pick up the cover glass with the hanging-drop slide in such way that the loopful of material is in the center of the concavity of the slide.

Place the preparation on the microscope stage, and move it until the drop is directly under the 16 mm. objective.

Remove the Abbé condenser, use the plane surface of the mirror, shut off most of the light by manipulating the mirror, and focus up, until the edge of the drop is distinctly in focus.

Move the slide until the edge of the drop is in the center of the microscopic field.

Change to the 4 mm. objective and the concave surface of the mirror, lower the objective until it touches the slide, adjust the light, then focus up very slowly until the drop comes into view. By focusing for the edge of the drop, the worker has a definite line for which to look. Bacteria are too pale to afford a good medium for focusing.

Take care not to turn the fine adjustment of the microscope too far, as the objective might crash into the cover glass of the preparation and break it. There is no way of sterilizing the objective without injury, and since the preparation contains living bacteria, there is danger of contamination.

Inoculation of Culture Media in Slants in Test Tubes

When the stopper is removed from the first tube, it should be held between the third and fourth fingers, and care should be taken that the end of the stopper which is to go back into the tube does not touch anything.

The tubes should be held in a slanting position, and the mouths heated by holding them in the flame of a Bunsen burner for a short time.

The tube from which the specimen is taken must be held in a slanting position, and the mouth flamed.

A platinum or nichrome wire in a glass rod is heated red hot and cooled.

A portion of the material to be planted is picked up with this wire and is inserted into the second test tube.

Beginning at the bottom of the slant, inoculate in a zigzag motion over the surface of the slant, taking care to touch the medium, but not to dig into it.

Flame the wire to red heat after withdrawing it from the tube.

Flame the cotton stopper, flame the top of the test tube, then replace the stopper.

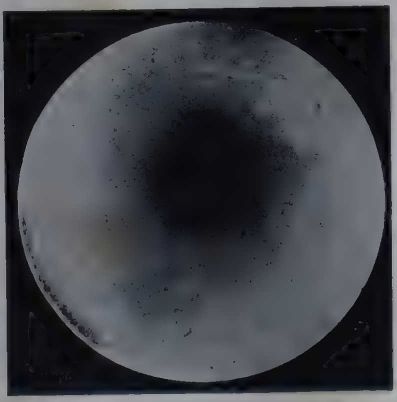

Fig. 339.

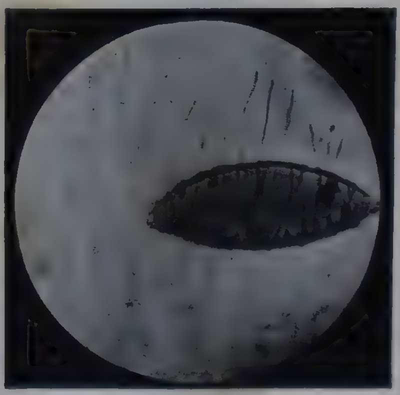

Fig. 340.

Fig. 339.—Colony of yeast from the air.
Fig. 340.—Contamination of cultures with molds and deep colonies.

Inoculation of Liquid Media

Using all sterile precautions (that is, flaming the mouths of the containers from which the specimen is taken, and the tube containing the liquid medium, and holding the plugs between the fingers), pick up a loopful of material to be planted, using a sterile platinum or nichrome wire. Make an emulsion of the material on the side of the tube just above the liquid. Replace the cotton plug, flame the wire, and mix the emulsion with the liquid by rotating.

Inoculation of Butts

Using all sterile precautions, that is, flaming the mouth of the tube from which the material is taken, and of the tube containing the medium, and holding the plugs between the fingers, pick up some of the material, using a sterile platinum or nichrome wire.

Introduce this material with one single stab into the medium, stabbing down to the bottom of the test tube. Replace the cotton plug and flame the wire.

Inoculation of Slants and Butts

This method is often used in examination of enteric organisms.

With the usual precautions, first stab the needle to the bottom of the medium, then streak the rest of the material on the needle over the surface of the slant.

When inoculating butts, take special care that the entire wire is well flamed (sterilized) and that contaminants from the holder are not added to the medium. This often occurs when using fluid media if the loop is shaken in order to force more material into the liquid.

Success in growing pure cultures depends greatly on proper plugging of the containers. If the medium is allowed to flow down the neck of tubes during the tubing process, particles of cotton often adhere to the glass. This greatly increases the chances of contamination.

SPECIAL CULTURE METHODS

Many organisms grow well under aerobic conditions. Some require anaerobic cultivation. It must be kept in mind that most aerobic organisms grow well also under anaerobic conditions. Thus not every bacterium which grows on anaerobic plates is an obligatory aerobe.

Making Anaerobic Cultures

1. Brewer Sodium Thioglycollate Medium

(Using a liquid medium without special apparatus) (Brewer Medium)

Brewer[1] has made use of several well-established principles and has developed a clear liquid medium which will remain anaerobic for more than one month when used in regular culture tubes without any type of seal. This medium possesses the unusual property of bringing about a reversible reaction; that is, if the medium is aerated by stirring or shaking, it again assumes an anaerobic state upon standing. It is called thioglycollate medium and is now available in powdered form from the Baltimore Biological Laboratory, Baltimore, Md. It is a facultative medium for the cultivation of obligatory anaerobes, microaerophiles, and aerobes (M-47, M-49).

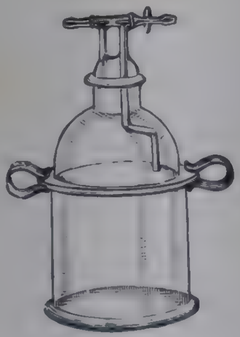

Fig. 341.—Novy anaerobic culture jar. (Courtesy E. H. Sargent & Co.)

Polypeptone broth containing 0.07 per cent agar serves as a base for this medium. It has been shown that small numbers of organisms grow much more readily if fractional percentages of agar are used, and Brewer stated that even this small percentage of agar lessens convection currents, thereby prolonging the anaerobiosis obtained without noticeably affecting the fluidity of the medium. The proper oxidation reduction potential is obtained by using 0.1% sodium thioglycollate. Methylene blue is added to serve as an indicator of the oxidation reduction potential. This small dye concentration (1:500,000) is nontoxic and exhibits no bacteriostatic action against any of the large group of organisms tested.

---

[1] Brewer, John H.: J. Bact. 39: 10, 1940.

The medium has the usual infusion broth color except at the surface where an aerobic layer has a green color due to the methylene blue. In inoculating and handling, the medium may assume a green color throughout, but will change again, in a few minutes, to its usual amber color when the anaerobiosis is re-established. The medium needs only the careful handling given the usual aerobic media. The tubes may be rotated after inoculation to distribute the inoculum. The tubed medium makes possible a liquid medium, the surface of which is aerobic while the subsurface is anaerobic; hence, the medium possesses a variable degree of anaerobiosis, making possible the cultivation of aerobes, micro-aerophiles, as well as anaerobes, in a single medium. It well may be called a facultative medium. Brewer's media are described as M-47, M-49.

A Petri Dish Cover and Technic for Use in the Cultivation of Anaerobes and Micro-Aerophiles. (Brewer Method[1])

John H. Brewer, of Baltimore, Maryland, who originated the thioglycollate medium for the cultivation of anaerobes,* has originated a very satisfactory method for the surface cultivation of anaerobes and micro-aerophiles without the use of anaerobe jars, petrolatum seals, or chemicals other than those included in the medium itself. In our laboratories, we have followed this method with signal success. We have found it a very satisfactory method for cultivating *Clostridium tetani* and *Cl. perfringens.* We have had occasion to use this method in connection with an investigation of samples of ham which were responsible for a case of food poisoning. We found that the predominant organism in this case was *Staphylococcus aureus* and that this method showed an anaerobic development of this organism. It is to be recommended very highly.

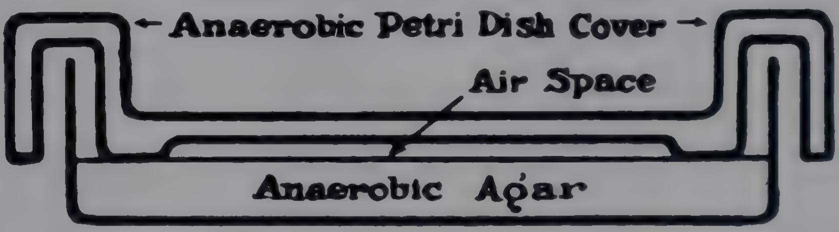

Fig. 342.—Cross section showing Brewer anaerobic Petri dish cover in use.

Technic.—

Pour any good infusion agar containing a satisfactory reducing agent into the usual Petri dish and allow to harden. Either a pour or streak plate may be made. After the agar has solidified, replace the Petri dish cover with the anaerobic lid which is so designed that it touches the agar at the periphery and results in trapping a small amount of air over the surface of the agar. The reducing agent in the medium uses up the oxygen in this small amount of air and an aerobic condition exists. The glass rim on the lid forms a seal with the moist solidified agar and no other seal is necessary. If 1 c.c. of 1:500 methylene blue is added to each liter of agar to act as an indicator, the reduced center of the medium in the dish becomes colorless, while the oxygenated periphery for about 5 mm. remains blue. For the preparation of Brewer's agar, see formula M-47 or M-49.

Brewer found that *Cl. tetani, Cl. novyi, Cl. septicum,* and *Cl. perfringens* give good surface colonies in 48 to 72 hours and that the plates may be incubated several days longer without drying out. In most cases the growth was much better than that obtained with the same culture in an anaerobe jar. If an unglazed porcelain top is used in pouring the plates, better isolation of surface colonies will be obtained. To facilitate opening the dish, the cover should be turned slightly to break the agar seal.

This technic may be used with the usual agar for obtaining partially anaerobic conditions for the cultivation of microaerophiles.

---

*Lab. Digest, Feb., 1942.

[1] Brewer, J. H.: Science 95: 587, 2475, 1942.

2. Using the Novy Jar

The jar should be tested for air leaks before use. All parts with a possibility of leakage should be thoroughly covered with petrolatum.

Place the cultures in the jar, and clamp the lid in place. There should be a rubber pad between the upper and lower parts of the jar at the point of contact.

Turn the stopcock located at the top of the jar, to open it. Attach the end of rubber tubing to one end of the stopcock, and attach the other end of the tube to the gas outlet. Allow the gas to flow into the jar until all air has been expelled. Close the stopcock. Turn off the gas. The exhaust may be burned off if desired.

Place the jar in the incubator for three days or longer.

3. Using Gradwohl-Drucker Anaerobe Culture Jar

The apparatus consists of a standard quart Mason jar and a cast aluminum top with two stopcocks. This cast aluminum top seals upon the Mason jar. Rubber tubing connects the shorter stopcock to the gas jet. Place the inoculated tubes or Petri plates in the jar and replace the lid. Open both stopcocks. Fill the jar with illuminating gas from the gas jet, burning off the excess. Burn for 15 to 20 minutes, then turn off the fire stopcock, then the gas stopcock, then the gas jet. Place the jar in the incubator for 24 hours or longer until the desired growth of cultures is obtained.

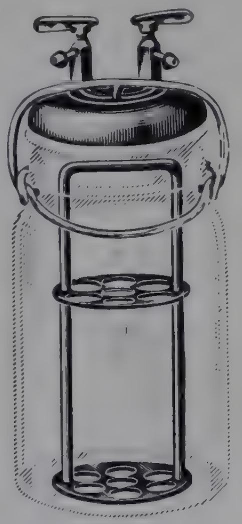

Fig. 343.—Gradwohl-Drucker anaerobic jar. (Courtesy Phillips-Drucker Co., St. Louis, Mo.)

4. Wright Method

Into a 100 c.c. lipless cylinder place about 1 inch of pyrogallic acid crystals.

Add enough 10% sodium hydroxide to dissolve the pyrogallic acid.

Place the culture tube in the dissolved pyrogallic acid. Immediately close the mouth of the cylinder with a rubber stopper. Place petrolatum around the stopper to make it airtight.

Place in the incubator for three days or longer.

5. Method of Consumption of Oxygen by a Second Bacterium

Inoculate half the surface of a Petri dish with the organism to be studied.

Inoculate the remainder of the plate with the *Bacillus subtilis* or *Serratia marcescens.*

Close the air space between the cover and the bottom of the Petri dish with modeling clay.

Place upside down in the incubator.

The *Bacillus subtilis* or *Serratia marcescens,* in growing, will consume the small supply of oxygen left in the plate.

The other organism, in this way, is afforded anaerobic conditions.

6. Sealed Tubes

Use tubes of any suitable medium, as, for example, semifluid agar formula M-50, chopped meat (M-12), or similar medium. Heat for a few minutes to expel the oxygen.

Cool and inoculate the medium.

Pour over the medium a layer of sterile liquid paraffin (petrolatum), using sterile precautions. The layer should be about ⅔ inch high.

Replace the plug and incubate.

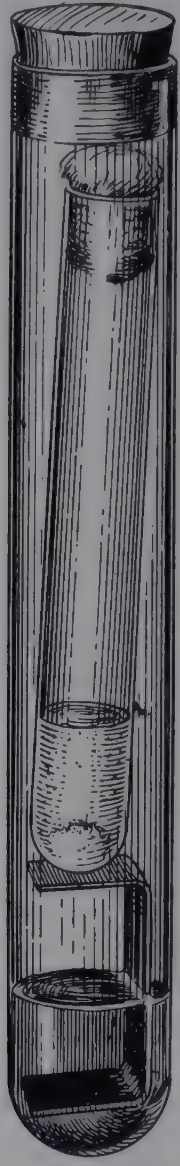

Fig. 344.—Wright method of making anaerobic cultures.

7. Spray Dishes

The Spray dish is a container, the lower part of which contains a ridge which divides the bottom of the dish. The upper section is similar to an extra heavy Petri dish and is used for preparing the culture. Pour the medium into the cover using sterile precautions.

Streak the medium with the inoculum.

Fill one half of the bottom of the Spray dish with 4 c.c. of a 20% solution of pyrogallic acid. Fill the other half with 10 c.c. of a 20% sodium hydroxide solution. Take great care not to mix the chemicals before closing the cover.

Place the lid, with the culture medium down, over the Spray dish so that the culture medium forms the lid. Fill the space between the cover and the Spray dish with modeling clay.

Shake the dish gently so that the pyrogallic acid and the sodium hydroxide mix, but take care that none of this solution splashes onto the culture medium. Incubate in the usual manner.

Cultivation in Carbon-Dioxide Atmosphere

Fig. 341 shows a type of apparatus which is used to admit carbon dioxide under strong pressure into a culture jar. Such apparatus is necessary for the cultivation of microorganisms which require carbon dioxide under high tension as, for example, *Brucella abortus*.

Other microorganisms require carbon dioxide under less tension (Neisseriae). There are several methods for producing such an atmosphere.

(1) Place inoculated plates in a container which can be tightly covered; for example, desiccator jar, Pyrex preparation jar, Petri dish container, coffee can, or any other available container. Place a lighted, smokeless candle in the container and close the lid. The flame consumes the oxygen and enough CO_2 is produced for the culture needs of the bacteria.

(2) Place a handful of oats in a one-quart container (e.g., desiccator) and moisten the oats with water. Fasten the lid of the container and incubate. This method may cause contamination of the culture plates with molds.

(3) Place in one-half of the bottom of the Spray dish 0.5 gm. sodium bicarbonate with enough distilled water to dissolve it. In the other half place 3% sulphuric acid. Place the lid containing the inoculated culture medium over the Spray dish, medium side down, and seal with modeling clay. Shake the dish from side to side to mix the contents in the bottom of the dish, taking care not to splash the liquid on the medium.

Egg Culture Methods

The Use of Chick Embryos in the Diagnosis of Certain Infections[1]

Egg culture methods are used not only for the propagation and isolation of viruses, but also for diagnosis of many bacterial diseases. The special value of this living medium has been demonstrated for culturing tubercle bacilli and such delicate organisms as *Hemophilus influenzae, H. pertussis, Brucella abortus, Pasteurella tularensis,* meningococci, and pneumococci.

Due to the speed of growth of bacteria in this medium, the method is an important factor in the early diagnosis of various bacterial diseases. In any laboratory which is set up for this work, there must be someone on duty 24 hours a day, to begin the procedure as soon as the specimen is delivered, and thereby permit proper examination, which hinges on the study of fresh materials, early diagnosis, and the subsequent establishment of proper treatment.

The egg as a culture medium has been applied particularly to the culture of spinal fluids in meningitis. The routine methods employed in many hospital bacteriologic laboratories have failed frequently to yield the etiological agent of this disease. The use of chick embryos is of special value when only a few organisms are present, or where the ordinary culture media might fail to detect them.

Most commercial chicken feed is now enriched with antibiotics; thus the source of the egg supply must be thoroughly checked. Antibiotics in the feed will diminish or prevent bacterial growth. Cortisone-treated chick embryos have been employed, and a marked increase in tissue reaction and stimulation has been noted. These cortisone-injected embryos seem useful for the cultivation of body fluids from persons under antibiotics or chemotherapy.[2]

Use a saline suspension of Cortone acetate made by emulsifying commercial cortisone. Drop 0.1 or 0.2 c.c. of this commercial cortisone from a tuberculin syringe onto the chorioallantoic membrane at least 2 hours before inoculating with the test suspension, which sensitizes the egg tissue for bacterial invasion. Not less than 2 eggs should be used per specimen.

Contaminated material may be freed from undesired bacteria by mixing 500 units of penicillin with or without 500 units of streptomycin with the sample, and allowing it to stand for 1 to 2 hours.

---

[1] Wolf, Herma: Lab. Digest **15**: 6, 1952.

[2] Brueck and Buddingh: Proc. Soc. Exper. Biol. & Med. **80**: 589, 1952.

Injection of methylene blue, 1% aqueous solution, is an excellent aid for visualizing parts of the egg, especially during training.

The following methods are satisfactory for bacteriologic studies, using the chorioallantoic membrane technic.

(A) Material.—

(1) A reliable source of fertile eggs with 7- to 12-day-old embryos.

Some workers prefer to purchase eggs containing younger embryos and then keep them in a 39° C. incubator, with sufficient moisture, until they are ready for use.

(2) A candling device. This may be purchased, or it may be homemade.

(3) A poultry incubator, 39 to 39.5° C., with egg trays and water container. A cardboard with holes in it may be used as an egg tray. A routine bacteriologic incubator will give good service.

(4) An apparatus to open the egg shell: a dentist's drill, a hand steel trocar, or a supply of safety razors fitted into a handle.

(5) A holder for egg inoculation: it may be combined with the candling device or it may be a special apparatus.

(6) Sterile tuberculin syringes with 27 gauge needles, or sterile capillary pipettes for inoculation.

(7) Sterile small forceps, preparation needles, and knife.

(8) Rubber suction bulb.

(9) Sterile cover glasses.

(10) Sterile paraffin-wax mixture.—

Paraffin	40 gm.
Beeswax	10 gm.
Castor oil	10 gm.

(11) Sterile saline, preferably containing 0.044% calcium chloride.

(B) Technics.—

(1) Burnet.[1]**—**

Incubate eggs in the poultry incubator, turning them over each day.

Candle 10- to 14- (preferably 12) day-old eggs to be sure that the embryos are alive. In the living egg, the embryos and the yolk sacs appear as dark bodies; the embryos are not too mobile when the eggs are turned, and the blood vessels are visible.

Mark the position of the embryo with a wax pencil on the eggshell.

Drill the eggshell over the natural air sac.

Drill a small window, about 2 sq. cm., in the side of the egg, where the chorio-allantoic vessels are visible.

Cover drillings with paraffin-wax mixture.

Put a drop of sterile saline on the fibrous membrane.

After a few minutes gently separate the chorio-allantois from the shell membrane.

With the rubber bulb, apply suction through the opening over the natural air sac, until the chorio-allantois falls off the shell membrane.

Completely open the window on the side of the egg, where now an artificial air sac has formed (after the chorio-allantois falls).

Using a tuberculin syringe or a capillary pipette, drop the inoculum on the chorio-allantois.

Seal well with paraffin-wax. Seal the opening over the former (natural) air sac.

Incubate the eggs for 6 days, observing them every day.

Using sterile technic, make smears from the surface of the chorio-allantois.

If histologic examination is desired, flood the chorio-allantois with the fixative, and remove after a few minutes.

(2) Hirst, Modified by Twyble and Mason.[2]**—**

Locate the embryo by candling.

---

[1] M. Research Council, Spec. Ser. No. 220, 1936; J. Bact. 44: 241, 1942.

[2] J. Immunol. 49: 73, 1944.

Sterilize the egg shell with alcohol.

Make a small hole over the natural air sac on the blunt end of the egg, using a probe.

Make a second hole over the region where the chorio-allantoic vessels are visible.

Deposit the material (usually 0.1 c.c.), using a sterile tuberculin syringe, into the second hole just beneath the egg shell.

Seal the holes with Scotch tape and incubate as above.

(3) Goodpasture and Budding, Modified by Gallaher and Kurachi.[3]—

Do not sterilize the surface of the egg.

Drill only one hole, over the area of the chorio-allantoic vessels.

Remove the shell and the fibrous membrane with a sharp knife.

Deposit the material on the chorio-allantoic membrane with a syringe or a capillary pipette.

Ring the window with sterile paraffin-wax, then cover it with a flamed cover glass, and proceed as above.

(4) Allantoic Sac Inoculation.—

The technic of Beaudette and associates[4] is recommended.

Deposit the inoculum about 1 cm. beneath the inner shell membrane with a 22 gauge needle, entering under the air cell of the egg.

(5) Yolk Sac Inoculation.—

Beaudette and associates recommend that a small drop of thin oil be deposited on the inner shell membrane to clarify it. This method is effective after a cap of the shell over the air cell is removed.

Beginners will do well to use a methylene blue solution to learn how to penetrate into the different parts of the egg. Control with a strong light will aid in the inoculation.

In working with developing chick embryos, sterility is most important, since many bacteria will cause death of the embryo. Contamination occurs very easily. It is of paramount importance that the eggs come from a hatchery which has chickens free from pullorum and other diseases. The age of the eggs is also important. Younger eggs are better for yolk sac inoculation.

(C) Special Methods.—

(1) Isolation of Mycobacterium Tuberculosis by Inoculation of the Yolk Sac of Embryonated Eggs.—

Material from patients with suspected tuberculosis, as spinal fluid, pleural exudate, gastric washing, sputum, tissue, or urine, may be inoculated. Within 4 to 5 days, acid-fast bacilli are readily demonstrable even from specimens in which the microorganisms were not found by direct smear and in concentrated specimen.

Embryos after 5 to 8 days' preliminary incubation at 37° C. are suitable. The yolk sac is inoculated through a small drill hole in the shell (see above) by means of a syringe with a 20 or 22 gauge needle. After injection, the drill hole is closed with melted paraffin.

Spinal fluid requires no preliminary preparation. It must be collected under aseptic conditions. An inoculum of 0.2 c.c. is used per yolk sac. Inoculate 5 to 6 eggs.

For **pericardial and pleural exudates**, a bacteriologic sterility test must be made by inoculating blood agar plates (M-28, M-29) and thioglycollate broth (M-47, M-48) with 0.2 to 0.5 c.c. amounts of the test fluid. Simultaneously inoculate 0.2 c.c. of material per yolk sac. Bacterial contaminants are controlled by the addition of penicillin or bacitracin, 500 units of penicillin and 500 units of bacitracin per c.c.

Gastric washings and sputum must be specially prepared.

Digest these with equal parts of 4% sodium hydroxide at 37° C. until all mucus and visible particles are dissolved.

Centrifuge at 2000 to 3000 r.p.m. for 30 to 60 minutes.

Remove and discard the supernatant fluid.

---

[3] Am. J. M. Technol. **10**: 2, 1944.

[4] Am. J. Vet. Res. **12**: 267, 1952.

Add a few drops of sterile 0.04% brom thymol blue.

Add to the sediment 6% sulphuric acid until green.

Suspend the sediment in 1 or 2 c.c. of saline containing 1000 units of penicillin per c.c.

Let stand for 2 hours in an incubator at 37° C.

Use 0.1 to 0.2 c.c. of this suspension per yolk sac as inoculum, and use 2 eggs routinely, or 3 if scanty growth is expected.

Tissues and exudates must be ground with sterile alundum and suspended in saline containing 1000 units of penicillin per c.c.; grind the tissue in a sterile mortar, using about 0.5 gm. of tissue and 3 to 5 c.c. of the saline. If the material is too thick for aspiration, dilute in saline containing 1000 units of penicillin per c.c. Inoculate at least 0.1 or 0.2 c.c. per each yolk sac, after letting it stand in an incubator at 37° C. for 2 hours.

Incubate inoculated eggs at 37° C.; turn them twice a day and observe at least once a day.

Examination.—

Inoculated eggs must be candled daily and discarded if the embryos die during the first 4 days. Beginning on the fourth day after inoculation, one embryo from each group should be examined daily.

Transfer the yolk sac, with aseptic precautions, to a sterile Petri dish.

Transfer approximately 1 c.c. of the yolk to a 2.5 by 10 cm. test tube.

Add 20 c.c. of 1% phenol.

Seal with a rubber stopper and shake vigorously for 5 minutes.

Allow to stand at least 2 hours.

Using a capillary pipette, carefully remove a small amount of the fatty layer at the surface, and smear it extremely thinly on the surface of one or more clean slides.

Allow to dry.

Fix in the flame.

Stain by the Ziehl-Neelsen method.

Examine microscopically for the presence of acid-fast bacilli.

In most instances, preparations made in this manner will contain typical acid-fast bacilli on the fourth day following inoculations.

To confirm the presence of *Mycobacterium tuberculosis,* inoculate guinea pigs, into the groin and intraperitoneally, with 0.5 to 1 c.c. from at least one yolk sac from a group of embryos used for the test. Tuberculin-test the guinea pigs at the end of three weeks, and sacrifice those with positive reactions. Proceed in the usual manner to examine for acid-fast bacilli in their organs.

(2) Meningitis.—

In many cases of meningitic infections, growth of bacteria can be demonstrated by egg inoculation when simultaneous agar cultures fail to permit their detection. Whereas growth on routine culture media is often sparse when few organisms are present in the specimen, and colonies do not develop for as long as 2 or 3 days, the presence of meningococci in the egg can be demonstrated within 10 to 24 hours after inoculation. This is a decided advantage for an early diagnosis.

Elimination of Gram-Negative Organisms

Method of Owen[1]

The presence of gram-negative organisms may interfere in the examination of wound secretions, pus, etc. Spreading Protei and Pseudomonades may impair the isolation of gram-positive cocci. Several methods have been devised for preventing the spreading of gram-negative bacilli. Use of potassium tellurite, as in medium M-41, or of sodium azide as in media M-21 and M-22, is good. Phenylalcohol plates (M-23) are helpful, too. The following method can be used if none of these other media are available.

(a) Culture pus or exudate in formula M-4.

---

[1] J. Bact. 52: 353, 1946.

(b) After 18 to 24 hours, transfer 0.1 c.c. of the growth in tube (a) to two tubes of ground beef medium M-12 consisting of a layer, about 1 inch high, of ground meat and 15 c.c. of beef heart infusion broth M-4, one tube containing 0.1 c.c. of 10% acetic acid, the other 0.2 c.c. of 10% acetic acid.

(c) Incubate 18 to 24 hours.

(d) Streak on blood agar plates M-28 or M-29, containing 5 to 6% of 95% alcohol.

Standardization of Bacterial Suspensions (McFarland)

Make a set of nephelometric tubes by mixing 1% sulphuric acid, c.p., with 1% barium chloride, c.p., according to Table 143.

TABLE 143

TUBE	1% SULPHURIC ACID C.C.	1% BARIUM CHLORIDE C.C.	CORRESPONDING DENSITY OF BACTERIA APPROXIMATELY MILLION PER C.C.
1	9.9	0.1	300
2	9.8	0.2	600
3	9.7	0.3	900
4	9.6	0.4	1,200
5	9.5	0.5	1,500
6	9.4	0.6	1,800
7	9.3	0.7	2,100
8	9.2	0.8	2,400
9	9.1	0.9	2,700
10	9.0	1.0	3,000

The tubes must be of uniform size and of resistant glass.

Plug tubes with rubber stoppers and carefully seal with paraffin. Set the tubes up in a rack.

For estimation, compare bacterial suspensions with the standards.

This set serves to determine approximately the number of bacteria present in a saline suspension. To estimate the bacterial density in broth cultures, make the set by dissolving the sulphuric acid and the barium chloride in sterile broth.

Some more modern procedures use photelometers. Standardize the curve by using the McFarland standards, above. Select the filter according to the photelometer and the color of the fluid in which the organisms are suspended.

PREPARATION OF VACCINES

Vaccines are killed suspensions of bacteria in phenol-saline, Chloretone, etc. An autogenous vaccine is made from bacteria derived from a patient's lesion. A stock vaccine is made from stock cultures of bacteria kept in the laboratory.

Preparation of Materials Needed.—

1. Several ½ ounce colorless wide-mouth bottles, with corks, sterilized in the dry heat oven at 170° C. for 2 hours.

2. Phenol and saline solution, made as follows:

Distilled water	1,000.0	c.c.
Sodium chloride, c.p.	8.5	grams
Mix thoroughly until dissolved		
Melted carbolic acid	5.0	c.c.
or		
Liquid carbolic acid	5.74	c.c.

Mix thoroughly until the carbolic acid is dissolved.

Filter through filter paper into wide-mouth bottles.

Fill about ⅔ full. Plug with nonabsorbent cotton. Tie paper over the top.

Sterilize in the autoclave at 15 to 20 pounds pressure for thirty minutes.

3. Tubes of culture medium for the bacterial growth, or Kolle or Blake flasks.
4. Platinum or nichrome wire.
5. Sterile 1 c.c. ampules.
6. Sterile syringe for transferring finished vaccine to ampules.

Making the Cultures.—

Select the medium on which the bacteria present in the lesion produce the best growth. Inoculate two culture tubes or one Kolle or Blake flask with material from the lesion. Record on record sheet.

Incubate at 37° C. for twenty-four to forty-eight hours, or until a good growth is obtained.

Identify the bacteria present by smears and colony study.

Record on the record sheet the type or types of bacteria present.

Proceed to isolate pure cultures by plating.

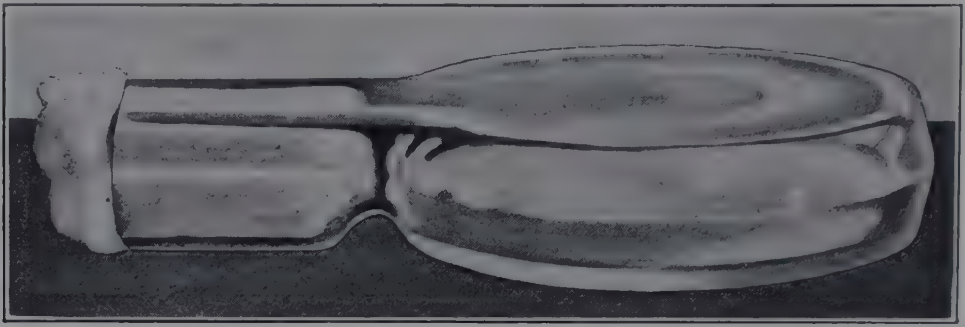

Fig. 345.—Kolle flask for vaccines.

Preparing the Suspension.—

Using a sterile dropper, or a sterile pipette, transfer a few c.c. of sterile phenol and saline solution to the surface of the two slants of bacteria. Enough phenol-saline solution should be used to cover the surface of the slant.

Use all sterile precautions in adding the phenol-saline solution to the culture medium to prevent access of spore formers.

Using a sterilized platinum or nichrome loop, loosen the growth from the surface of the slants, so that the living bacteria are suspended in the phenol-saline solution.

Flame the mouth of the test tubes and of the ½ ounce wide-mouth bottle.

Pour the suspension of living bacteria into the bottle.

Replace the cork, and hold in place with adhesive tape.

Shake in the shaking machine vigorously for at least five minutes, or shake by hand for fifteen to thirty minutes, or until all clumps of bacteria have been broken, and the bacteria are suspended evenly throughout the solution.

Sterilization.—

Place the suspension of bacteria in a water-bath regulated at 60° to 70° C. for one to three hours. Too little heat will fail to kill the bacteria, and too much heat may destroy the efficiency of the vaccine.

Sterility Test.—

Place the suspension of bacteria in the refrigerator after making the sterility test. Transfer several loopfuls of the suspension to two tubes of the type of culture medium used in the original cultures.

Incubate one of these aerobically, and the other anaerobically for three to ten days at a temperature of 37° C. and also use formula M-47, M-48, or M-49.

If no growth occurs at the end of this time, the vaccine is sterile, and may be diluted. If a growth appears, the vaccine must be placed in a water-bath at 80° C. for one or two hours, and another sterility test made at the end of this time.

The vaccine cannot be used unless it is sterile.

Counting (Wright's Method).—

Draw out a long capillary pipette in the flame.

Place a wax pencil mark at the end of every inch, beginning at the tip. The tip must be broken off squarely.

Have ready several clean glass slides, and cover glasses.

Have, also, a clean watch glass, on which are placed several drops of 2.5% sodium citrate solution.

Have ready a sterile puncture point used in making a blood count.

Work quickly.

Shake the contents of the vaccine bottle thoroughly.

Using a sterile dropper, withdraw several drops of the vaccine and place on a sterile watch glass. Use all sterile precautions, so as not to contaminate the vaccine.

Puncture the finger with the puncture point. The worker's own blood may be used.

Draw into the pipette 2 volumes of sodium citrate solution.

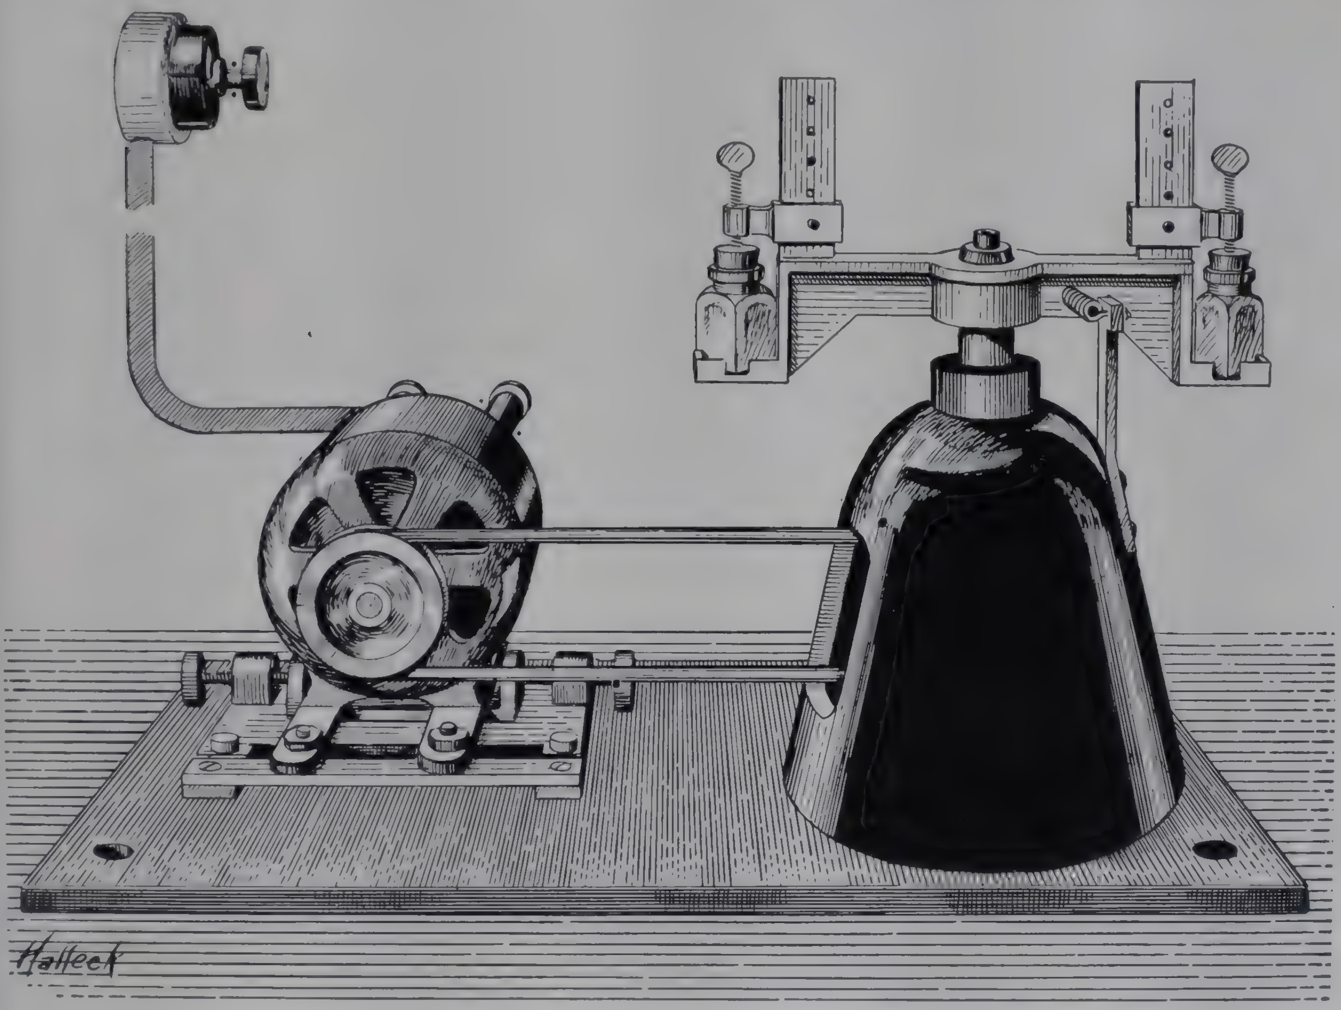

Fig. 346.—Shaking machine used in the manufacture of vaccines.

Admit a bubble of air after the two volumes of citrate solution.

Draw up 1 volume of blood.

Admit a bubble of air.

Draw up 1 volume of bacterial suspension.

Blow out upon a glass slide.

Mix thoroughly by sucking in and out of the pipette, taking care to avoid air bubbles.

Distribute to several slides.

Draw out a film in the manner of making a blood film.

Allow to dry.

Fix in methyl alcohol for five minutes.

Stain with dilute Giemsa stain for thirty to forty-five minutes, or stain immediately without fixation with Wright stain, page 620.

Use the oil immersion objective.

Count and record all the red blood cells and bacteria in successive fields, until 500 red blood cells have been counted.

Calculation.—

We know the number of red blood cells in a c.c. of blood. By making a comparison of the number of bacteria in a volume of vaccine equal to a volume of blood containing 500 red blood cells, we can compute the number of bacteria in a c.c. of the original vaccine.

Use the following formula:

Number of bacteria counted: X : : 500 : 5,000,000,000 (5 billion).

X equals the total number of bacteria in 1 c.c. suspension.

Example:

There were 750 bacteria counted in the fields in which there was a total of 500 red blood cells counted.

750 : x : : 500 : 5,000,000,000.

500 x equals 3,750,000,000,000

x equals 3,750,000,000,000 divided by 500 or 7,500,000,000 (7½ billion) bacteria in 1 c.c. of vaccine.

Diluting.—

The final vaccine suspension often contains 200,000,000 bacteria per c.c. (This number may be varied to suit individual cases.)

The vaccine in its present state contains 7½ billion bacteria per c.c.

The vaccine must be diluted so that each c.c. contains the correct number of bacteria, or 200,000,000.

Divide 7,500,000,000 by 200,000,000 to obtain the amount of dilution.

7,500,000,000 divided by 200,000,000 is 37.5.

Each c.c. of the present vaccine suspension must be diluted to a volume of 37.5 c.c. to obtain a bacterial count of 200,000,000.

Using all sterile precautions, place 1, 2, or 3 c.c. of the suspension (depending on the total volume desired after dilution) in a sterile graduated cylinder.

By means of a sterile 10 c.c. syringe, or a sterile pipette (20 c.c.), add the phenol-saline solution to the bacterial suspension until the desired volume is obtained.

Mix, and ampule.

Ampuling the vaccine.

Using a sterile syringe, and taking care to avoid air or other contamination, place the vaccine in ampules in 1 c.c., 2 c.c., or 5 c.c. quantities, as desired. The vaccine may also be placed in serum bottles, 20 c.c. in each vial.

Seal the ampules hermetically in the flame, and test for leakage after cooling, by shaking the contents thoroughly, holding the ampule upside down while shaking.

The serum vial is stoppered with a rubber stopper specially constructed to allow puncturing with a syringe needle when the contents are to be withdrawn. These rubber stoppers are sterilized in the autoclave at 15 pounds pressure for thirty minutes before using.

About 25 c.c. of the remainder of the vaccine are stored in serum vials so as to be on hand in case a refill is needed.

The vaccine should be labeled with the strain of bacteria present, the number of bacteria per c.c., the lesion from which they were obtained, the diluent, the patient's name, and the name of the physician.

For example:

Name of Patient Name of Physician.

Each c.c. of this vaccine contains 200,000,000 killed *Staphylococcus aureus* (suspended in phenol-saline solution) derived from abscess on forearm.

INOCULATION OF EXPERIMENTAL ANIMALS FOR CLINICAL DIAGNOSTIC PURPOSES

The use of experimental animals is necessary to verify certain bacteriologic procedures. The animals of choice are white mice, white rats, guinea pigs, and rabbits. It is necessary to procure healthy animals. For this purpose, one must be sure to buy his animal stock from reliable animal dealers with assurance that the animals have not been previously used by other laboratories for experimental purposes.

The animals must be kept in cages which can be readily cleaned. Provision must be made for the escape of urine from the bottom of the cage through the use of porous material or actual troughs.

Mice.—Mice may be fed on white bread and oats. Drinking water may be supplied through the special drinking apparatus which was introduced by Ehrlich and modified by Dunker.

Guinea Pigs.—The guinea pigs must be kept in dry roomy cages preferably with the bottoms covered with straw. They should be protected against sudden changes in temperature conditions. While guinea pigs were originally tropical or subtropical animals, in their changed location they stand the winter cold very well. They should be fed in summer on grass and pieces of vegetables, particularly cabbage. In winter, they may be fed hay and oats. Boiled potatoes are also good. Care must be exercised in changing their food supply in the spring and fall because of the likelihood of intestinal irritation. Artificially prepared foods can now be obtained for mice, guinea pigs, and rabbits.* A moderate amount of green vegetables, cabbage, etc., should also be given. When guinea pigs are being fed on cabbage or vegetables in summer it is well to give them very little water, but when they are given dry food they should be freely supplied with water.

Rabbits should be kept in roomy cages with plenty of straw. Their food requirements are about the same as for guinea pigs.

Cages of all experimental animals must be kept clean and disinfected at intervals.

Injection of Animals.—For the injection of animals, one must have on hand clean sterilized 2 c.c. glass syringes and 23-gauge 1-inch needles. To inject white mice, seize them at the nape of the neck and lay them on their backs, holding the tail or hind legs so they are stretched out and immovable. Subcutaneous injections are made by simply lifting the skin, after sterilization with iodine, and inserting the needle through the skin, care being taken in working around the abdomen not to penetrate the abdominal wall. Guinea pigs may be held in the same manner. For intravenous work on rabbits, select a marginal vein in the ear. The rabbit is placed upon a table, an assistant holds him securely while one or the other ear is selected for the injection. With a pair of fine scissors, the hair along the marginal vein is clipped off, the skin disinfected with bichloride of mercury or a small dab of iodine, the needle thrust into the marginal vein, and injection made.

For intra-abdominal or intraperitoneal injections, the rabbits or guinea pigs are secured on a special board, the abdominal wall lifted by the fingers so that no part of the intestine comes along with it, and injection is made with a needle in such manner as to avoid puncture of the intestines.

After the inoculation, the instruments used should be sterilized. The animals should be marked. Mice may be marked by placing a drop or two of various colored aniline dyes on their fur. Guinea pigs and rabbits may be marked by thrusting a very fine staple through the ear holding the numbered tag. These numbered tags may be bought from any supply house. For information on holding of animals, see pages 1494, 2041, and 2042.

---

*Purina Mills, St. Louis, Mo., manufacture excellent feed or chow for laboratory animals.

The date of inoculation, number of tag, material, etc., should be entered in a notebook. The animal should be observed at frequent intervals. Notes should be made as to any signs of sickness. When animals die, they must be autopsied. Mice are autopsied by being placed on a board and tacked down with a tack through each extended extremity. Use sterilized instruments. With a pair of fine scissors the median incision is made and the visceral conditions are observed. Bacteriologic cultures sometimes must be made from autopsies of animals. These must be taken under strict aseptic conditions. The same method may be applied in autopsies on rabbits and guinea pigs.

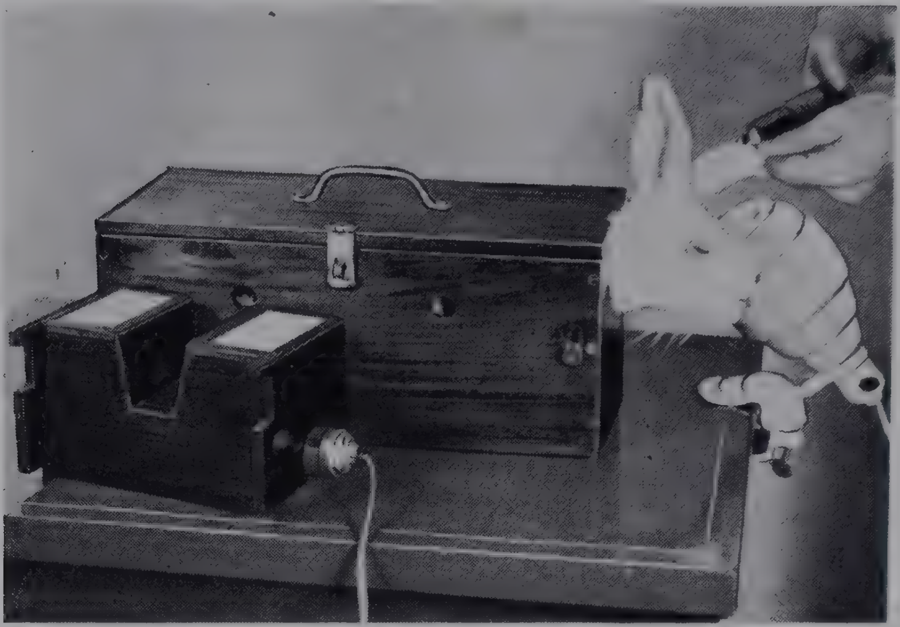

Fig. 347.—Beohm device for injecting into the marginal ear vein of a rabbit.

A very ingenious method for holding a rabbit so as to facilitate the injection of solutions into the marginal ear veins was described by E. B. Beohm.* This permits one to see that the needle is securely in the vein and that the blood is being pushed back through the venous system and not going out into the tissues. It consists of a light unit attached to a rabbit box, or a spotlight bed lamp which also works very well. This can be clamped to the edge of the table so that the rabbit's ear can be held out over the lens. Fig. 347 shows this type of lamp in use.

Another device is described in the chapter on Serology, pages 2041, 2042.

THE PRESERVATION OF BACTERIAL CULTURES

Maintaining a large collection of stock cultures of bacteria is a serious and difficult undertaking. Teaching institutions and type collecting agencies are confronted with this task which requires time, materials, and effort. It may involve the possible loss of biologic, immunologic, and cultural characteristics and occasionally the loss of the strain through such agencies as contamination, drying of the medium, and contact with accumulating metabolites. A voluminous literature has grown up on this question. Morton and Pulaski[1] worked out a method of preservation under paraffin oil which they claim has many distinct advantages. It reduces the frequency of contamination, especially with molds. No preliminary treatment of the cultures is necessary. All the organisms tested lived longer under oil than in the control tubes. Changes in cultural and biochemical characteristics have not been observed. The cultures are available at all times for transplantation without interfering with the preservation of the stock culture. The method is applicable to single colonies or mass cultures. It is advantageous in working with unstable variants, where occasional transferring to fresh media or growth in mass culture results in a change in the developmental stage of the strain. No seals, such as rubber caps, waxes, cements, etc., are needed. No special apparatus is needed, such as a centrifuge, desiccator, or vacuum pump. The method of choice recommended by these workers is as follows:

---

*J. Lab. & Clin. Med. 26: 12, 1936-1937.

[1] J. Bact. 35: 163, 1938.

Organisms are grown on appropriate solid media, such as infusion agar, blood agar, etc., slanted so as not to give too long a slant. After good growth has taken place, the slant is covered with sterile heavy paraffin oil, or mineral oil, to a height of 1 cm. above the top of the slanted surface.

Attention must be called to the following points: The oil should be well above the uppermost level of the medium. The medium in this way cannot dry out and separate from the wall of the tube and float to the surface of the oil, in which event the organisms are usually found dead. The quality of the oil is very important as any rancidity or toxic substance is harmful to the organisms. They have found that mineral oil of Parke, Davis and Company has proved very satisfactory. It is preferable to sterilize the oil in the dry heat oven at 150° to 170° C. for one hour; during autoclaving moisture becomes mixed with the oil, giving it a milky appearance. Precaution is necessary in flaming the loop after it has been withdrawn from the oil, since plunging directly into the flame results in spattering. This may be prevented by warming the loop very gently before heating to redness, or by plunging into a beaker of boiling water, then flaming to redness in the usual manner. In our laboratories we have kept cultures alive for six months with this method. It is our method of choice.

Difco stock agar formula M-115 and BBL cystine trypticase base M-6 are excellent media for maintaining cultures of fastidious organisms.

Molds are grown on dextrose-free media.

Salmonellae are kept best in semisolid agar-gelatin M-84.

Vi cultures of Salmonellae are kept on Kauffmann's egg medium M-58c. These cultures are kept in the refrigerator and never left at room temperature except for a few minutes necessary for transfers. After transplanting, put the egg slants with the new inoculum in the incubator for 24 hours, then transfer them directly to the refrigerator.

Dehydration in vacuum, however, should be practiced whenever possible. Some organisms do not tolerate lyophilization well.

CLASSIFICATION OF THE PATHOGENIC BACTERIA

For complete classification of bacteria, refer to the most recent edition of D. H. Bergey, *Manual of Determinative Bacteriology*, Baltimore, The Williams and Wilkins Company.

Smooth and Rough Colonies

Repeated transplants of cultures often bring about loss of virulence of bacteria and frequently changes in their cultural characteristics.

The colonies on solid media become rough and dry, and in broth produce a characteristic granular deposit. The usual or ordinary form of bacterial colony is termed ''smooth''; when cultural changes in association with loss of virulence are present, the colony is termed ''rough.'' This change from smooth to rough is usually represented by the symbol S → R. A single species of bacterium can give rise to both these two distinct types of colonies. Roughness is in some cases related to loss of the complex carbohydrate associated with the capsule of the organism. Some bacteria are roughish in appearance even in their normal virulent form; for example, anthrax bacilli and hemolytic streptococci. This is due to the physical arrangement of the bacteria.

The change S → R is accompanied by a definite loss of serologic specificity and often by a definite loss of virulence. Hemolytic streptococci are an exception to the general rule, since the colony given by the normal virulent form is finely granular, not smooth, and the virulent form, which rises from it and has lost its type-specific antigen, is smoother than the normal form. When making vaccines of streptococci, rough colonies should be chosen since they are more antigenic than smooth colonies. Four different antigenic factors are involved with the typhoid bacillus. Failure always to use smooth colonies containing the complete antigen may explain why older work with vaccines was unsuccessful. This explains many irregularities in agglutination and other immunologic reactions.

The S-type colony of one species of bacteria may be regular, dome-shaped, homogeneous, and have a smoothly curved edge; the R-type colony has a roughened surface, granular consistency, sharply angular edge, and is larger and flatter than the S-type. There are many intermediate types. Smoothness and roughness vary with the species. One type of colony may arise from the other, but the production of S-forms from R colonies is the more difficult. Reliable stable types can be maintained almost indefinitely by repeated colony selection. The S → R change is easily made by the pneumococcus with loss of virulence, and antigenic and cultural changes.

The complete antigen of a virulent organism is made up of protein and carbohydrate, the latter being a partial antigen responsible for the type-specificity. The R-type has lost its ability to produce the carbohydrate portion; it, therefore, is not antigenic (type-specific). An R-organism can be converted into an S-form of another type by appropriate methods. Changes S → R and R → S can take place in the animal body and in the test tube.

Characteristics of smooth or S-type: Soft butyrous growth on agar; homogeneous clouding of broth and homogeneous suspensions in physiologic saline; active motility of the motile species; specific carbohydrate and capsules in the capsulated species; normal size and shape of cells; marked biochemical activities; somatic and flagellar or capsular antigens; coarse flocculation with antisera; usually virulent and toxic if a pathogen (although some streptococci are more virulent in the R form); associated with acute infections; sensitive to bacteriophage; resistant to phagocytosis; efficient immunizing agents.

Characteristics of rough or R-type: Granular, tenacious, or friable growth on agar; granular growth in broth; spontaneous agglutination in saline; usually lack flagella in the motile species and capsules in the capsulated species; cells vary in size, often filamentous with branching and fungus-like growth; reduced biochemical activities; somatic or group antigens only; usually lack virulence and ability to produce toxins; more common in chronic infections and in convalescence; less sensitive to bacteriophage; susceptible to phagocytosis; usually poor immunizing agent.

Gram-positive rods, such as *B. anthracis* and many clostridia, are pathogenic, and have their typical biochemical properties only in the rough form.

DESCRIPTION OF INDIVIDUAL BACTERIA[1]

Staphylococci (Micrococci)

Morphology: Spheres, 0.8 to 1.0 micron, occurring singly, in pairs, but more commonly in bunches which resemble bunches of grapes. They form a design-like arrangement in smears from solid cultures.

---

[1] Revised from Bergey's Manual of Determinative Bacteriology, Williams & Wilkins Co., 1948.

Stain: Gram-positive.

Colonies: Growth abundant, colonies confluent, circular with unbroken edge, shiny, opaque, pigmented. They ferment lactose, sucrose, mannitol with acid formation.

Staphylococcus aureus forms a cream to golden orange pigment.

Staphylococcus albus and **epidermidis** form a white pigment.

Staphylococcus citreus forms a lemon yellow pigment.

Staphylococci cause localized abscesses; such as, boils, carbuncles, furuncles, etc. They are found in tonsillitis, osteomyelitis, etc.

While many strains forming orange pigment are pathogenic, the number of organisms producing white colonies and equipped with pathogenic power is less. It is necessary, therefore to subject staphylococci isolated from lesions to further tests:

(a) Hemolysin.—Two types of lysin are found: the alpha-lysin which causes the appearance of a hemolytic zone around colonies on blood agar formula M-28 or M-29 after 24 hours' incubation at 37° C.; and the beta-lysin which cause hemolysis on plates incubated for 24 hours at 37° C., and then placed for 24 hours in the refrigerator.

(b) Coagulase.—Test according to R-4. Most pathogenic staphylococci produce coagulase.

(c) Fermentation of Mannitol.—Many pathogenic staphylococci form acid from mannitol when tested in medium formula M-45.

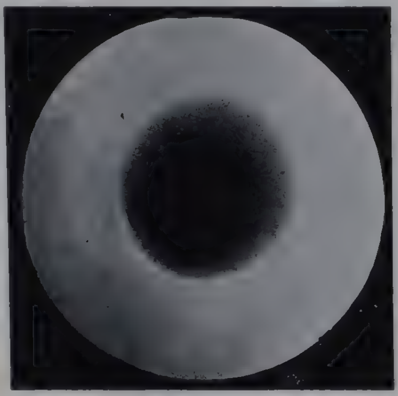

Fig. 348.

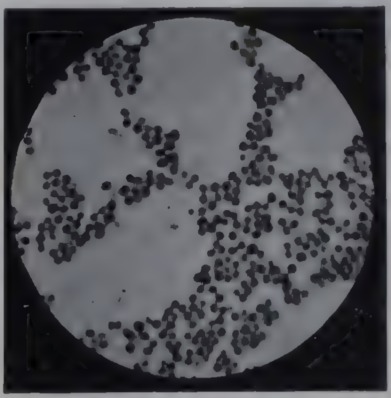

Fig. 349.

Fig. 348.—Colony of *Staphylococcus albus* on dextrose agar.
Fig. 349.—*Staphylococcus aureus*. (×950.)

(d) Liquefaction of Gelatin.—This is determined by inoculation of medium M-84 according to technic R-7, and on Stone's medium formula M-46.

Food poisoning staphylococci are subjected to the cat test which is described on page 1689.

For isolation of pathogenic staphylococci use blood agar plates formula M-28 or M-29. Excellent results are obtained with phenol red mannitol and salt agar M-45. This plate, described by Chapman,* may be used when only staphylococci are to be isolated; for example, in cases of intestinal upsets, from suspected food. Stone-Chapman medium (M-46) serves for further differentiation. The determination of hemolysis and coagulase confirms the diagnosis of a pathogenic staphylococcus.

For the detection of staphylococci in heavily contaminated material, plating to blood agar plates M-28 or M-29 is not always satisfactory. It may be necessary to use media with sodium azide (M-21) or phenylethyl alcohol (M-23). Food for examination should be ground in broth (M-1), then plated to blood agar M-28 or M-29 containing 3% sodium chloride, phenol red mannitol agar (M-45), and Chapman-Stone medium (M-46). Colonies showing mannitol fermentation are tested for coagulase formation (R-4), especially when a zone around them on the Chapman-Stone agar shows that they liquefy gelatin.

Serology.—This is rarely used for routine diagnosis. With the aid of precipitation tests, most staphylococci may be divided into two groups, A and B, the hemolytic types belonging mostly to group A. This classification of Julianelle was revised by Durfee[1] and extended. Fiske, and later McClure and Miller,[2] separated types of staphylococci by the bacteriophage method.

---

*Chapman, G. H.: J. Bact. 48: 555, 1944.

[1] J. Bact. 44: 589, 1942

Agglutination and precipitation tests with the serum of the patient have no practical value.

Report.—It is suggested that *Staphylococcus albus* which does not form hemolysin or coagulase and has no action on gelatin or mannitol should be considered a contaminant. Instead of reporting *Staphylococcus aureus* as such an adjective ''hemolytic'' or ''coagulase-positive'' should be added.

Treatment with antibiotics and sulfonamides may change the biologic properties of staphylococci. The ability to produce pigment is lost first.

Sarcinae

Morphology: Spheres, varying in size from 1 to 2 microns. Arranged in packets showing three dimensions. The number of cells in each varies with the species.

Stain: Gram-positive, although they decolorize rapidly.

Colonies: Growth abundant, colonies confluent. They look like colonies of staphylococci.

Sarcina flava forms a lemon yellow pigment.

Sarcina aurantiaca forms a golden orange pigment.

Sarcinae are nonpathogenic.

Streptococci

Streptococci are divided into three groups, the grouping depending on their reaction with blood. **Streptococcus hemolyticus group** (including *Streptococcus pyogenes, scarlatinae, mixtus*, etc.) hemolyze blood.

Streptococcus viridans group (including *Streptococcus salivarius* [*mitior*], *faecalis*, etc.) form methemoglobin from hemoglobin.

Streptococcus nonhemolyticus group (including *Streptococcus anhemolyticus, saprophyticus*, etc.) do not react with blood.

Morphology: Spheres in chain formation, varying greatly in size, the cocci showing variations within the same and different chains. 0.5 to 1.0 micron in diameter.

Stain: Pathogenic streptococci stain gram-positive in neutral or alkaline media; gram-negative in acid media.

Many of the nonpathogenic varieties are gram-negative.

Colonies: Pinpoint, growth scant, colonies distinct. Show definite reaction with blood if they belong to either of the first two groups.

They are round, with lacelike, or slightly corrugated edges.

Macroscopically they are elevated and shiny.

Streptococci are the cause of many severe pus infections; they also cause erysipelas, scarlet fever, etc. They produce bacteriemia frequently. They are found in mastoiditis, infections of the bones, joints, serous cavities, etc.

Streptococcus pyogenes is the common streptococcus found in very many acute infectious processes, such as blood stream infections, mastoiditis, middle ear disease, cellulitis, infections of sinuses, bone and joint infections, metritis, and many others.

Streptococcus scarlatinae is the streptococcus found in the throats of scarlet fever patients, and thought to be the cause of scarlet fever.

Streptococcus puerperalis is found in general puerperal septicemia.

Streptococcus erysipelatos is the cause of erysipelas.

Streptococcus epidemicus is the cause of epidemic sore throat.

Streptococcus anginosus is found in sore throats.

Streptococcus stenos is found in many inflammatory conditions in man.

Streptococcus mixtus is found in many pyogenic inflammations.

Streptococcus infrequens is found in various human infections.

Streptococcus salivarius (mitior) is found in abscesses of teeth and in endocarditis.

---

[2] Canad. M. A. J. 55: 36, 1946.

Streptococcus morbilli has frequently been found in blood, nose, throat, and conjunctiva of measles cases.

Streptococcus faecalis is found in the intestinal tract.

Streptococcus saprophyticus has been isolated from the vagina and from the nasopharynx in acute catarrhal inflammation.

Streptococcus anhemolyticus is a normal inhabitant of the mucous membranes of the mouth, nose, vagina, and intestines.

Many authors question the validity of the classification of streptococci according to their ecology, and suggest that hemolysis and serologic tests should be the chief means of differentiation.

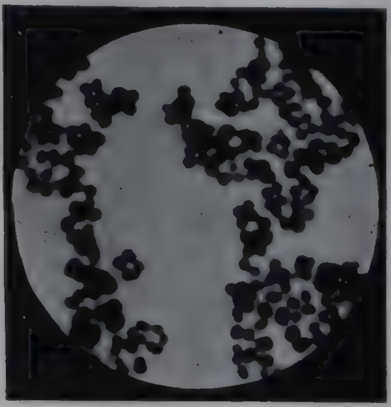

Fig. 350.

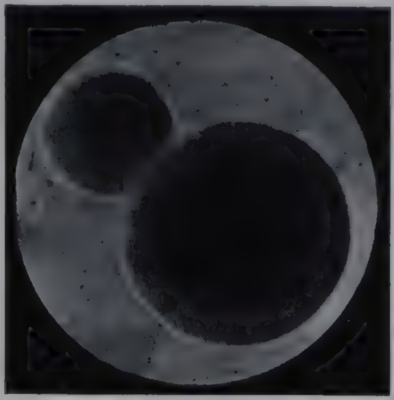

Fig. 351.

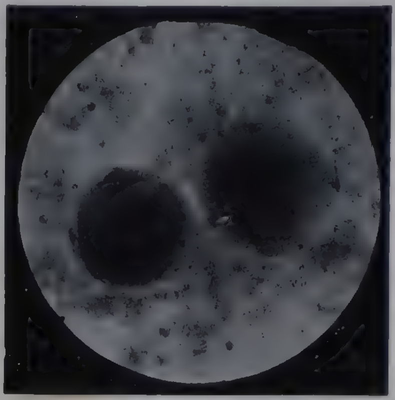

Fig. 352.

Fig. 350.—*Sarcina flava.* (×950.)

Fig. 351.—Colonies of *Streptococcus hemolyticus* on blood agar. Note that all the blood cells have been dissolved.

Fig. 352.—Colonies of *Streptococcus viridans* on blood agar. Note only partial hemolysis of blood cells.

Classification of Streptococci.—(See R-3.) Brown described two different types of reaction in blood agar plates, as follows:

α. A green discoloration and partial hemolysis of the blood corpuscles, forming a rather indefinitely bounded zone, 1 to 2 mm. in diameter, outside of which is a second, narrow, clearer, not discolored zone. Very few corpuscles remain in the outer, clearer zone, and these are never discolored. Even after 48 hours' incubation, this narrow outer zone of hemolysis does not always develop. If a plate, which has developed the typical appearances, is reincubated 24 to 48 hours, and then placed in the refrigerator for a further 24 hours, a double series of rings will develop frequently, so that the colony is surrounded by a hazy discolored ring, a clear hemolyzed ring, a second hazy ring, and a second clear ring.

β. These colonies are surrounded by sharply defined, clear, colorless zones of hemolysis, 2 to 4 mm. in diameter. No corpuscles can be seen within this zone. These zones develop more rapidly than those of the alpha type, often seen after 18 hours' incubation. They undergo no change in the subsequent 24 hours in the icebox.

The β-hemolytic strains just described correspond to the old classification of Schottmüller, called *Streptococcus hemolyticus.* The α-hemolytic strains may be regarded as equivalent to his *Str. viridans.* In bacteriologic circles, "hemolytic streptococcus" really means a strain that causes β-hemolysis on blood agar; a "nonhemolytic streptococcus" means a strain that either produces α-hemolysis or gives rise to no change at all.

Fermentation Reactions of Streptococci.—

Fermentation reactions are now employed as auxiliary rather than as primary differential criteria. Streptococci isolated from pathogenic lesions in man usually ferment lactose and salicin, but seldom mannitol, raffinose, or inulin, and produce acid without clot in milk. Streptococci commonly found in the human mouth, which are of the α-hemolytic type, frequently ferment raffinose, but fail to ferment salicin, inulin, and mannitol, and produce coagulation in milk. The fermentation tests must be carried out in serum broth (M-7), or cystine-trypticase base with the fermentable substances (M-6).

The Antigenic Structure of Streptococci.—

This problem has been well studied and worked out by Lancefield, who prepared extracts from different strains of streptococci and tested them against homologous and heterologous antisera by means of the precipitin reaction tests. She differentiated three different antigenic components. One of these antigens is an acid-soluble protein. Lancefield names this the "M substance." Another component is a complex carbohydrate found in hemolytic streptococci. It is analogous to the noncapsular carbohydrate component that characterizes the species *Str. pneumoniae*. She divided various strains of streptococci into groups. Twenty-one out of 23 strains possessing the polysaccharide antigen were called Lancefield's Group A and were derived from human sources, mainly from cases of acute infection; 18 of 21 strains belong to Group B, derived from cattle, mainly from cases of mastitis; 49 strains belong to Group C, derived from various animals, guinea-pig, cow, rabbit, horse, fox, pig, and fowl, etc., all suffering from definite infections; 8 strains belonged to a fourth group, D, derived from cheese; and 3 strains belonged to a fifth group, E, all isolated from certified milk.

Group A has been further differentiated into a number of different types by the type-specific, acid-soluble protein components. Group B is also divided into several antigenic types. There also have been added to this classification groups F, G, H, K, L, and M.

Group A.—These streptococci contained the Group A carbohydrate component described by Lancefield. They can be divided into a number of different serologic types by agglutination reactions or by precipitin reactions. Group A streptococci, in addition to producing β hemolysis in blood agar plates, form a soluble hemolysin. They produce a final pH of 5.0-5.6 in dextrose broth; they do not hydrolyze sodium hippurate; they do not reduce methylene blue in milk; they ferment trehalose but not sorbitol; they may or may not grow in 10 per cent bile agar, and seldom grow in 40 per cent bile agar. They ferment salicin, lactose, seldom mannitol, and very seldom raffinose or inulin. The strains that have been adequately identified as belonging to this group have, in the main, been derived from infections in man—tonsillitis, scarlet fever, cellulitis, erysipelas, puerperal fever, other types of septicemia, acute bronchopneumonia, otitis media, and so on. They have also been found in the throat, nasopharynx, or nose, of normal persons.

Group B.—These streptococci share in common a group-specific antigen that is carbohydrate in nature and differs from the group-specific antigen of Group A. They are divided further into a number of antigenic types, of which three have so far been identified, either by precipitation or agglutination tests against type-specific antisera. The type-specific antigens within this group are apparently not acid-soluble proteins, but complex carbohydrates of a different chemical structure from the carbohydrate that determines group-specificity. They may or may not produce β-hemolysis in blood agar plates. They differ from Group A strains in that they produce a lower final pH in glucose broth, hydrolyze sodium hippurate, and usually grow both on 10 per cent and 40 per cent bile agar. Like Group A strains, they do not reduce methylene blue in milk, but they resemble Group A in fermenting trehalose but not sorbitol. Most Group B strains have been isolated from cases of mastitis in cattle but occasionally they have been isolated from the normal human throat and vagina.

Group C.—These strains share in common a group-specific antigen that differentiates them from the other groups. They produce β-hemolysis on blood agar plates, and form a filtrable hemolysin. They produce in glucose broth a final pH intermediate between that produced by Group A strains on the one hand and by Group B strains on the other; the range covered by this group varies between pH 4.5 and pH 5.4. They do not hydrolyze sodium hippurate. Most strains of Group C grow on 10 per cent bile agar, but very few on

40 per cent bile agar. They can be further differentiated into three subgroups. One of these subgroups ferments neither trehalose nor sorbitol, another ferments sorbitol but not trehalose, and a third ferments trehalose but not sorbitol.

Group D.—This group, which was differentiated by Lancefield, possesses a common group-specific antigen, the chemical nature of which has not yet been determined. They produce β-hemolysis on blood agar. They do not produce a filtrable hemolysin. They produce a low final pH in glucose broth, 4.2 to 4.8. They grow freely on 10 per cent and 40 per cent bile agar. They reduce methylene blue in milk. They are heat resistant, most strains withstanding a temperature of 60° C. for thirty minutes. They do not hydrolyze sodium hippurate, usually but not always ferment trehalose and sorbitol, always ferment lactose and salicin, and usually but not always mannitol. They tend to assume the diplococcal rather than the streptococcal grouping. They have been derived from cheese and human feces.

Group E.—These strains have been isolated from cow's milk by Lancefield.

Group F.—These possess a group-specific antigen, by means of which they may be identified. They grow slowly on blood agar plates, forming minute pinpoint transparent colonies surrounded by a narrow zone (1.5 to 1.8 mm. in diameter) of β-hemolysis. They are identical with the strains described by Long and Bliss as ''minute hemolytic streptococci.'' They produce a final acidity in glucose broth of pH 4.8 to 5.2. They do not hydrolyze sodium hippurate. They do not reduce methylene blue in milk. They do not grow either on 10 per cent or on 40 per cent bile agar. None ferment sorbitol but some strains ferment trehalose. They ferment lactose and salicin. This group has been found in cultures from the human throat and probably are responsible for some cases of tonsillitis.

Group G.—These strains share also in common a group-specific antigen that distinguishes them from any of the other named groups. There is a controversy as to the final pH produced by them in glucose broth. Lancefield and Hare give a pH of 4.6 to 5.2, but Plummer gives to them a pH of 4.4 to 4.6. They do not hydrolyze sodium hippurate. They grow on 10 per cent bile agar, but do not multiply on 40 per cent bile agar. They do not reduce methylene blue in milk. They ferment trehalose, but not sorbitol. They ferment lactose. Most of these strains have been isolated from man, monkey, or dog. They seldom cause very severe infections.

Groups H and K.—They appear to differ from each other and from the other groups of hemolytic streptococci, in regard to their group-specific antigens They have been isolated from the nose or throat of normal persons.

Groups L and M.—These groups have been established more recently. M group streptococci were found in dogs.

Alpha-Hemolytic Streptococci.—Alpha-hemolytic or ''viridans'' streptococci usually grow at 45° C. if of animal origin. The latter hydrolyze starch. *Streptococcus endocarditidis* is a member of the viridans group.

The most important member of the ''viridans'' group is the Streptococcus of subacute bacterial endocarditis *(Streptococcus s.b.e.)* described by Niven and White[1] as:

(a) alpha hemolysis; (b) arginine positive; (c) inulin positive (M-6 or M-7); (d) raffinose negative (M-6 or M-7); (e) no action on sodium hippurate R-11; (f) often growth on media containing 40% bile; (g) does not grow on 6.5% sodium chloride-containing-media (medium made from M-18); (h) produces viscous growth in broth containing 5% sucrose, because of dextran formation; (i) does not respond well to penicillin treatment.

Lactic Streptococci.—These grow well at 10° C. and reduce methylene blue. They are present in dairy products, and are considered nonpathogenic.

Enterococci.—These survive 60° C. for 30 minutes, grow in the presence of 6.5% sodium chloride, and in media with strongly alkaline reactions. Some of them can be grouped with Lancefield's serum ''D,'' and are hemolytic. They are usually found in the intestinal contents.

Micro-Aerophilic Streptococci.—These organisms are usually isolated from wounds, intestinal contents, genitourinary tract, and blood stream. Most of them are nonhemolytic or belong to the viridans type. Many aerobic streptococci become microaerophilic under the influence of penicillin treatment.

---

[1] J. Bact. 51: 717, 1946.

Anaerobic Streptococci.—These are found in pus, genitourinary tract, blood stream (principally in puerperal sepsis and diseases of the lower abdomen). Most of them are strongly proteolytic. Their classification is vague.

In the study of **aerobic streptococci** the following reactions are of greatest importance:

(a) **Hemolysis.**—Streaked, poured, and poured-streaked blood agar plates M-28 or M-29 are used.

(b) **Inulin Fermentation.**—Most streptococci do not ferment inulin in formula M-6 or M-7.

(c) **Fermentation of Trehalose and Sorbitol.**—Many strains of group C and all strains of group K fail to ferment trehalose. Some strains of groups A, D, F, G, and H may be trehalose-negative. Sorbitol is fermented only by E strains and many C and D strains.

(d) **Hydrolysis of Sodium Hippurate.**—All strains of group B and many strains of group D produce hydrolysis of this compound. The reaction is tested according to R-11.

(e) **Fibrinolysin.**—It is determined with the aid of R-5.

The primary isolation of streptococci from uncontaminated material, such as blood, cerebrospinal fluid, etc., is carried out in trypticase soy broth (M-3), chopped meat medium (M-12), brain heart infusion broth (M-4), and on blood agar (M-28 or M-29). Microaerophilic as well as other streptococci grow well in thioglycollate broth (M-47, M-48).

For the isolation of enterococci, the S.F. enrichment medium of Hajna (M-112) is recommended.

Sodium azide blood plate (M-21) and phenylethyl alcohol plate (M-23) are excellent media for the isolation of streptococci from contaminated material; e.g., throat swabs. The sodium azide blood broth (M-19) is an excellent shipping medium for such material.

Fermentation is tested in broth M-5 with tryptose or trypticase, and in cystine trypticase medium M-6. One-half per cent of the fermentable substances is added to the base.

SEROLOGY

Griffith's slide agglutination test is difficult to carry out in routine laboratory practice because of the great number of cross-reactions. The precipitation technic is, therefore, preferred by many workers.

(a) **Production of Precipitating Sera.**—The antigen for all group sera, with the exception of group D, is prepared by growing the culture in buffered extract broth formula M-2 for 24 hours. Add enough 1% formolized saline to make the final formol concentration 0.05%. Store in the refrigerator for 48 hours. Make tests to determine if organisms are dead. If they are not, prolong the storage. Immunize rabbits directly from these suspensions. Group D streptococci must be centrifuged and resuspended in saline before being used for inoculation (Coffey).

Inject 1 c.c. amounts of these antigens into rabbits each day for 6 successive days. Remove some blood and test. If the test bleeding shows a high enough titer, bleed the rabbits 5 to 7 days after the last injection. Test the sera with homologous and heterologous streptococci for specificity and titer.

(b) **Preparation of Extract From Tested Organisms, Coffey Technic, Modified.**—Grow streptococci in trypticase soy broth formula M-3 for 24 hours. Use a large inoculum to start the growth. Incubate and centrifuge for one hour at 2500 to 3000 r.p.m. Decant the supernatant fluid and add saline to the sediment equal to $\frac{1}{5}$ the original volume of the broth. Add N/1 hydrochloric acid in amount equal to $\frac{1}{20}$ the volume of the saline-sediment mixture. Heat in the boiling water bath for 20 minutes. Transfer to the refrigerator. When cool, centrifuge and decant the supernatant fluid. Add to the supernatant fluid 1 drop of brom thymol blue indicator (page 32) and adjust the reaction to pH 7.0 to 7.2 with N/1 sodium hydroxide. Centrifuge again and use the supernatant fluid.

(c) **Another method (Lancefield)** recommends the use of the ''C'' substance: Add to the growth in buffered neopeptone broth M-2, after 18 hours' incubation, an equal amount of N/10 hydrochloric acid. Let stand 18 hours, then centrifuge. Heat the precipitate on the boiling water bath for 10 minutes, then cool and centrifuge. Decant the supernatant fluid and pour it into 4 volumes of 95% ethyl alcohol. Let stand for 24 hours, centrifuge, keep the sediment on the boiling water bath until the alcohol has completely volatilized off. Dissolve the sediment in an amount of saline equivalent to the volume of the original neopeptone broth.

(d) **Precipitation Test.**—

Prepare tubes 8 mm. in diameter, in rows, one row for each serum. For routine examination, three rows, corresponding to A, B, and C group sera, are used. Each row has six tubes.

Use the antigen undiluted, diluted 1:10, and diluted 1:100.

Tube	1	2	3	4	5	6
Serum	0.2	0.2	0.2	0.0	0.2	0.2
Antigen from unknown organism	0.2 undil.	0.2 dil. 1:10	0.2 dil. 1:100	0.2 undil.	0.0	0.0
Antigen from known specific organism	0.0	0.0	0.0	0.0	0.0	0.2 undil.
Saline	0.0	0.0	0.0	0.2	0.2	0.0

This table shows the set-up of each row. The controls are antigen control (tube 4), serum control (tube 5), and test with a homologous organism.

Incubate for 10 minutes in a water bath at 37° C. and determine if a ring has formed at the point of contact between the serum and the antigen. If no ring formation is observed, mix the contents and reincubate for 2 hours at 37° C. Observe for precipitation. If the reaction is still negative, keep the tubes in the refrigerator for 12 to 14 hours before taking the final reading.

Reliable commercial sera are produced by Lederle, Inc.

Determination of the Antistreptolysin Titer, Rantz and Randall[1]

(a) **Preparation of Lysin.**—Grow Richards strain, or any other strain of known good hemolysin producing streptococci belonging to group A, in meat infusion broth containing 0.2% dextrose, 2% proteose-peptone, and buffered by the addition, after autoclaving, of 0.2% sodium bicarbonate in sterile solution.

Centrifuge after 24 hours. To each 100 c.c. of the supernatant fluid add 42.9 gm. of ammonium sulphate, and let stand at 20° C. Centrifuge and dissolve the sediment in phosphate buffer pH 7.0, and make up to 1/25 of the original volume of the culture with the buffer solution. Dialyze in cellophane sacks for 18 hours against running tap water. Add 9 gm. sodium chloride to each liter of the dialyzed material, and sterilize by passing through a Seitz filter.

Phosphate buffer pH 7.0 is made by dissolving 14.2 gm. of disodium phosphate · 12 H_2O and 3.63 gm. of monopotassium phosphate in a liter of distilled water.

(b) **Determination of Combining Unit.**—Dissolve 1.6 gm. sodium hydroxide in 1000 c.c. of an isotonic buffer of pH 6.5.

Buffer pH 6.5 is made by dissolving 4.2 gm. sodium chloride, 3.17 gm. monopotassium phosphate, and 3.58 gm. of disodium phosphate · 12 H_2O per liter of solution.

Make a fresh solution of 0.15 gm. cysteine hydrochloride in 25 c.c. of this solvent.

Set up mixtures of the lysin and the buffered cystine:

c.c. lysin	0.35	0.30	0.25	0.20	0.15	0.10
c.c. cysteine	0.15	0.20	0.25	0.30	0.35	0.40

After 10 minutes add to each tube 1 c.c. of a standard antistreptolysin, containing one unit per c.c. Incubate for 15 minutes in the water bath at 37° C. Add to each tube 0.5 c.c. of a 5% suspension of rabbit blood cells suspended in the pH 6.5 buffer without sodium hydroxide. Incubate for 45 minutes. Centrifuge. That amount of lysin which just failed to produce hemolysis is the combining unit.

(c) **Determination of Antistreptolysin Titer.**—Dilute the concentrated lysin (b) to the degree determined in the previous test with isotonic buffer. A further dilution is carried out in the buffered cysteine solution at the time of use, so that the combining unit will be present in a final volume of 0.5 c.c. The lysin is ready for use after 10 minutes' exposure to the reducing agent (alkaline cysteine) and does not deteriorate within 60 minutes.

---

[1] Proc. Soc. Exper. Biol. & Med. 59: 22, 1945.

Set up the reaction as follows:

SERUM DILUTIONS

	1:10		1:100					1:500				
C.c. diluted serum	0.8	0.2	1.0	0.8	0.6	0.4	0.3	1.0	0.8	0.6	0.4	0.2
C.c. isotonic buffer	0.2	0.8	0.0	0.2	0.4	0.6	0.7	0.0	0.2	0.4	0.6	0.8
C.c. reduced lysin	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5
Unit per tube	12	50	100	125	166	250	333	500	625	833	1250	2500

Incubate in the water bath at 37° C. for 15 minutes. Add to each tube 0.5 c.c. of the buffered rabbit red blood cells. Incubate for an additional 45 minutes.

The last tube in which hemolysis has *not* occurred indicates the antistreptolysin titer of the serum.

A control serum of known titer should be included as a check.

More than 200 units is considered a pathologic finding.

ANIMAL INOCULATION

Mice are usually susceptible to pathogenic human streptococci.

Warning.—In cases treated with antibiotics the biology of the streptococci may be greatly changed. If experiments with hemolysin production on blood agar plates fail, use R-3 for the determination of this activity, preferably with a suspension of 5% sheep blood cells. Mix 0.5 c.c. of these cells with 0.5 c.c. of the broth culture and incubate for 2 hours at 37° C.

It is best to collect material from patients suspected of having streptococcus infections into broth containing penicillinase (M-20) *or* clarase and p-aminobenzoic acid, because treatment with penicillin or sulfonamides or both is often instituted before the specimens are collected.

SENSITIVITY TEST

The Dick Test for Susceptibility to Scarlet Fever

This test is based upon the assumption that the streptococcus is the cause of scarlatina. In 1885, Kline suggested that the streptococcus might be the cause of scarlet fever. In 1899, Class, of Chicago, and Gradwohl, of St. Louis, described an organism, a diplococcus, which was found in the throat of scarlet fever patients. With it, they were able to reproduce a febrile disease with desquamation in young hogs. In 1923, the Dicks, of Chicago, established facts which seemed to prove that the hemolytic streptococcus is responsible for scarlet fever. It is reasonable now to assume that the hemolytic streptococcus that is responsible for scarlet fever in one person may cause merely a harmless throat infection in another person. In England, Griffith worked out 28 different types of hemolytic streptococci. Types I and II were reported as predominant in London scarlet fever patients and other types were found elsewhere. In Chicago, Bailey found types II, III, and VI predominant in patients admitted to the Municipal Hospital in the years 1934 and 1935.

Some workers have attempted to prove that scarlet fever is due to a virus, but until more evidence is brought forward, it is proper to recognize the hemolytic streptococcus as the cause of this disease.

Purchase the Dick toxin for skin tests from any reliable biological house. This product is made so that 0.1 c.c. represents the quantity for injection.

Cleanse the flexor surface of the forearm with alcohol.

Using a 1 c.c. tuberculin syringe, inject intradermally exactly 0.1 c.c. of the Dick toxin.

With another syringe, inject 0.1 c.c. sterile physiologic salt solution about 2 inches below the test injection.

Needles should be the same as for the Schick test.

Wait twenty-four hours.

Read the reaction in a good light.

If the saline injection shows a reaction, disregard the result of the test.

If the saline injection shows no reddening, the test may be read.

Regard any reddening of the skin at the area of inoculation as a positive reaction

It is the custom of some observers to disregard any reaction of less than 1 cm. diameter.

A positive reaction indicates that the patient is susceptible to scarlet fever infection.

The Blanching Test for Diagnosis of Scarlet Fever

By injecting a small amount of scarlet fever **antitoxin** beneath the skin of the rash, a diagnosis of active scarlet fever infection can be made.

If the rash blanches at the point of inoculation, it is a true scarlet fever rash, not a drug rash.

Pneumococci

(Diplococcus Pneumoniae)

Morphology: Oval or spherical organisms, 0.6 to 0.8 micron by 1 micron. They may occur singly, in pairs, or in short chains, the chains showing the pair formation. In fresh specimens, and often in cultures, they show a capsule, which surrounds the single organism, or the pair, or the chain. They are lancet-shaped, and arranged along the long axis.

Stain: Gram-positive.

Colonies: Pinpoint, distinct colonies. Margin is entire; colonies are grayish. Blood agar shows these colonies with a zone of methemoglobin, indistinguishable from colonies of *Streptococcus mitis (viridans). Diplococcus pneumoniae* is soluble in bile and ferments inulin. *Str. viridans* is not bile soluble and does not ferment inulin.

Growth is scant on plain agar.

This organism is the common cause of lobar pneumonia and is associated with inflammations of the upper respiratory tract. There are now thirty-three recognized types of pneumococci differentiated by agglutination with specific serum or by the Neufeld reaction

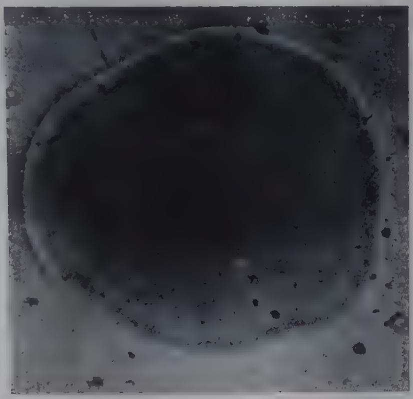

Fig. 353.—Twenty-four-hour colony of *Neisseria gonorrhoeae* on Gradwohl special hormone brom cresol purple medium.

Pneumococci must be tested for the following:

(a) **Hemolysis.**—Blood agar M-28 or M-29 or R-3 will show the alpha type of hemolysis.

(b) **Bile Solubility Test.**—

All pneumococci are bile soluble. Bile solubility may be tested with bile, sodium desoxycholate, or sodium lauryl sulphate. The method is described under R-10.

(c) **Inulin Fermentation.**—Test for inulin fermentation in M-6 or M-7.

Trypticase soy broth M-3 and brain heart infusion M-4 are recommended for the isolation of pneumococci from blood and cerebrospinal fluid. Material such as sputum is streaked on blood agar plates M-28 or M-29. The species-diagnosis is carried out by typing. This is useful only when the organisms have capsules. Capsules may be lost under the influence of therapy. It is necessary, therefore, to ascertain, by the use of capsular stains, if the organisms are typable.

The best enrichment is the mouse inoculation.

Mouse Injection for Use With Sputum Typing in Pneumonia

This method is used when the sputum fails to show the Quellung reaction in direct typing, and also to verify the type when the Quellung reaction has been found. If the sputum is very thick or tenacious, add a small amount of sterile saline or broth to facilitate ejection through the needle.

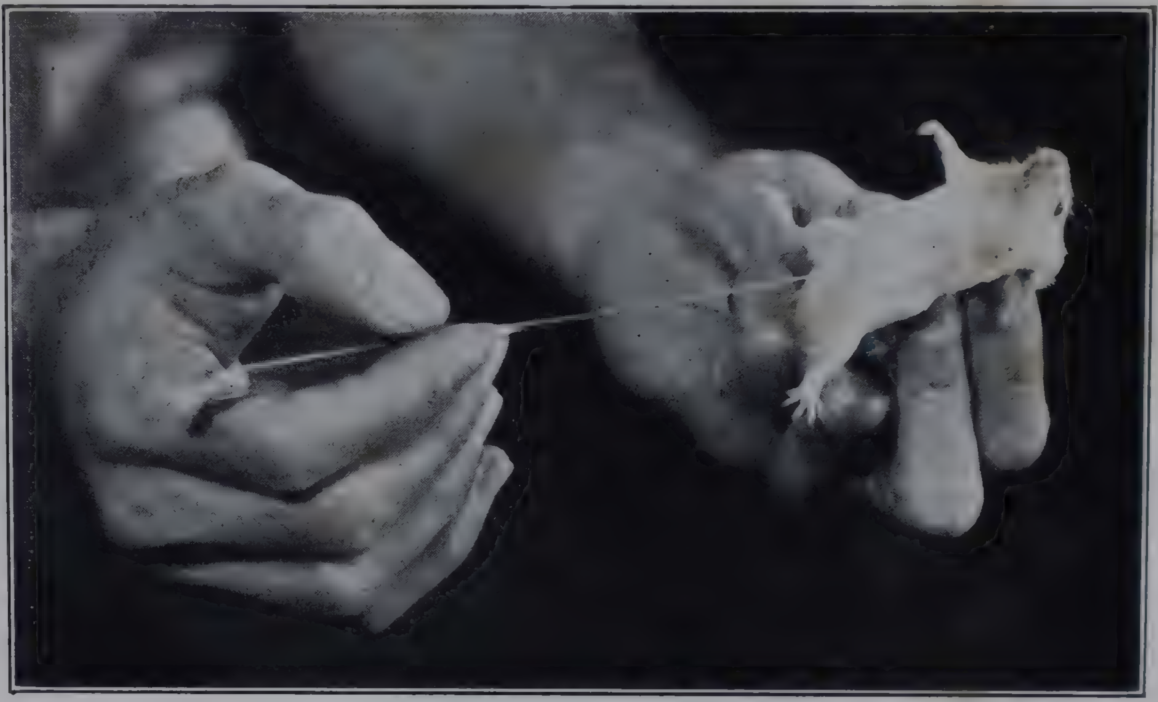

Fig. 354.—Correct method of holding a white mouse for intraperitoneal injection.

Pick up the mouse by the tail using the right hand. Then grasp the mouse by the nape of the neck with the thumb and index finger of the left hand. (This can be done more easily if the mouse is holding on to the edge of the table or wire of its cage with its front feet.) Maintaining this position, turn the mouse over, pulling its tail down the center of the palm toward the wrist. Hold the tail and left hind leg down with the little finger. With the middle and ring fingers, hold the loose skin of its back tightly. Locate the soft depression near the right hip of the mouse. Swab this area with iodine. Inject 1.0 to 1.5 c.c. of sputum intraperitoneally into the soft spot, using a syringe and intradermal needle (about ¼ inch long). After 4 to 6 hours, or sooner if the mouse appears ill, hold the mouse in the same position and tap the abdomen. Use a capillary-dropper with a fine yet not flexible end. Insert this into the abdomen of the mouse and withdraw fluid for typing.

SEROLOGY

Typing of Pneumococci

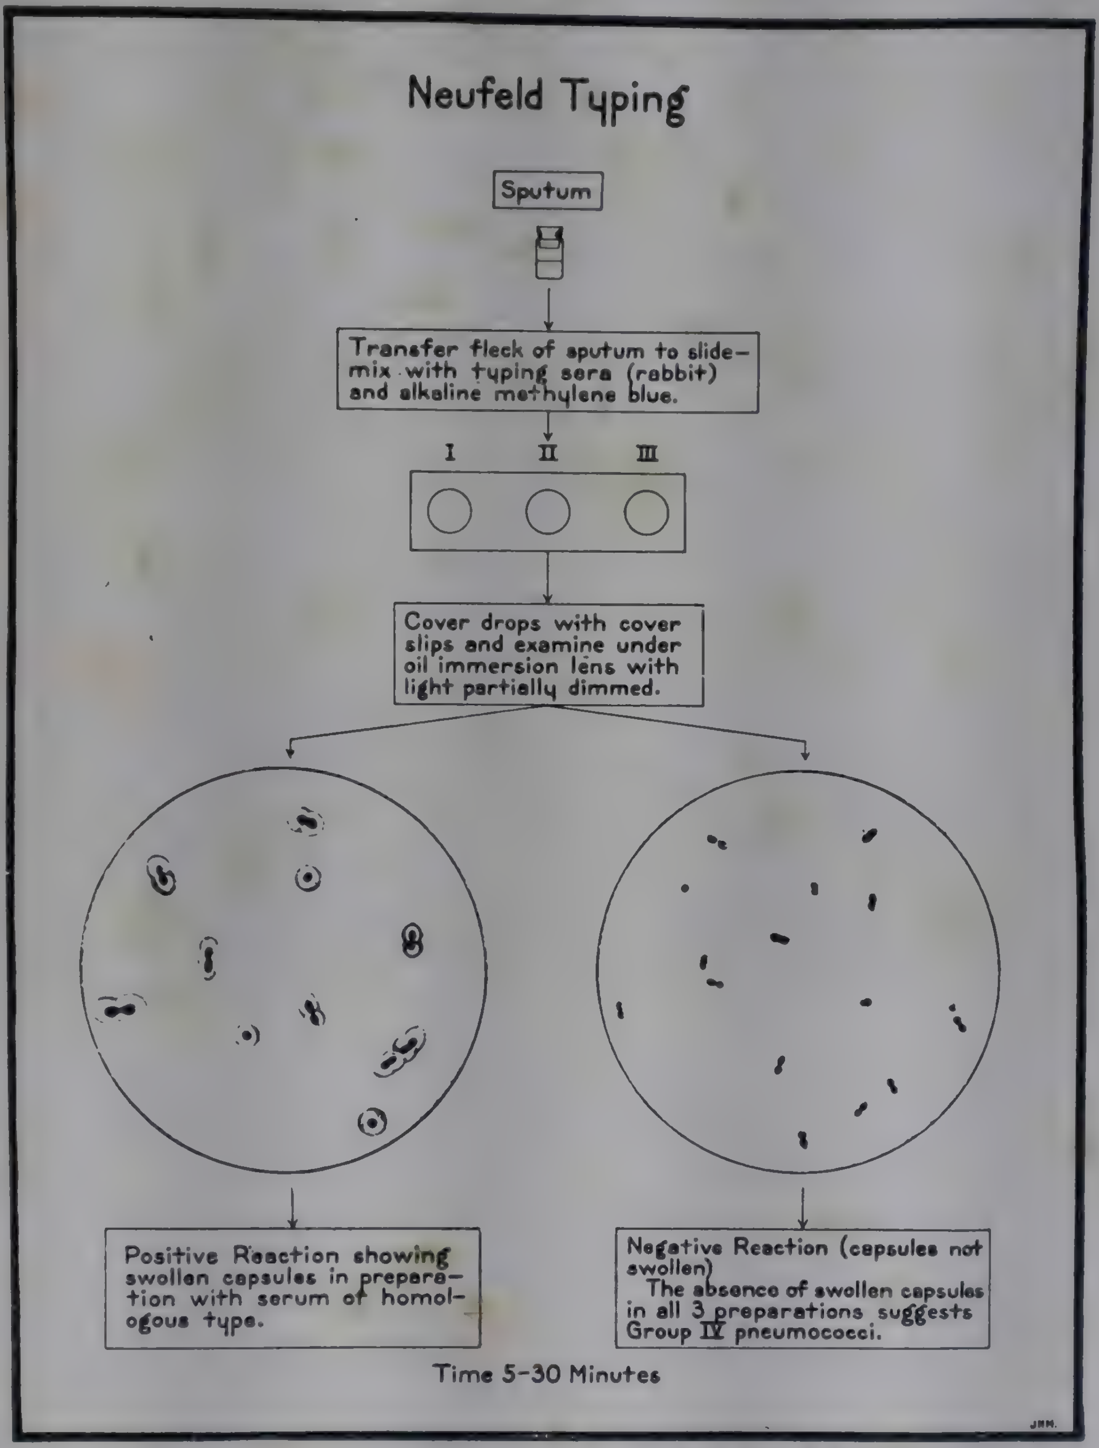
The Neufeld ''Quellung'' Reaction

This is the method of choice for quickly and accurately typing pneumococci. It was first described by Neufeld and later modified by Sabin.

The word ''Quellung'' means the swelling of the capsule of the pneumococcus when it comes in contact with its homologous serum.

Technic.—The typing sera may be obtained from Wyeth, Inc., Philadelphia.

There are six pooled sera available: mixture A, containing Types I, II, and VII; mixture B, containing Types III, IV, V, VI, and VIII; mixture C, containing Types IX, XII, XIV, XV, XVII, and XXXIII; mixture D, containing Types X, XI, XIII, XX, XXII, and XXIV; mixture E, containing Types XVI, XVIII, XIX, XXI, and XXVIII; and mixture F, containing Types XXIII, XXV, XXVII, XXIX, XXXI, and XXXII.



Neufeld Typing
Sputum
Transfer fleck of sputum to slide—mix with typing sera (rabbit) and alkaline methylene blue.
I
II
III
Cover drops with cover slips and examine under oil immersion lens with light partially dimmed.
Positive Reaction showing swollen capsules in preparation with serum of homologous type.
Negative Reaction (capsules not swollen)
The absence of swollen capsules in all 3 preparations suggests Group IV pneumococci.
Time 5-30 Minutes
JRH.

Mass. Dept. of Public Health.

Fig. 355.—Schematic representation of steps in Neufeld typing together with a positive and negative reaction.

Using a platinum* loop, place a small fleck of sputum on each of six cover slips. Add to each bit of sputum 2 or 3 times the quantity of the various mixtures, using a different pooled serum for each cover glass. Add two loopfuls of Loeffler's methylene blue solution to each bit of sputum. Mix thoroughly with a platinum loop and invert on ordinary glass slides, pressing them down to make a thin layer of stained sputum between the cover glass and the slide. Each slide must be properly labeled. Examine the preparation with the oil immersion objective with the diaphragm partially closed. Make a note of which mixtures show swelling of the capsules of the pneumococci. When a mixture is found which gives a positive reaction, the sputum is then tested against monovalent sera for each type included in the mixture.

---

*On nichrome.

For example, capsule swelling occurred in mixture B, which contains Types III, IV, V, VI, and VIII. Prepare five coverslips with sputum on each and then add 2 or 3 times the quantity of Types III, IV, V, VI, and VIII to the respective cover glass. Mix with a platinum loop, invert over a glass slide, press down, and examine with the oil immersion objective. Report the types which show swelling of the capsules. If the preparation does not contain enough methylene blue, a small amount may be added with the platinum wire.

A positive reaction is indicated by the appearance of definitely outlined capsules about the pneumococci present in the sputum. The sharpness of the outline of the capsule is perhaps of more diagnostic importance than the degree of swelling. A positive reaction usually takes place within a few minutes. If no reaction occurs immediately, the preparation may be examined again at the end of 30 minutes. In pneumococci with negative reaction, the capsule will appear as a halo without definite outline. Sabin stated that the reaction is so specific that the type diagnosis may be made if only one swollen capsule is seen in the preparation. A positive reaction usually takes place within a few minutes.

When the Neufeld technic is used with sputum containing many Type III organisms, the organisms may appear in large masses without definite capsular swelling. In such cases, it may be necessary to dilute the sputum with saline to obtain definite swelling of the capsule.

Sputum, if kept on ice, may be typed quite satisfactorily even when several days old. The method is also applicable to cultures, spinal fluid, pus, etc.

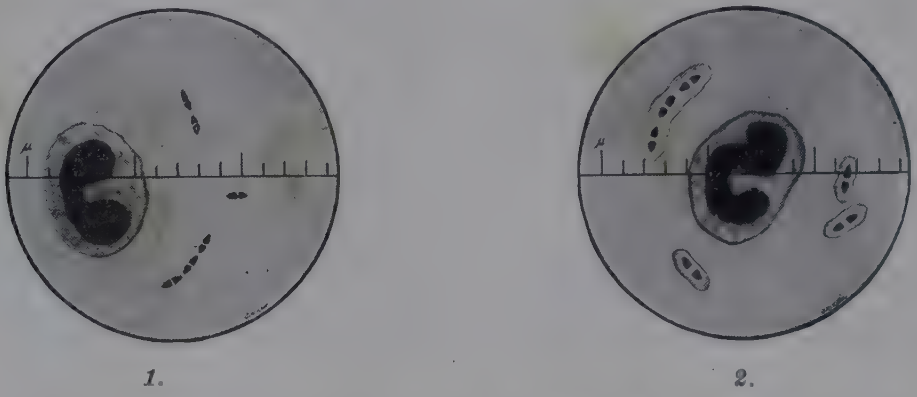


Fig. 356.—Neufeld reaction showing, *1*, negative and, *2*, positive results. Note the size of the swollen capsules on *2* as compared with the leukocyte. (Courtesy Dr. A. B. Sabin and J. A. M. A.)

Sabin or "Stained Slide" Agglutination Test[1]

The mouse peritoneum is injected with 1 or 1.5 c.c. of sputum, and after three or four hours a glass capillary is filled with peritoneal fluid directly through the abdominal wall. Capillary drops of fluid are expelled onto a slide and mixed with the different typing sera either individually or in groups. The one in which pneumococci become clumped is the one in which serum and organisms are the same. The others serve as controls.

If there is no clumping, the type or group of types may be excluded; if there is clumping in a group test, the sera of the types contained in it are separately applied until the type which causes the clumping is found. A bile solubility test should be done on the broth culture of the organisms (R-10).

Krumwiede and Valentine Precipitation Test

Filtrates of sputum, cerebrospinal fluid, urine, and pleural exudate may contain pneumococcus precipitinogen in the absence of the organisms because of autolysis of the bacteria. Such substances may be found also in the peritoneal cavity of mice.

The fluid suspected of containing pneumococcus precipitinogen is used for precipitation reactions in the same manner as streptococcal extracts described on page 1490.

NEISSERIAE

Neisseria Gonorrhoeae (Gonococcus)

CULTURE METHODS

Ever since the publication of the work of Neisser in 1879 on the gonococcus, and its cultivation by Bumm in 1885 on human blood serum, the exactitude of bacteriologic gonococcal diagnosis has been taken too much for granted. There has been too much reliance placed on the Gram stain as a definite means of identification. This stain shows many gram-negative diplococci which are not gonococci, but which resemble them morphologically. The variability of the gram reaction, as reported by the Committee of Bacteriological Technic, of the Society of American Bacteriologists[1] is well known among bacteriologists, but practitioners have been altogether too confident concerning the reliability and infallibility of the Gram stain. Churchmann[2] showed that with some organisms the Gram reaction is ''stable,'' and with others ''unstable.'' Stearn and Stearn[3] showed that to obtain a successful differentiation between positives and negatives, the Gram technic should be performed at a controlled reaction of about pH 4.0. While the Committee report showed that the Gram technic is more useful in diagnostic work than it is in pure culture work on unknown bacteria, we believe some of its fallacies and shortcomings may be operative in the field of gynecologic bacteriologic diagnosis.

Ghon,[4] Mucha, and Wiesner,[5] among others, reported the finding of gram-negative diplococci in the rectum, vagina, and respiratory tract that were not gonococci, although morphologically they appeared to be such.

An interesting side light on the question of the staining characteristics and morphology of gonococci has been furnished by the work of S. Ramsine and S. Milochevitch.[6] They based their work upon a statement made by Nicolle on the important role played by cocci taking the Gram stain, called Synococci, which are found in postgonococcal urethritis. They quote Delbanco and Lorentz, who studied clinically and bacteriologically diplococci taking the Gram stain. Wichmann and Schlunk confirmed the observation of Delbanco and Lorentz on these diplococci, and showed that they had diminished in virulence. Kandyba succeeded in obtaining a race of diplococci taking the Gram stain, particularly in pure cultures of gonococci in vitro, heated to 40° C. Neither of these others succeeded in transforming this diplococcus into a typical gonococcus.

Several forms of modifications in morphology of gonococci have been described; namely, the macrogonococcus of Le Sodier and J. Verge,[7] elongated forms of A. Cohn,[8] and x forms.[9] Ramsine and Milochevitch, in cultivating gonococci, have found typical forms which appeared and disappeared spontaneously. They observed some that do not take the Gram stain, some that form macrogonococci, others that take the Gram stain. They have changed the appearance of this organism by placing it in contact with gonococcus filtrate, grown in broth or ascitic fluid. They found a remarkable adaptation of this diplococcus in a medium of broth and ascitic fluid. They also found that these organisms varied in their tinctorial properties, and in their size. They proved that they could transform some gram-positive organisms to gram-negative. This was done by reversing the method. Gonococcus S^4 and S^5 returned to the typical form in five generations, Coccus A^1 and A^3 in six generations. By the action of Protargol and by heating at 42° C. for two hours, they changed the gonococcus to a gram-positive diplococcus.

[9] Medycyna doswiadczalna i. spoleczna 1: 359, 1924.

Their conclusions were that the gonococcus is susceptible to pathogenic degradation as well as to evolution in morphology and biology; that specific heat and chemical agents create conditions favorable to this evolutionary behavior; and that this evolutionary process is reversible; that is, the gonococcus may be transformed into gram-positive diplococcus and vice versa.

The author has, for a long time, entertained serious doubt concerning the correctness of diagnoses made at times by gynecologists and urologists who relied on clinical symptoms and history, plus the finding of gram-negative intracellular diplococci in smears from various portions of the urogenital tract; namely, urethra, vagina, Bartholin glands, and cervix. This question has not been given close study and proper consideration even at the hands of laboratory workers. The clinical worker, while dissatisfied with the situation, manifestly could do little or nothing to clarify it. We have for years followed the examples of others in reporting on smears in this stereotyped fashion, "gram-negative diplococci resembling gonococci." In some cases, it is a matter of little or no importance to the referring physician to go any further than this, yet in other cases, particularly of a forensic nature, it is of paramount importance to state whether, from the laboratory standpoint, it *is* or *is not* a gonorrheal infection. Hence some other more exact method of clinching the diagnosis must be used. Culture methods alone seem to be adequate.

CHARACTERISTICS OF NEISSERIA GONORRHOEAE

Morphology: Spheres, 0.6 to 1.0 micron, with one side slightly flattened, particularly when in juxtaposition with another organism. They occur singly, in pairs, or in isolated clumps, but never form chains. Smears from colonies show autolysis, the autolysis becoming more marked the older the colony.

Stain: Gram-negative. They decolorize slowly.

Colonies: Small, translucent, finely granular with lobate margin, grayish white with a pearly opalescence by transmitted light.

Colonies are usually distinct, but may be confluent, particularly if transplanted frequently. Growth may be abundant if a rich medium is used.

Gonococci are characterized by the following reactions:

(a) **Growth only on enriched media**, that is, plates containing serum, ascitic fluid, blood, or supplementary substances.

(b) **Positive oxidase reaction.**—This is carried out according to the method described under R-18. It must be noted that meningococci and many bacilli also give this reaction.

(e) **Fermentation of dextrose, no action on maltose.**—These tests are carried out by inoculating serum broth containing the carbohydrates formula M-7 or cystine trypticase base M-6 with the addition of a suitable indicator and the fermentable substance.

The number of culture media for growing gonococci recommended in the literature is legion, and the results apparently are easy of accomplishment. The desiderata for a workable culture medium for isolation and identification of the gonococcus from female patients are: it should grow the organism quickly; distinctive colonies of gonococci must appear; there must be distinctiveness to the colonies of those other gram-negative organisms that so closely resemble it.

We have elaborated a technic for the cultivation of gonococci which has been eminently successful both in our hands and in those of other workers. It seems to eliminate the objectionable features heretofore encountered. This method published by us in 1926[1] is a modification of Mulzow.[2] The method has been further modified and fully described.[3]

The method embodies the use of a special agar M-37. The plate method is used for all diagnostic purposes. Ascitic fluid is the enrichment fluid in the medium but blood serum from a guinea pig or rabbit may be substituted. Caution must be exercised in obtaining ascitic fluid in a sterile manner since it cannot be heated or filtered to rid it of bacteria. We prefer small Petri dishes for economic purposes; namely, those 75 mm. in diameter. The ascitic fluid and the special gonococcus agar, of course, are kept separate until ready for use. In order to use this material, we place 2 or 3 c.c. of sterile ascitic fluid in a sterile Petri dish. A tube containing the special Gradwohl gonococcus agar is melted and, while fluid, but not hot, with sterile precautions, the agar is poured on the ascitic fluid in the plate, the plate is covered, rotated to mix, and then is allowed to solidify. There should be enough of the combined ascitic fluid and agar when solidified to completely cover the plate to a height of one-half the total height of the Petri dish.

Inoculation of Plates with Gonorrheal Material

Material should be obtained from high up in the organ examined, and should be procured with a platinum loop instead of with a sterile swab. This platinum loop should be a very small one so that only a very small quantity of pus is picked up. The purpose of the very small drop is to get a very thin streak over the surface instead of a heavy streak. In other words, we wish to get distinct isolated colonies. Inoculations are made by streaking the surface of the plate with a small drop on the loop in a zigzag manner so that there will be a definite isolation of the growing bacteria. In making the streak, great care should be exercised that only the very top surface of the medium is streaked; in other words, we should not dig into the medium. Incubate these plates with the covers on top instead of upside down so that there will be an ample supply of water of condensation. With this precaution, together with a pan of water in the incubator, there is no further need for furnishing moisture. Emphasis is to be laid on the fact that in order to grow gonococci, these plates should be inoculated *at once* with material fresh from the living human body.

Plates that have been kept in a refrigerator ready for use should be warmed to body temperature before inoculation. Plates that are dried out should not be used.

Characteristics of the Gonococcus on the Gradwohl Medium

All colonies exhibiting a yellow zone around them are to be regarded as nongonorrheal colonies since gonococci do not ferment levulose, and therefore do not cause a change of color of the indicator (brom cresol purple). Examinations for identification of gonococcus colonies should be microscopic, followed by a stained smear from the colony. In examining the stained smear, look especially for autolysis, which becomes more marked with the age of the colony.

---

[1] J. A. M. A. 87: 242, 1926.

[2] J. Infect. Dis. 36: 419, 1925.

[3] Gradwohl, R. B. H.: Urol. & Cutan. Rev. 35: 7, 1931.

If transplants are intended, they should be made within forty-eight hours after the original inoculation, otherwise autolysis will prohibit a successful subculture. See page 1640 for complete description of colonies.

This method has been very useful in practice, both in the male and the female, but its application is possibly more important in the female. This is especially true of cases with forensic features. The method is equally important in diagnosis and in the estimation of cure. In this connection, note the following statement of Vonderlehr,[1] in his review (1941) of the status of the venereal disease control program in mobilization and national defense, "The need continues to exist for the development of facilities for the culture of the gonococcus in public laboratories. The culture remains the most efficient method for the determination of cure in this disease." In the ordinary case of purulent discharge from the male urethra, a demonstration of gram-negative diplococci in the smear suffices in most instances to satisfy a physician that he is dealing with a case of gonococci. But, if there should be any doubt expressed by the patient as to the correctness of this diagnosis, it is the physician's duty to prove that gonococcic infection really exists. This can be done only by culture methods. From time to time, we have seen cases of unspecific purulent urethritis in the male due to organisms other than the gonococcus; it is this type of case that requires a culture diagnosis.

In the female, the question of divorce often hinges upon the result of the diagnosis of gonorrhea. Manifestly, no physician would want to endanger the peace and security of a household by an incorrect diagnosis of gonorrheal infection. In the case of women accused of prostitution and supposed gonorrheal vaginitis, it is equally necessary for the forensic physician to be sure of his ground. Gram-negative diplococci in the male or female are not necessarily gonococci.

It is therefore to be accepted as a proved fact that the growth of the gonorrheal colony on this medium is sufficient proof of gonorrheal infection. On the other hand, the failure to find gonococcic colonies is negative proof that gonorrhea does not exist. The question has been raised in court whether the failure to find gonococci on the plate may not mean the absence of gonorrheal infection. To this argument the answer may be given that a repetition of the attempt and a failure to find gonococci after several examinations on this medium should be sufficient proof to exclude the existence of gonococcus infection in the material examined.

There is another field in which this method is very useful; namely, in the diagnosis of so-called cases of gonorrheal vaginitis in children. Most of these cases show a purulent vaginitis and the presence of gram-negative diplococci in the smears. Some years ago, through the courtesy of Dr. John R. Vaughan, a gynecologist in St. Louis, we were furnished with a number of plates from supposed cases of gonorrheal vaginitis in babies. In twenty-five cases submitted by Vaughan, only two showed positive *Neisseria gonorrhoeae* colonies. The remainder showed gram-negative streptococci. In twenty-three, therefore, out of twenty-five cases, the term "gonorrheal vaginitis" was incorrect.

---

[1] Vonderlehr, R. A.: Am. J. Pub. Health 31: 1027, 1941.

Brown, Soule, and Kleine[1] reported the successful use of this medium in cultivating gonococci in cases of true gonorrheal vaginitis in children. Their cultivation work, which was in connection with the treatment of gonorrheal vaginitis in children, showed gonococci in many of the cases examined. The sources of infection in their group were as follows: contact with a member of the family already infected by sleeping with that person, use of common towels, toilet, linens, bath, etc., accounted for most of the cases. They state that only one of the patients developed the infection in an institution. Their cases showed a vaginal discharge of a heavy green-yellow pus, occasionally blood-tinged due to erosions and ulcerations of the mucous membrane. The vulva, hymen, and vagina were usually reddened and often edematous. Their diagnosis was confirmed by demonstration of typical biscuit-shaped intracellular gram-negative diplococci on direct smear, and culture of the organisms on Gradwohl's special hormone agar medium.

Primary Isolation

For primary isolation, culture in a carbon dioxide atmosphere is essential (see pages 1472 and 1575). Gradwohl medium (M-37) and chocolate agar (M-31 to M-33) are the media of choice. Of the latter, chocolate hemoglobin agar with yeast (M-33) is recommended. Modifications of this, M-35 and M-36, are good.

The plates must be incubated for 48 hours, then an oxidase test (R-18) is performed.

Of the preserving media, that of Hirschberg (M-34) is good. Shipping on slants (M-35) is recommended.

Serology

"Typing" of gonococci with the aid of chicken sera is possible but of little practical value. Serotype I is usually from recent cases; II is often an old culture.

ANIMALS

No animal inoculation tests are used.

Neisseria Meningitidis (Neisseria Intracellularis) (Meningococcus)

Morphology: Morphologically similar to gonococcus. They do not autolyze as rapidly as the gonococci.

Stain: Gram-negative.

Colonies: On blood agar, they are small, slightly convex, transparent, glistening. On Gradwohl gonococcus medium, they resemble the macroscopic colonies of the gonococcus.

They grow also on other media used for gonococci, and well under aerobic conditions.

Colonies differ from those of the gonococcus in that they are larger and have a tendency toward confluence.

They cause epidemic meningitis.

The following reactions are characteristic for meningococci:

(a) **Positive oxidase reaction.**—This is performed according to R-18. Hemophilus, Enterobacteriaceae, and a number of other organisms give the same test.

(b) **Fermentation of dextrose and maltose.**—This reaction is tested by inoculating serum broth containing these carbohydrates, M-7, or cystine trypticase base, M-6, with a suitable indicator and 1% carbohydrate of the type to be tested. Meningococci ferment both carbohydrates.

---

[1] J. Missouri M. A. 31: 313, 1934.

To isolate the organisms from blood, spinal fluid, petechiae, etc., culture in chopped meat medium M-12, trypticase soy broth M-3, brain heart infusion M-4, or any other semifluid medium containing no inhibitory substances is recommended.

For transportation, use media M-34 and M-35.

SEROLOGY

The Agglutination Test for the Identification of the Neisseria Meningitidis (Meningococcus)

Meningococcus agglutinating serum may be purchased from any reliable biological house. The exact dilution and technic of the test depend in a large measure on the type of serum that is used, and the biological house that manufactures it.

Make the following dilutions of the immune serum in physiologic saline:

1. 1:10, made by adding 1.0 c.c. serum to 9.0 c.c. saline.
2. 1:20, made by adding 0.5 c.c. serum to 9.5 c.c. saline.
3. 1:50, made by adding 0.2 c.c. serum to 9.8 c.c. saline.
4. 1:100, made by adding 0.1 c.c. serum to 9.9 c.c. saline.
5. 1:10, made by adding 1.0 c.c. serum to 9.0 c.c. saline.

Use a 0.2 c.c. pipette graduated in 0.001 c.c. for measuring the serum. (This is the pipette used in the Kahn precipitation test for syphilis for measuring the antigen dilutions.)

Place 1 c.c. of each of the above dilutions of serum into its respective test tube 1, 2, 3, 4, and 5.

Emulsify colonies of the organism to be tested in each of the serums in tubes 1, 2, 3, and 4. Use enough bacteria to produce a slight cloudiness.

Do not place any bacteria in tube 5, as it is the serum control tube.

Place the tubes in a water-bath at 37° C. for several hours, reading at the end of every hour.

If flocculence occurs, the reaction is positive, and the organisms are meningococci.

If no flocculence occurs, the organisms are not meningococci.

Caution: Take great care that the emulsion of the organisms in the serum is complete, or false flocculence due to faulty technic will be observed.

Before placing the tubes in the water-bath, observe for any coarse particles of improperly emulsified colonies.

Typing

Types I and III meningococci contain the same specific carbohydrates; they are therefore classified together as Group I. Type II is the only recognized member of Group II. Types II "alpha" and IV have been found more often in recent years. Type I is found more often during epidemics, Type III between outbreaks.

(a) **Preparation of the Sera, Phair and Noble.—**

Grow "smooth" strains on agar with 5% rabbit blood M-28, M-29. Incubate for 24 hours. Suspend the growth in buffered 0.85% sodium chloride, pH 6.8, and standardize to match number 8 tube of the McFarland nephelometer (page 1477). Inject the suspension into the wing vein of chickens in doses of 0.1 to 0.5 c.c., every second day. A good serum is usually obtained in 10 to 14 days.

To immunize rabbits, use 3 to 5 courses each consisting of 3 daily injections, with one week's intermission between the courses.

(b) **Agglutination Test to Determine Type.—**

The rapid method is recommended.

To 0.1 c.c. of serum add 0.1 c.c. of the bacterial suspension. Prepare two such mixtures with each type serum.

Shake tubes slowly for 2 minutes.

To one tube add 0.85% saline pH 6.8; to the other add 0.85% saline pH 7.8.

Read the agglutinations.

If the meningococci show spontaneous agglutination, the results are better in the tubes containing saline of pH 7.8. Many strains are, however, inagglutinable at this reaction, and react better at pH 6.8. If serial dilutions are tested, dilute the sera 1:1, 1:2, 1:4, 1:8, 1:16, and 1:32. In such cases, agitate the tubes longer; 3 minutes is the recommended time.

Nomenclature of Meningococci*

Common Use	*Recommended by Committee*
I	A
II	B
II alpha	C
IV	D

Quellung Reaction

Type II "alpha" is easily identified by the capsular swelling method similar to that used for pneumococci. Other types do not always have capsules.

Halo Formation

To infusion nutrient agar M-15 add 5% specific meningococcus serum, and pour in plates. Prepare such plates with each type specific serum.

Collect the growth of meningococci from blood agar slants and put large loopfuls on the plates. One may test 6 to 12 cultures on each plate.

Incubate for 48 to 72 hours and inspect for precipitate forming a halo around the colony masses.

WARNING.—If the patient is being treated with sulfa drugs, gonococci and meningococci become atypical. They occur extracellularly, lose their typical shape, and may even become gram-positive.

Neisseria Catarrhalis
(Micrococcus Catarrhalis)

Morphology: Morphology similar to that of the gonococcus. They do not autolyze.

Stain: Gram-negative.

Colonies: They grow on any medium abundantly. They are small, circular, grayish white to dirty white, with erose margin. The twenty-four-hour colony on Gradwohl gonococcus medium resembles the gonococcus twenty-four-hour colony, but does not show striations. They do not ferment any carbohydrates.

Usually nonpathogenic. They may cause severe conjunctivitis.

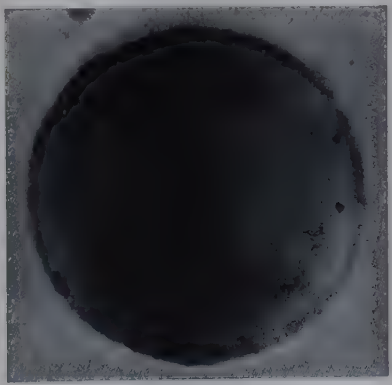

Fig. 357.—Forty-eight-hour colony of *Neisseria catarrhalis* on Gradwohl agar M-37.

Neisseria Sicca
(Micrococcus Pharyngis)

Morphology: Morphology similar to that of the gonococcus. They do not autolyze.

Stain: Gram-negative.

---

*From Branham: Bact. Rev. 17: 175, 1953.

Colonies: They grow best on blood agar, or any medium with enriching fluid. They are grayish, somewhat dry, crumbling when an effort is made to remove them. They form acid in dextrose, maltose, levulose, and sucrose.

They do not form a pigment.

Usually nonpathogenic.

Neisseria Perflava

(Chromogenic Group I.)

Morphology: Similar to Sicca.

Stain: Gram-negative.

Colonies: Growth is abundant. Colonies are small, circular, slightly raised, greenish gray by reflected light, greenish yellow and semiopaque by transmitted light. Surface smooth and glistening. Growth adherent to the medium. They form acid in dextrose, maltose, levulose, and sucrose. They are nonpathogenic.

Neisseria Flava

(Chromogenic Group II.)

Morphology and **staining characteristics** similar to *Neisseria perflava.*

Colonies similar to *N. perflava.* They ferment dextrose, maltose, and levulose. Nonpathogenic.

Neisseria Subflava

(Chromogenic Group III.)

Morphology and **staining characteristics** similar to *N. perflava.*

Colonies: Similar to *N. perflava.* They form acid in dextrose and maltose. Nonpathogenic.

GAFFKYA

Gaffkya Tetragena

(Micrococcus Tetragenus)

Morphology: Spheres, usually about 1 micron in diameter, occurring in groups of four, and surrounded by a wide pseudocapsule.

Stain: Gram-positive.

Colonies: Growth is abundant on simple agar. They form acid in dextrose and lactose. Colonies are circular, white, smooth, glistening, entire. Found in sputum in tuberculosis. Pathogenic when injected into guinea pigs.

Klebsiella Pneumoniae

(Friedländer Bacillus)

Morphology: Short, plump rods, with rounded ends, often four to five times as long as they are broad. They occur singly, in pairs, and in thread formation. A wide capsule surrounds the single organism, the pair, the chain or the thread. Nonmotile. Nonspore-forming.

Stain: Gram-negative.

Colonies: Growth abundant, colonies large, mucoid, spreading, white, convex, glistening, entire. Most strains form acid and gas from dextrose and sucrose.

Many strains ferment lactose with acid and gas formation.

May cause fatal lobar pneumonia; bronchitis, bronchopneumonia, etc. They sometimes cause food infections.

This organism is now being classified with Enterobacteriaceae as Aerobacter. It gives a positive Voges-Proskauer reaction and seldom hydrolyzes gelatin. The citrate test is usually positive; indol is not formed. Dextrose is always fermented with gas production; lactose fermentation is the rule.

Klebsiella pneumoniae grows well on ordinary media and may be isolated on agar. The most favorable medium for its differentiation is eosin methylene blue agar M-71 or M-72 on which colonies resembling Aerobacter are usually formed.

Further differentiation is carried out as with other Enterobacteriaceae (see page 1528).

Serology.—Types A, B, C, and X may be differentiated by the capsular swelling method used for the typing of pneumococci, using appropriate sera.

Recently Klebsiella and Aerobacter are considered one group, belonging to more than 100 serologic types.

MYCOBACTERIUM TUBERCULOSIS

Mycobacterium Tuberculosis (hominis) (Koch)

(Bacillus Tuberculosis, Human Type)

Morphology: Rods, from 0.15 to 0.35 micron by 0.5 to 4.0 microns. They occur singly and in occasional threads. May show branching.

Usually occur in isolated clumps of organisms lying side by side.

Stain: Gram-positive and acid-fast. They may show beaded forms which take the dye more brightly than the rest of the organism.

Colonies: Growth is abundant after about six to eight weeks' incubation.

Colonies are dry, crumpled, raised, yellowish, occasionally reddish.

They emulsify with difficulty. Require special media. Cause human tuberculosis; transmissible to guinea pigs.

Mycobacterium Tuberculosis (bovis)

(Bacillus Tuberculosis, Bovine)

Morphology: Rods, shorter and plumper than the human type. From 1 to 1.5 microns in length. Very short forms frequently intermixed with larger forms.

Stain: Irregularly stained. Gram-positive. Acid-fast.

Colonies: On egg medium, they are small, flat, grayish, confluent, moist, glistening. They are the cause of bovine tuberculosis, transmissible to man.

Media favorable for the growth of tubercle bacilli are those of Petrik M-58, Tarshis, M-58a, Whalen, M-58b, Dorset, M-59, Petragnani M-61, Loewenstein M-60, Dubos M-62, and others. Bovine organisms grow better on media without glycerol. Uncontaminated material can be inoculated on media which do not contain inhibitory dyes (brilliant green or malachite green, crystal violet, etc.). Contaminated material must be prepared by concentration methods (see page 1613). Examination of urine and gastric material requires special methods (see pages 1628 and 1646).

Tubercle bacilli are differentiated from smegma bacilli by the use of the Pappenheim stain (page 1412); from leprosy bacilli by their growth on egg media.

Refer to page 1475 for culture of tubercle bacilli by the egg culture method.

SEROLOGY*

Tuberculin Skin Tests of Von Pirquet for the Diagnosis of Tuberculosis

The Scratch Test

Koch's old tuberculin (O. T.) may be obtained from any reliable biological supply house.

Cleanse the patient's forearm with alcohol.

Make three scratches (superficial) in the skin, each scratch about ½ inch in length, and at a distance of about ½ inch from each other.

Into the first two scratches (test), rub a small amount of tuberculin, using a sterile match stick.

Into the third scratch, rub a small amount of sterile physiologic salt solution (control).

---

*See page 2092 for the Weltmann reaction.

Allow these to dry.

Instruct the patient to return to the laboratory for examination at the end of 24, 48, and 72 hours.

If the reaction takes place within twenty-four hours, he need not repeat the visits.

A positive reaction is characterized by a slight swelling along the scratch, and an area of inflammation surrounding the inoculation.

The saline control should show no swelling or redness. If there is a reaction due to saline, the result of the test is unreliable.

A negative reaction shows no change in the skin.

A positive reaction persists for several days.

The Koch Subcutaneous Tuberculin Test

In this method Koch's old tuberculin is used. This is a filtrate of a concentrated bouillon culture of tubercle bacilli containing the toxin of the bacteria. It produces a focal as well as a general reaction. Before applying the tuberculin test take the temperature of the patient for several days to determine variations. Contraindications to the test are a markedly febrile course, general miliary tuberculosis, acute or advanced tuberculosis, tuberculous meningitis, the terminal stages of other diseases, and during convalescence from acute febrile diseases. The usual dose is 0.5 milligram.

A positive reaction consists in an elevation of at least one degree Fahrenheit, focal reaction, and a local reaction at the site of the injection. If no reaction is produced, repeat the injections, increasing the dosage gradually every three to five days until as much as 5 milligrams have been given.

Intradermal Tuberculin Test of Mantoux

In this test a measured amount of old tuberculin is injected between the layers of the skin. A positive reaction indicates a case of present tuberculosis infection. A negative reaction is of the greater value in diagnosis. For this test we need the following solutions: five solutions of old tuberculin: 1 in 10; 1 in 100; 1 in 1000; 1 in 10,000; 1 in 20,000. They may be purchased ready for use, and if kept in a cool place, will remain potent for three years.

Technic.—

Sterilize a 1 c.c. tuberculin syringe and several 26 gauge ½ inch hypodermic needles. Sponge the forearm with alcohol. Fit a needle to the tuberculin syringe, with the bevel of the needle on the same side as the graduations on the syringe. Fill the syringe to 0.2 with the old tuberculin. Pinch the skin and press in the needle until the lumen just disappears. The injection raises a white wheal. In patients who have had recent hemoptysis, skin or joint disease, the initial dosage should be 0.1 c.c. of 1 in 10,000.

Read the reaction on the second to fourth day. An area of erythema ⅜ inch or more in diameter is positive. The more marked reactions show swelling and at times necrosis. When the reaction is negative repeat the test, using 0.1 c.c. of 1:1,000 dilution, and if still negative forty-eight hours later, repeat, using 0.1 c.c. of a 1:100 dilution, etc.

The Vollmer Tuberculin Patch Test*

This is a quick, accurate, painless test obviating the use of instruments as well as injury to the skin. Thoroughly cleanse and defat, with acetone, the area of the skin of the inner side of the forearm or sternum (recommended for children) or upper spine (recommended for infants). Then apply the patch firmly. Instruct the patient not to disturb the patch for 48 hours, and to avoid getting it wet. The second day after removal, the patient returns to the laboratory for interpretation of the test.

A *positive* reaction appears as an infiltrated elevated reddened square. The central control square appears pale. If the patient is sensitive to adhesive tape, there may be irritation due to the tape, but this does not interfere with reading of the reaction.

---

*Material for the Vollmer Patch Test may be obtained from Lederle Laboratories, Inc., New York, N. Y.

If directions for making and reading the test are carefully carried out, the results will be found superior to the von Pirquet test and comparable to those of the Mantoux test. Late reactions should be reported to the physician.

Interpretation of Tuberculin Reactions

The tuberculin reaction is a reliable test for hypersensitiveness to tubercle bacillus toxin; by that we mean past or present tuberculous infection. The negative reaction is of most value in clinical diagnosis. When tuberculosis nears a fatal termination, sensitiveness to the tuberculin injection is depressed so that we have no reaction in any case of tuberculosis just before death.

In children, a negative reaction is useful to exclude tuberculosis in chronic cervical adenitis, prolonged anorexia, debility following bronchopneumonia, whooping cough, or measles. A positive reaction in a child of two years or over does not of itself prove an active tuberculosis. It is well to use additional data to establish diagnosis. If complete healing of a tuberculous infection occurs and the bacilli die, the tuberculin reaction after a time becomes negative. Sometimes, infection becomes well walled off, often in a calcified nodule, but still the bacteria remain alive and we note a positive tuberculin reaction. A markedly positive Mantoux reaction in a patient with indefinite physical signs suggests some active focal infection which, under unfavorable hygienic conditions, may spread and form extensive disease.

See the chapter on Hematology for changes in the blood picture upon injections of tuberculin, method of Bredeck, page 795.

ANIMAL INOCULATION

Animal Inoculation.—Test guinea pigs for sensitivity to tuberculin by injecting 1 mg. of old tuberculin intracutaneously. Wait three days, and if the test is negative, inject the material to be examined for tubercle bacilli into the groin, under the skin. It is advisable always to inject guinea pigs in the same side, for example, the left side.

After 4 weeks, make tuberculin skin test on the animal. If positive, report as such.

Kill animal after eight weeks and perform an autopsy, including histologic examination of regional glands and organs.

Mycobacterium Leprae

(Leprosy Bacillus) (Hansen Bacillus)

Morphology: Rods, 0.3 to 0.5 by 1 to 8 microns, parallel sides and rounded ends, often in clumps or rounded masses, or in groups, side by side, rarely bent or curved.

Stain: Gram-positive, staining unevenly, at times beaded; acid-fast.

Colonies: This organism has never been successfully cultivated. It is considered the cause of leprosy, or Hansen's disease.

The organisms stain red with the Ziehl-Neelsen stain, resembling the tubercle bacillus. They differ from the tubercle bacillus, being usually grouped in masses held together by mucus, called ''globi,'' or in cigarlike bundles. They are found in most cases of leprosy in the mucous membranes of the nose, in the lymph which oozes from superficial erosions of the skin, and in the scrapings from the corium or after curetting of the epidermis. They are usually also found in huge numbers in tissue sections in the lepromatous types. The bacilli are also found in the peripheral nerves, as well as in the liver and other viscera in advanced cases of Hansen's disease.

It is not known whether the bacilli live outisde human tissues. The actual mode of contagion is also obscure. Some believe that prolonged personal contact with the patient must exist before the disease is acquired. Direct inoculation on the skin with development of an initial lesion has been reported by some observers, but it is generally accepted that the disease may have access to man through the mucous membranes of the nose and mouth.

The Histamine Test

Place a drop of 1:1,000 solution of histamine phosphate on the affected skin to be tested.

Place another drop at a point between the suspected area and the adjacent normal skin, and a third drop on the normal skin.

Lightly prick the epidermis through these drops, using the point of a hypodermic needle, being careful not to cause bleeding.

Immediately dry the drops of histamine with cotton, and carefully watch the sites of the test.

Within 25 to 40 seconds, the *normal skin* shows an area of erythema with irregular outline, usually 5 to 20 mm. in diameter, later reaching as much as 5 cm.

In 60 to 100 seconds, a wheal forms in the erythematous area, centered by the point where the needle entered the epidermis. After 3 minutes, a hemorrhagic point may appear at the site of the needle prick. The wheal usually measures 2 to 5 mm. in diameter.

The reaction persists for approximately 20 minutes, but at times the erythema and the wheal are still present after 45 minutes. There are individual variations due to age, room temperature, and local circulatory conditions. The test cannot be made on the skin of Negroes.

Between the affected and the normal skin, the test shows the same succession of phenomena on the normal half of the skin, but on the affected half, the erythematous reaction stops abruptly and is absent on that part of the skin, but the wheal is always present without the peripheral erythema.

On the *anesthetic skin,* erythema is wholly lacking, while the wheal is present and remains the usual length of time.

The test causes no subjective sensations, either on the normal or on the affected skin.

The test is read as normal or abnormal, and not as positive or negative.

Any type of degenerative peripheral neuritis may give an abnormal histamine test, and therefore it is not exclusively diagnostic of leprosy. The test is not reliable when performed at a room temperature below 24° C. or when performed on aged persons with slow or impaired peripheral circulation. It is important in the differential diagnosis between leprosy and syringomyelia, since in the latter condition the histamine test is normal.

The Lepromin Test (Mitsuda Test)

This test consists essentially of an intradermal injection of lepromin, an antigen prepared from tissues rich in Hansen bacilli. It is made by boiling lepromatous tissues in isotonic solution of sodium chloride for 1 hour, after which the mass is ground in a mortar, and 20 c.c. of 0.9% solution of sodium chloride are added for each gram of ground tissue. After repeated and thorough mixing and grinding, the supernatant fluid is pipetted off, filtered through gauze, and stored in a sterile container.[1]

The liquid is autoclaved at 120.° C. for 15 minutes, 0.5% phenol added, and distributed to rubber-capped vials ready for use. It is a cloudy, milky emulsion containing numerous bacilli (globi), and the tissue elements of the leproma. If kept in a dark, cool place, it retains its activity for a long time Seitz-filtered antigens are inactive.

Technic.—

Inject 0.1 to 0.15 c.c. of lepromin intradermally either into the skin of the scapular region or upon the anterior surface of the thigh.

At the end of 24 to 48 hours, there is a light erythema which is attributed to the presence of foreign protein material and which disappears in a few days, usually in 3 or 4. The site of the test then remains apparently normal until the beginning of the third week when, if the test is positive, a slight papular infiltration is noted, gradually increasing in size until it attains the size of a pea. The infiltration is deep and its color is bright red. There might be some tenderness on pressure and, occasionally, formation of a central necrotic focus with ulceration, resulting in a permanent scar.

---

[1] Rotberg: Rev. brasil. leprol. 5: 45, 1937.

The test should be evaluated on about the thirtieth day after the injection. If there is no reaction or only a small (less than 5 mm.) infiltration, the test is negative.

The test is positive in about 90 per cent of normal individuals, in practically all cases of tuberculoid leprosy, and in about 50 per cent of patients with the simple inflammatory type. It is negative in practically every case of lepromatous leprosy, in about 10 per cent of apparently normal persons, and in about 50 per cent of patients with simple inflammatory leprosy.

It is a *prognostic test.* If the test is negative in a person without symptoms of leprosy, that person is susceptible to the disease. The test is applied to prospective employees of leprosaria; those with negative Mitsuda tests are not permitted to serve in such institutions.

Diagnosis

Diagnosis is made by smears from the mucous membrane and by making sections of suspected lesions. These lesions show granuloma with typical bacilli present. The bacilli multiply in the lymphatics of the corium and subcutaneous tissues, with development of large monocytic cells which engulf the organisms in such large numbers that a microscopic view of such a cell shows it filled with round, acid-fast bacilli. These cells have been called "leprosy cells."

The complement fixation test for syphilis is frequently positive and can be of no aid in the differential diagnosis. This might be due also to a concomitant infection with syphilis or yaws.

Table 144[2] shows the correlation of the clinical manifestations of leprosy with the histopathologic changes, the immunologic response, and the bacteriologic findings.

TABLE 144[2]

CLINICAL	PATHOLOGY	IMMUNOLOGY	BACTERIOLOGY
Lepromatous Nodules, lepromas, diffuse infiltration "en nappe," loss of eyebrows, rhinitis, leonine facies, fever, and peripheral pains Mutilations: Nose, extremities	Diffuse infiltration of dermis, foam cells, "Leprazellen" with globi. Atrophy of the epidermis Atrophy of hair follicles and glands Areas of necrosis	Mitsuda test negative in 90%	Skin: Many bacilli, singly, in bundles, and globi; in sections and capillary blood Nerves: Numerous bacilli singly and in bundles in and between nerve fibers in sections
Tuberculoid Flat, dark red infiltrations, well-defined geographic, annular borders; enlargement of nerves, no fever, atrophy of hands. Includes the old neural types	Patchy sarcoidlike areas of infiltration around blood vessels, hair follicles, and glands. Foam and giant cells, no globi Nerves: Profuse infiltration, same type	Mitsuda test positive in 90%	Skin: Occasional bacilli in sections Nerves: Occasional bacilli in sections
Simple Inflammatory Macular lesions with little or no elevation; pink, red, or dyschromic areas of anesthesia without clinical changes	Lymphocytic infiltration around blood vessels, glands, and hair follicles. No foam or giant cells, no globi	Mitsuda test positive in 40 to 50%; negative in 50 to 60%	No bacilli or only occasional in sections

---

[2] V. Pardo Castelló in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, St. Louis, 1951, The C. V. Mosby Co.

Mycobacterium Lacticola
(Smegma Bacillus)

Morphology: Rods, usually more plump than the tubercle bacillus, variable in size.

Stain: Gram-positive and acid-fast.

Colonies: On glycerin agar, isolated colonies, becoming lobulated and velvety, grayish, butyrous. Differentiated from tubercle bacillus by its inability to produce lesions in guinea pigs. Nonpathogenic.

Another acid-fast nonpathogen is the *Mycobacterium phlei* (the hay bacillus), which is probably identical with the smegma bacillus.

CORYNEBACTERIA

Corynebacterium Diphtheriae
(Bacillus Diphtheriae)

Morphology: Rods, varying greatly in dimensions, 0.3 to 0.8 micron in breadth and 1.0 to 8.0 microns in length. They occur singly, or in palisade formation. They are straight or slightly curved, frequently swollen at one or both ends. They do not stain uniformly, but have granules or bars of more deeply staining properties.

Stain: Gram-positive.

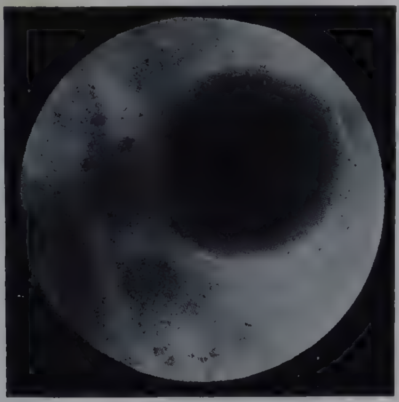

Fig. 358.

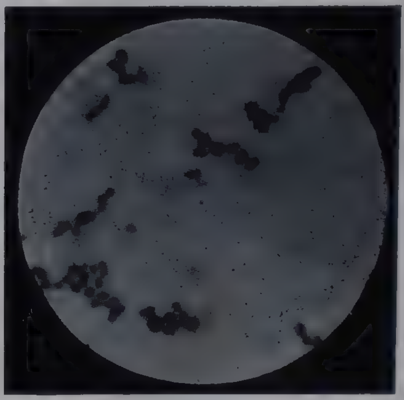

Fig. 359.

Fig. 358.—Colony of *Corynebacterium diphtheriae* on blood agar.
Fig. 359.—*Corynebacterium acnes.* (×950)

Colonies: On blood serum media they are grayish to creamy, moist, smooth, slightly raised, margin entire. On blood agar, they turn the blood brown.

Growth is moderately abundant. They are the cause of diphtheria. They kill guinea pigs within four days.

All strains ferment dextrose but not lactose or sucrose. The best differentiation of the types is determined by a study of the growth on tellurite media M-41 to M-43.

THE GRAVIS, MITIS, AND INTERMEDIATE TYPES OF C. DIPHTHERIAE

These types of *C. diphtheriae* were first described by Anderson, Happold, McLeod, and Thomson[1] in 1931. They noted a difference in appearance of diphtheria bacilli when grown on heated blood agar medium containing potassium tellurite. These two different colonies, black or gray-black, when subcultured and tested by the usual methods, gave all the reactions of typical toxigenic *C. diphtheriae.* They were differentiated in other ways—by their power to ferment starch and glycogen, by their growth in broth, and by the production of hemolysis. It is interesting to note that in Leeds, where this study was made during a severe epidemic of diphtheria, one of the two types was isolated from the severe and fatal cases, while the other type was isolated only from mild cases. For this reason McLeod and his associates called one type *C. diphtheriae gravis,* and the other *C. diphtheriae mitis.* They noted, too, the existence of a certain number of intermediate strains, corresponding neither to the gravis nor to the mitis type. Subsequently these same workers noted that the "intermediate" strains formed a third type, with well-differentiated characters of its own. This type came from cases which were more severe than those cases caused by mitis strains but less severe than those cases caused by gravis strains. Robinson and Marshall,[2] in a similar study in Manchester, confirmed the occurrence of the three types described by McLeod and his colleagues; but in the Manchester series the intermediate strains were more numerous than either the gravis or the mitis.

---

[1] J. Path. Bact. 34: 667, 1931.

The characteristics of these three types may be summarized[3] as follows:

> "**C. diphtheriae gravis.**—Gives a gray or gray-black 'daisy head' colony on blood-tellurite medium, the degree of striation of the surface and crenation of the edge varying considerably. Ferments dextrin, starch, and glycogen (in addition to dextrose and maltose, which are fermented by all types of *C. diphtheriae*). Gives surface growth and granular deposit in broth, generally with an early (2-3 days) reversal of the pH to the alkaline side. Usually nonhemolytic. Stained films from 18-hour cultures on Loeffler's medium (the morphology of *C. diphtheriae* grown on the blood-tellurite medium is quite atypical) show bacillary forms with one or two darkly staining areas, the rest of the cell staining very lightly. Metachromatic granules are rare, and when present are very small. Some 60 per cent of gravis strains conform to this morphology, the others may show much the same appearance as mitis or intermediate strains.
>
> "**C. diphtheriae mitis.**—Gives a convex, smooth, black, shining colony on blood-tellurite medium, with an entire edge. It does not ferment starch or glycogen. The fermentation of dextrin is variable. Gives diffuse turbidity in broth, with a nongranular deposit. Surface growth is infrequent; when it occurs, it is soft. There is later a reversal of pH to the alkaline side (4 to 5 days). It is usually hemolytic. The bacilli stain very irregularly, and metachromatic granules are very prominent.
>
> "**C. diphtheriae (intermediate).**—Gives a small, flat colony on blood-tellurite medium, with a central, raised, black or gray-black portion, and a lighter, slightly crenated periphery. Does not ferment starch or glycogen. Fermentation of dextrin is variable. Gives a fine granular deposit in broth, with no surface growth. There is no reversal of pH. This type is consistently nonhemolytic. The morphology is very characteristic, about 98 per cent of the bacilli being barred."

The most reliable criteria for the differentiation of these three types are the type of colony formed on blood-tellurite medium and the power to ferment starch and glycogen.

The three types of McLeod are also differentiated from one another in antigenic structure. Ewing[4] examined 106 gravis or starch-fermenting and 50 non-starch-fermenting strains. The gravis strains fell into five different serologic types, and none of these were antigenically similar to any of the non-starch-fermenting strains. Thirty-five mitis strains yielded four different antigenic groups, and 15 intermediate strains yielded four groups. Murray[5] examined 78 gravis, 70 mitis, and 102 intermediate strains, and was able to differentiate three different antigenic types of gravis, four of mitis, and four of intermediate. There was no antigenic relationship between the three different types.

[5] J. Path. Bact. 41: 439, 1935.

DIFFERENTIATION OF DIPHTHERIA BACILLI FROM OTHER ORGANISMS BY POTASSIUM TELLURITE MEDIUM

Tellurite and copper sulphate are used in media selected for the primary isolation of diphtheria bacilli to inhibit the growth of gram-negative rods and many cocci. Streptococci and staphylococci, however, grow on these media. The action on Loeffler's slant M-10 is based upon the more rapid multiplication of the diphtheria bacillus on these media. When a Loeffler slant is inoculated and not observed for 24 hours or longer, the secondary flora will outgrow the Corynebacteria. Therefore Loeffler's medium should be used only when examinations of the slants after 10, 14, 16, and 18 hours are contemplated.

From Loeffler's medium the growth must be transferred to a tellurite plate (M-41 to M-43), from which are inoculated serum broth with dextrose and sucrose M-7, cystine trypticase (M-6) with dextrose and sucrose or proteose-peptone broth with dextrose and sucrose M-5. These tubes must be observed for 5 days.

Transfer pure cultures to Loeffler or blood agar tubes M-28, M-29, and use the growth to test for virulence.

VIRULENCE TESTING

(a) **Chicken Test of Frobisher and Associates.***—Inject Plymouth Rock or Rhode Island strain chickens, 7 to 20 days old, with 50 to 100 units of antitoxin into the areolar tissue dorsally between the wing insertions.

After one hour inject about 1 to 2 c.c. of the bacterial growth from Loeffler or blood agar tubes into the same area. Use four chicks, two protected with the antitoxin and the others unprotected.

Virulent strains usually kill both unprotected chickens within 24 hours. In surviving animals, wing paralysis may indicate the toxicity of the culture.

(b) **Subcutaneous Injection.**—Inject one guinea pig with 3 units of diphtheria antitoxin per each gram of weight, intraperitoneally, 24 hours before the experiment.

Inject this guinea pig and an unprotected guinea pig with the washings from the surface of a Loeffler slant, making the injections subcutaneously. Observe for 10 days. Death occurs most often within 5 days. Virulent strains produce a circumscribed local in filtrated lesion with necrosis but the control pig shows a normal skin.

(c) **Multiple Intracutaneous Test.**—Several cultures may be tested on the same animals. Inject one guinea pig with 3 units of diphtheria antitoxin per gram weight, intraperitoneally, 24 hours before the experiment.

Inject 0.15 c.c. of the suspensions of growth on Loeffler slants into the shaven skin of the abdomen of a guinea pig protected with antitoxin and into another guinea pig not so protected.

Observe for necrosis in 24 hours and again in 48 and 72 hours.

(d) **Plate Method, Elek[1] and King[2] et al.**—Prepare sterile paper strips; soak them in diphtheria antitoxin, 500 units per c.c.

Press strips into medium M-44.

Streak bacteria from 18-hour-old broth culture in M-3, across the strips.

Observe for zones of precipitation in 24, 48, and 72 hours.

SEROLOGY

The Schick Test for Determination of Susceptibility to Diphtheria Infection[3]

Schick toxin and controls may be purchased from any reliable biological house. This toxin is diluted and ready for use.

0.1 c.c. of this mixture is 1/50 the minimum lethal dose of diphtheria toxin. This is the quantity to be injected.

Disinfect the flexor surface of the forearm.

---

*Am. J. Hyg. 35: 381, 1942.

[1] Brit. M. J. 1: 493, 1948.

[2] Am. J. Pub. Health 39: 1314, 1949.

[3] White, B., Bunney, W. E., and Malcolm, W. G.: J. Immunol. 32: 93, 1932.

Withdraw the mixture in the vial using a 1 c.c. tuberculin syringe with a 23 gauge ½ inch needle. The syringe should be graduated in 0.1 c.c. The beveled edge of the needle should be in line with the graduations of the syringe.

Push the needle between the layers of the skin until the point is well covered by the skin.

The injection is to be made intradermally; hence, care must be taken not to give a deep inoculation. The point of the needle can be seen under the skin if the injection is made correctly. Inject 0.1 c.c. of the mixture between the layers of the skin. A small white wheal will form.

Saline Control.—About 2 inches below this test puncture, inject 0.1 c.c. of sterile physiologic saline.

Protein Control.—After the injection of the Schick toxin inject 0.1 c.c. of the heated mixture (control) intradermally about 2 inches below the saline injection. If the reaction is not read until the third or fourth day, this last injection may be omitted. Protein reactions occur within twenty-four hours, and can therefore be eliminated in the final reading.

Reading the Reaction

The patient is instructed to return to the laboratory every day for four days. If a reaction occurs within twenty-four hours, it usually is not a diphtheria reaction. If the reaction is due to a hypersusceptibility to saline, the saline control will show a zone of inflammation, and a swelling. If the reaction is due to proteins, the reaction is much more vigorous than the true Schick reaction, and will reach its height within twenty-four to forty-eight hours.

A negative reaction is indicated by no change in the skin.

A positive reaction is accompanied by a swelling and a zone of inflammation around the point of inoculation. The zone of inflammation is about 1 or 2 centimeters in diameter around the point of inoculation. The inflammation gradually disappears, and is replaced by a browning of the skin accompanied by a slight area of necrosis. The slight brown discoloration may persist for several months.

A positive Schick test is indicative of susceptibility to diphtheria infection.

A negative reaction indicates immunity to diphtheria infection.

After the toxin has been diluted with the saline, it cannot be used for a period longer than twenty-four hours.

Corynebacterium Pseudodiphtheriticum
(Pseudodiphtheria Bacillus of Hoffmann)

Morphology: Rods, with rounded ends, 0.3 to 0.5 by 0.8 to 1.5 microns, fairly uniform in size, without swollen ends. Barred forms may be found, although polar granules are usually seen.

Stain: Gram-positive.

Colonies: On blood serum media, they are opaque, grayish to cream-colored, smooth, homogeneous, entire, fairly abundant. May be differentiated from diphtheria bacilli by their inability to produce disease in lower animals. Nonpathogenic. They do not ferment any carbohydrate.

Corynebacterium Xerose
(Bacillus Xerosis)

Morphology: Rods, showing polar staining, occasionally club-shaped forms.

Stain: Gram-positive.

Colonies: Thin, grayish, adherent. Growth scant, and slow. Nonpathogenic. They form acid in dextrose, levulose, galactose, maltose, and sucrose. Cultivated on Loeffler's blood serum medium or Petroff's egg medium.

Corynebacterium Acnes

(Acne Bacillus)

Morphology: Rods, varying in dimensions, usually 0.5 by 0.5 to 2.6 microns, sometimes slightly club-shaped. Show alternate bands of stained and unstained material. In transplanted cultures, the rods occasionally assume coccoid forms. They group in palisades.

Stain: Gram-positive.

Colonies: Small, grayish colonies, circular, transparent. Original growth on Petroff's egg medium under micro-aerophilic conditions. Original growth scant; transplants may show abundant growth of glistening colonies. They show slight acid formation in dextrose. Found normally in hair follicles and sweat glands; often present in acne.

ENTEROBACTERIACEAE

Gram-negative, nonsporeforming microorganisms, all of which ferment dextrose. Mostly inhabitants of the intestinal canal. Under pathologic conditions, isolated from blood, pus, urine, etc.

Salmonella Typhosa

Morphology: Rods, 0.6 to 0.8 by 1.0 to 1.5 microns, occurring singly, in pairs, short chains or threads. Motile with peritrichous flagella.

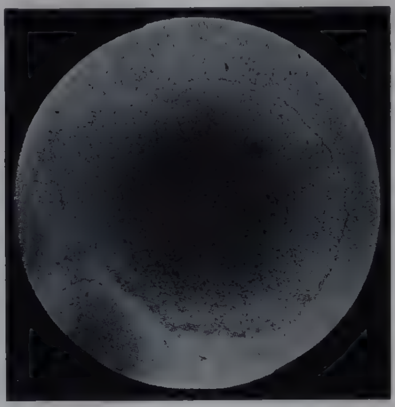

Fig. 360.

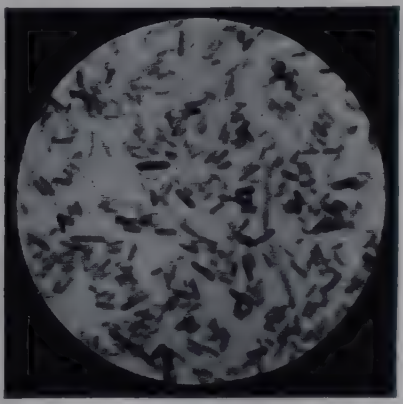

Fig. 361.

Fig. 360.—Colony of *Salmonella typhosa* on nutrient agar. (×950.)
Fig. 361.—*Salmonella typhosa.* (×950.)

Colonies.—Colonies are whitish to grayish, transparent to opaque, often with undulate margins. On media with ferric salts, colonies are more yellow and brownish. On agar media with bismuth sulphite, M-69 and M-70, after 48 hours they are flat, with broad dark halo and metallic sheen in reflected light; flat or convex; grow into the medium.

Biochemistry.—Biochemistry is the same as that of Salmonellae but *S. typhosa* does not form gas. It is a moderate producer of hydrogen sulphide.

SEROLOGY

S. typhosa has the antigenic structure IX, XII:d of Salmonellae. Types may be distinguished by the use of phage-typing introduced by Craig and Yen[1] which is carried out by mixing inocula of the organism tested with type phages on a 1% agar plate. As many as 12 tests may be performed on one plate. The plate is incubated and the action of the phage suspensions upon the growth of the typhoid bacilli read.

Only cultures containing Vi antigen are considered for phage typing. Exceptions, however, were described. The phage typing has great importance for public health investigations.

Salmonella[2]

Salmonellas have become one of the major problems of physicians, veterinarians, epidemiologists, and laboratory workers. Hundreds of types and varieties belonging to this genus are known to date, and the number of newly described strains increases constantly. Attempts to simplify this complex group of microorganisms by considering all or most of the types of *Salmonella* just variants of one bacterium were shattered by the difference in epidemiologic nature of the diverse strains. The wide dispersion of Salmonellas constitutes a health problem of staggering proportions. These organisms are pathogenic for man and animals and they are present in all places inhabited by these hosts, thereby creating problems in all climates.

---

[1] Canad. Pub. Health J. 29: 449 and 484, 1938.
[2] Felsenfeld: Am. J. Clin. Path. 12: 584, 1945.

The old theory, called the ''Doctrine of Kiel,'' taught that there are ''human adapted'' and ''animal adapted'' Salmonellas, the first group causing generalized infections, the second attacking man rarely and in such cases producing only gastroenteritis. Thanks to the efforts of Hormaeche and his school, the ''Doctrine of Montevideo'' is now being generally accepted. This theory asserts that persons contracting Salmonella infections react in very different fashions depending on several factors, among which the age and the general health of the patient, and, to a lesser extent, the strain of the organism are most important. Thus, septic infections and meningitis are more frequent in infants and in young animals, due to the lesser resistance of this age group. Similarly, higher mortality is observed in old people, mainly among those suffering from other diseases or confined to institutions.

The clinical picture of salmonellosis may be described as follows:

1. Salmonella fever, the ''paratyphoid disease'' of former authors.
2. Salmonella septicemia, with irregular temperatures, and often grave prognosis, producing eventually local inflammatory lesions.
3. Salmonella gastroenteritis, which, according to Hormaeche and associates may be
   a. Choleriform
   b. Dysentery-like
4. Localized infections, including appendicitis-like syndromes, genitourinary inflammations, cholecystitis, etc.
5. Symptomless carrier status.

Statistics do not always differentiate between Salmonella fever and Salmonella septicemia. These two groups are, therefore, united into one.

While most Salmonellas follow the general rules of the Montevideo doctrine, it is also apparent that the type involved in the infection may play an important role in the disease produced; e.g., ''paratyphoid bacilli'' and *S. sendai* are more prone to produce Salmonella fever, while *S. choleraesuis* often causes septicemia; *S. give* provokes only enteritis; and *S. typhimurium* can be the cause of any form of salmonellosis. With the increase in the number of observations of Salmonella strains in man, however, more and more cases are described which tend to prove that most of these organisms can produce, under favorable circumstances, any form of salmonellosis.

NOMENCLATURE, MORPHOLOGY, AND BIOCHEMISTRY

The generic name, *Salmonella,* is derived from Salmon, the investigator who described the first member of the genus, *S. choleraesuis.* Difficulties in the exact limitation of the species belonging to this genus cause most authors to prefer the taxonomic designations ''types'' and ''members'' instead of "species." A variety of sources was used as origin for the nomenclature employed for these types. In the beginning, organisms which caused typhoid-like fevers were designated as paratyphoid bacilli A, B, and C. Other members of the group were named according to the disease caused: *S. enteritidis, S. typhisuis, S. abortus ovis,* etc. Certain types received names of the animals in which they were first discovered, as in the case of *S. anatis* or *S. meleagridis.* Salmonellas rarely bear the name of the investigator who first described them, as *S. schottmuelleri.* Eventually it became an established custom to name newly discovered types after the state or country where they were isolated: *S. virginia, S. georgia, S. panama.* If a new strain is described in a state the name of which already occurs on the list of these organisms, the name of the town where the organism was found is employed: *S. illinois—S. urbana, S. champaign; S. kentucky—S. lexington.* When the names of the state and the city have been used to designate Salmonella types and a new strain is discovered in the same city, the name of the hospital where the patient is treated serves this purpose, e.g., *S. berlin—S. virchow, S. cophenhagen—S. bispebjerg.* Interesting examples of nomenclature are *S. selandia* and *S. orion,* named for the ships which carried the first patient suffering from such infection.

The genus *Salmonella* is composed of gram-negative, aerobic and facultative anaerobic, nonsporeforming, mostly motile bacteria, which produce acid and gas from dextrose, mannitol, and maltose, but do not ferment lactose, sucrose, salicin, or adonitol; do not produce indol or acetyl methyl carbinol; do not coagulate milk and do not liquefy gelatin. All members of the genus possess antigens which fit into the White-Kauffmann scheme.

Among the organisms in which the taxonomic position in this genus is dubious, the foremost place is occupied by *Salmonella typhosa,* the typhoid bacillus. This organism forms no gas, only acid, from fermentable substances. The antigenic structure and the disease which it causes, however, have assured the typhoid bacillus a permanent place in the Salmonella scheme. Nongas-forming, also called "anaerogenic," variants of Salmonellas, other than *S. typhosa,* are not uncommon in the literature, as strains of *S. typhimurium, S. schottmuelleri, S. enteritidis* which produced acid and no gas. *S. gallinarum,* also called *Shigella gallinarum,* is another organism which has a typical antigenic structure but forms acid with no gas from fermentable substances. As it is nonmotile, it is often classified with Shigellas. Another nonmotile organism is *S. pullorum,* which, in addition to this irregularity, does not always ferment maltose. Hinshaw and associates, however, showed that strains which do not ferment maltose are typical in other respects.

There are numerous exceptions to the definition of the genus *Salmonella,* mainly biochemical in nature. These strains are nevertheless accepted because of their other qualities. For instance most strains of *S. typhisuis* do not ferment mannitol. There are indol forming variants of *S. eastbourne, S. enteritidis,* and *S. panama,* as well as acetyl methyl carbinol producing variants of *S. choleraesuis.* Finally, *S. dar es salaam, S. abortus bovis, S. canastel,* and *S. schleissheim* liquefy gelatin. These differences, however, are rather rarely encountered and there is little doubt that they may be neglected in routine laboratory work.

Many attempts have been made to use biochemical reactions as a basis for the differentiation of Salmonella types. One of them was the desire to divide

Salmonellas into two groups one of them forming, the other not forming hydrogen sulphide. Most of these organisms form hydrogen sulphide. The detection of this reaction, however, depends on the richness of the peptone used in the preparation of the culture media on sulphur compounds and on the indicator employed in the detection. The tabulations of hydrogen sulphide producing Salmonellas used in most laboratories, however, are not compiled for the purpose of detecting traces of such biochemical activity, but reflect experience with many strains on standard media. According to these charts, all strains of *S. paratyphi* (with the exception of its variety durazzo), *S. choleraesuis* (the "american" or diphasic variety), *S. abortus equi, S. typhisuis;* many strains of *S. gallinarum, S. sendai,* and *S. newcastle,* and a few strains of *S. dublin, S. abortus ovis,* and *S. typhosa* do not possess the ability to change the indicator used in Kligler's or in Hajna's media or in the bismuth sulphite agar.

TABLE 145.—NOMENCLATURE OF SALMONELLAS

ACCEPTED DESIGNATION	SYNONYMS
Salmonella paratyphi	*Bacillus paratyphosus* A *Bacterium paratyphosum* A *Salmonella paratyphi* A Paratyphoid A bacillus

Salmonella hirschfeldi	*Bacillus paratyphosus C* *Bacterium paratyphosum* C *Salmonella paratyphi* C Paratyphoid C bacillus
Salmonella choleraesuis	*Bacillus suipestifer* *Bacterium suipestifer* *Salmonella suipestifer* Hog cholera bacillus
Salmonella typhosa	*Bacillus typhosus* *Bacterium typhosum* *Salmonella typhi* *Eberthella typhosa* Typhoid bacillus
Salmonella enteritidis	*Bacillus enteritidis* *Bacterium enteritidis* *Salmonella enteritidis* "Gaertner" Gaertner bacillus
Salmonella gallinarum	*Shigella gallinarum* *Bacterium gallinarum* Fowl typhoid bacillus

Xylose was used for many years to differentiate *S. paratyphi* from other organisms of the genus. It has since been shown that while *S. paratyphi* never ferments this substance, many strains of *S. typhosa, S. typhimurium, S. anatis, S. newington,* and others decompose xylose.

The utilization of d-tartarate was believed to be a differential diagnostic means of distinguishing "human" from "animal" Salmonellas. Later examination demonstrated that many *S. schottmuelleri, S. typhimurium, S. pullorum, S. gallirarum,* and others do not follow this rule.

The only occasion where special biochemical reactions serve as a criterion for the identification of individual types occurs in the first members of the group "C" of Salmonellas and their monophasic varieties. In addition, biochemical reactions may help to distinguish *S. pullorum* from *S. gallinarum,* when the first does not produce an appreciable amount of gas or is slow in its production. Table 146 shows the biochemical reactions utilized in these cases.

ANTIGENIC STRUCTURE

The antigenic structure of the members of the genus *Salmonella* was presented in the White-Kauffmann scheme which had to be enlarged as newly discovered strains were described. New charts were published by Edwards and Bruner, Mickle, Bornstein, and others.

In order to elucidate the complex serologic structure of these bacteria, it must be taken into consideration that Salmonellas show different types of variation which affect their antigenic structure. The following is a brief review of these variations.

H—O Variation

The designations "H" and "O" originate from the observation of the spreading (H) and nonspreading (O) colonies of Protei. Subsequently these observations led to the study of the somatic and flagellar antigens of these and other organisms. It was established that "O" antigens are somatic antigens, resistant to heat and alcohol and giving a granular agglutination which develops best when the mixture of antiserum-antigen is incubated at higher, e.g., 50° C. to 56° C., temperature for several hours. The "H" antigens are flagellar antigens, thus present only in motile organisms; they are resistant to formol but not to heat or alcohol and give fluffy clumps in the agglutination test which takes place at lower temperatures, e.g., 37° C., and develops rapidly, usually within two hours.

The "O" antigens are designated by Roman numerals. The division of Salmonellas into groups "A," "B," "C," etc., is based upon these antigens. It

*0 = fermentation absent; + = fermentation present.

was found to be necessary to divide some of these groups into subgroups. The group "F," also called "Further organisms," is steadily increasing with the discovery of new strains and with the acceptance of new "O" antigens as Salmonella antigens.

Some strains occasionally lack one of the "O" antigens which is usually present in their structure. While previous tabulations, mainly those of European workers, emphasize such deviations, recent authors regard them as mere variations. These antigens are enclosed in parentheses in American tabulations.

Form Variation

This term is used to designate the quantitative differences in a part of the somatic antigen. It usually involves antigens I, VI, and XII. Because of this variation, antigen XII has been alternately introduced and excluded from Salmonella tabulations.

V—W Variation

The antigen Vi (also called V) was originally discovered in inagglutinable cultures of *S. typhosa* and was thought to be connected with virulence. The Vi antigen was found to occur in *S. typhosa, Paracolobactrum ballerup,* the "East African" variety of *S. hirschfeldi,* and in some strains of *S. newport.* It is less resistant to heat than other somatic antigens. It may be preserved by dehydration at a temperature of 60° to 70° C. when its suspension in absolute alcohol is treated *in vacuo.* Colonies of organisms containing Vi antigen are slightly more opaque than the "W" colonies and have a ground glass appearance in reflected light. The loss of the Vi antigen is connected with the colony change from "V" to "W" form. While "V" colonies are susceptible to phage action, "W" colonies are not. The phage susceptibility of "V" forms is utilized in the typing of *S. typhosa* strains by the method of Craigie and Yen. While the susceptibility to phage action decreases during the V—W variation, the susceptibility of the strain to phagocytosis increases. An organism gradually losing its Vi antigen first shows a decrease in its ability to absorb Vi antibodies from anti-Vi sera, then a tendency toward reduction in agglutinability with Vi antiserum is demonstrable. Finally, the strain shows the typical "O" structure of the organism.

S—R Variation

When this phenomenon was first described, it applied to the colony form and to the stability of the growth in broth cultures. As the original smooth (S) growth on solid media becomes rough (R), the colonies appear to have a rough surface and irregular borders, and the broth cultures form a granular sediment. Slight grades of roughness may be discovered according to the method of Pampana by mixing a drop of a heavy suspension of the organism with a drop of 1:500 acriflavine. When the culture is rough, agglutination occurs.

The "R" form differs from the "S" not only in colony morphology but also in its loss of other characteristics, including specific "O" agglutinability, ability to absorb and to produce antibodies, toxicity for mice, biochemical activity, and other properties. In practical laboratory work, the greatest difficulties are encountered while "typing" strains which do not as yet reveal morphologic roughness but have become serologically rough. Such organisms are frequently encountered among colonies fished from strongly selective media, as the plate of Wilson and Blair, or among strains which have been maintained for a considerable period of time on carbohydrate media before antigenic analysis. A certain number of these strains can be serologically evaluated by using the technic of White which consists of suspending the growth from the surface of an agar slant in absolute alcohol, heating this mixture for one hour at 60° C., then draining and resuspending it in saline.

The "R" cultures contain a nonspecific somatic antigen, which seems to be common to groups or even to the entire genus Salmonella. A related genus-specific "R" antigen is present in rough Shigella strains. Thus, roughness of the culture renders it serologically nonspecific.

Rough cultures are often isolated from chronic carriers. Felsenfeld discovered two such cases which came under observation at a time when no more smooth forms but only rough colonies could be detected in the stools. Both carriers were found during surveys of food handlers. In the first case the organisms were isolated from the stools for a period of three weeks; in the second only one fecal specimen contained such bacteria. The rough colonies from both cases showed traces of the "O" antigen of group "B." All attempts to revert the cultures to the "S" form resulted in failure, so that it was impossible to establish the diagnosis of the types involved.

The variations described above concern solely the "O" antigenic structure and not the "H," with the exception of cases where the "R" variation has progressed so far that motility has been affected.

Phase Variation

The "H" antigens are flagellar antigens and therefore present only in motile cultures. When strains of motile Salmonellas are plated, two types of colonies are observed in most cases. One group of colonies possesses antigens which were originally considered specific for the type, while the other group of colonies shows antigens which are common to many Salmonellas and were, therefore, considered nonspecific. Thus the antigens characterizing the "phases" were called "specific" and "nonspecific," antigens of the first group being designated by small Latin letters and those of the second by Arabic numerals.

When the specific "H" antigens became so numerous that all the letters of the alphabet had been employed, later investigators found it necessary to designate newly discovered antigens by using index numbers attached to the letter "z," "z_1," "z_2," etc.

It has become an established custom to call the "specific" phase the "first" phase, the "nonspecific" the "second" phase. Kauffmann and Mitsui proved that certain antigens present in the first phase may also occur in the second phase. They introduced the terminology "alpha" and "beta" phases, which was subsequently eliminated. Edwards and Bruner succeeded in inducing artificial phases and accomplished much toward the reduction of the confusion which clouded the concept of phase variation. Seligmann and associates described a new phase, which they called "X." The importance of this phase has not as yet been clarified.

Salmonellas which occur only in one phase are known as "monophasic." Organisms found only in the first phase are called "monophasic, specific," while those present only in the second phase are termed "monophasic, nonspecific." Occasionally one of the phases may be weak and it is necessary to enhance it by using cultural and serologic aids. Edwards and Bruner recommended the addition of agglutinating serum to semisolid agar, thereby suppressing one phase and permitting the spread of organisms containing the other phase. Hajna described a simple modification of this technic. He uses U-shaped culture tubes which are filled with a mixture of Edwards and Bruner semisolid agar (M-84) with the addition of a small amount of agglutinating serum of the phase to be suppressed. The medium is inoculated with the culture by barely penetrating the surface of the agar in one branch of the tube. The phase which was not suppressed by the serum may be isolated from the growth in the uninoculated branch of the U-tube, after incubation.

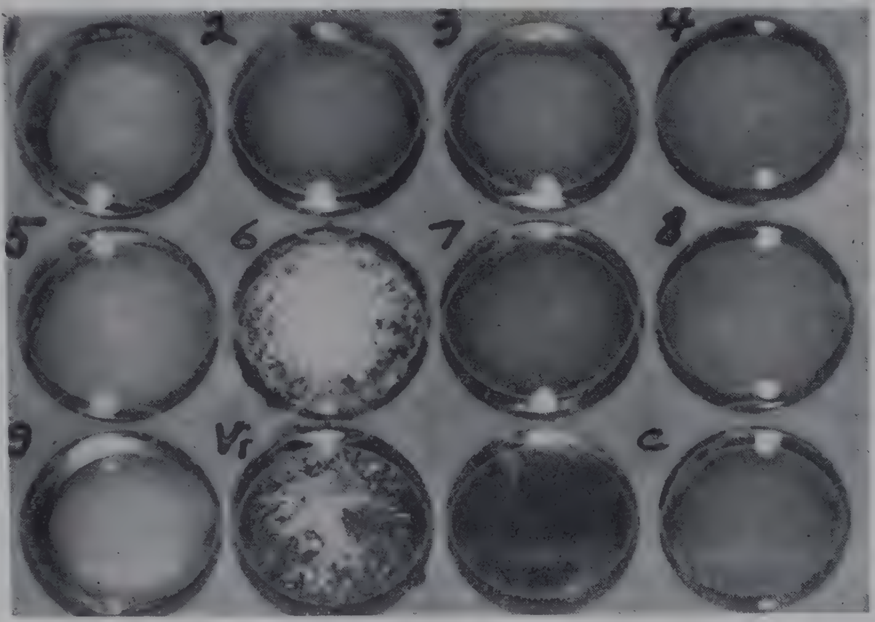

Fig. 362.—Slide agglutination tests involving *S. typhosa.* The numbers are the numbers of the sera ("O" sera) and the last is "Vi." "C" is the control. (Courtesy Dr. Oscar Felsenfeld.)

SALMONELLA TYPING

The antigenic properties and their variations are utilized practically in the serodiagnosis of Salmonellas, which is called "typing." The ideal method would be to have on hand single factor sera prepared against each antigenic component, and to test every strain with all of them. For practical purposes, however, it is not necessary to use such an elaborate system. For the typing of all known Salmonellas 31 "O" sera, one "Vi" serum and 39 "H" sera are utilized, from which single factor sera are prepared by absorption when necessary. Edwards and Bruner and Mickle have enumerated these sera and presented methods of preparation. For smaller laboratories the use of shorter series of sera was found satisfactory, giving special consideration to the frequency of the occurrence of Salmonella strains in different localities. Thus, *S. paratyphi* is rare in the United States; *S. enteritidis* is more frequent in Europe; *S. dublin* in East Africa and South America; *S. hirschfeldi* in the tropics.

It must be realized that many types are not brought to the attention of those bacteriologists who publish statistics. Many laboratories diagnose *S. typhosa, S. pullorum,* and *S. gallinarum* by simple means. Considerable scientific material is also being lost in laboratories which perform agglutinations only with sera against *S. typhosa, S. paratyphi,* and *S. schottmuelleri,* and report the results according to the highest agglutination titer, or discard the culture as ''negative'' if no agglutination occurs. With the advent of centers which are prepared to test any suspicious organism, the correct diagnosis can be easily ascertained. The most active Salmonella centers in America are: Communicable Disease Center, Chamblee, Georgia, the National Salmonella Center at Beth Israel Hospital in New York, N. Y.; the Institute of Hygiene, Montevideo, Uruguay, and others.

Even smaller laboratories may diagnose a large number of Salmonellas, using selected sera and keeping in mind that the types accounting for about 95 per cent of all isolated strains in the United States are those listed in Table 147.

TABLE 147.—FREQUENCY OF SALMONELLAE IN THE UNITED STATES, IN MAN

The small laboratory should have two means for the serologic identification of Salmonellas: a polyvalent serum for the diagnosis of the genus by a single agglutination test and a few ''O'' and ''H'' sera which enable the bacteriologist to differentiate at least the most frequent strains.

Polyvalent sera have been described. Table 148 shows the preparation of two such sera. They are best used in test tube agglutination tests, incubating for two hours at 56° C. Seligmann (1947) described an excellent pooled polyvalent serum, which is preferred by many workers.

It is recommended that specific agglutinating sera be used for the ''O'' agglutination covering the members of the groups ''A'' to ''E.'' The preparation of agglutinating sera is best accomplished by adhering to the well-established method of Edwards and Bruner. This procedure is also followed here, incorporating slight modifications.

Table 149 shows the antigenic structure of the organisms used for the preparation of anti-''O'' sera in this abbreviated series. One rabbit is utilized for the production of each serum. The organisms are cultivated on the surface of nutrient agar slants for 24 hours; then the growth is washed off with saline and kept in the boiling water bath for two hours, to destroy "H" antigens. The animals are injected using 0.25, 0.5, 1.0, and 2.0 c.c. of the bacterial suspensions, at four-day intervals. Six days later the rabbits are bled.

The absorbing organisms are grown on nutrient agar plates. After 24 hours' incubation, the growth is washed off with saline, centrifuged, the supernatant liquid discarded and replaced with serum diluted 1:9 with saline. After 2 hours' incubation at 50° to 52° C., the suspensions are centrifuged and the supernatant fluid saved after adding 1:10,000 Merthiolate.

For the performance of the agglutination tests, unabsorbed sera are diluted 1:5 and 1:10. Absorbed sera are used undiluted. Saline suspensions of the unknown cultures grown on agar serve as antigens. The cultures may be heated in the boiling water bath for one hour before testing. Slightly rough cultures must be treated with alcohol, according to the method of White described above in the section dealing with S—R variation.

The test is performed on a slide: a drop of the serum is mixed with a drop of the antigen, the slide tilted for about one minute and the results read. Table 149 shows the sera recommended for "O" agglutination tests.

More than 90 per cent of all Salmonellas will react with these "O" sera. If no agglutination occurs and the organism shows biochemical reactions typical for Salmonellas, the bacteria are tested with sera prepared against the group ''F,'' or, if such sera are not at hand, the strain is mailed to a Salmonella center for identification.

Both multiple and single factor sera are used for ''H'' agglutination tests. In order to prepare these sera, the organisms are cultivated in motility medium M-83 which assures the best production of the flagellar antigen. When necessary, the technic of Edwards and Bruner or of Hajna is used to elicit the suppressed phase, as described under ''Phase variation.'' Growth obtained from the bottom of a tube of Edwards and Bruner's medium, or from the uninoculated branch of the Hajna U-tube, is transferred into broth. After 18 to 24 hours of incubation the culture is diluted with an equal amount of 0.6 per cent formol containing saline: Rabbits receive 0.5, 1.0, 2.0, and 3.0 c.c. injections of these suspensions, utilizing the same technic as described for the preparation of ''O'' sera.

In order to produce single factor sera, the technic of Edwards and Bruner is used to absorb the multiple factor sera. The organisms utilized for the absorption are grown on nutrient agar plates, 10 cm. in diameter. After 24-hour incubation, the growth is washed off with sufficient saline to give 0.5 c.c. of a bacillary suspension from each plate. The growth from several (usually 5 to 10) plates is added to each c.c. of serum which is diluted 1:9 with saline, and the mixture incubated for two hours at 50° C. The organisms are then removed by centrifugation. In the ''double absorption technic'' two consecutive absorptions are carried out. Table 150 presents the organisms used for the preparation of such single factor sera, giving the number of plates used for the absorption as well as those sera which are used to suppress phases of Salmonellas. Only those sera are included in the tabulation which are considered essential for a small laboratory.

*Monophasic unnamed organisms.

Tube agglutination tests are used to determine the ''H'' antigens. Kauffmann originally recommended the performance of slide agglutination tests for the determination of both ''O'' and ''H'' antigens. Experience has demonstrated that test tube agglutinations are more reliable because cross reactions which frequently occur among ''H'' factors are more easily eliminated. The titer of the sera for typing of ''H'' antigens must be higher than 1:1,000, so that ''O'' antigens do not interfere with the reaction. For this reason the sera are used in dilutions near their final titer. Equal amount of diluted serum (usually 1:1,000) and formolized antigens are used in single tube tests.

The unknown organism is grown in nutrient broth and, after 24 hours, 1 or 2 drops of concentrated Formalin are added. The tests can be carried out after 3 hours or more. The reactions are read after a few minutes and again after one hour's incubation at 50° to 52° C. in a water bath.

When the unknown Salmonella shows the reactions of only one phase, attempts should be made to enhance the other phase, except in cases where a group of ''H'' antigens was found which occurs exclusively in monophasic types.

Antigens f, g, m, s, and t are present mostly in the first phase only.

Single-factor 2, 5, 6, and 7 sera are preferred to unabsorbed 1,2; 1,5; 1,6; and 1,7 sera.

Recent simplifications have discarded antigens 3, 4, 10, 11, o, z_1, z_2, z_8, z_9, z_{17} as diagnostic factors. Furthermore, *Salmonella ballerup* (and the related *S. hormaeche* and *S. exeter* types), as well as *S. arizona*, have been taken off the list of Salmonellae. They are now members of the Ballerup and Arizona groups, respectively, of paracolon organisms.

Lists of Salmonellae are never up to date. It is felt, therefore, that the names of the 286 Salmonellae known at this writing should not be included in this textbook, since extensions of the list would be necessary every month or so.

Only a simplified schedule of typing is given here. This procedure must be modified, especially outside the United States, to suit local conditions. The addition of p, q, and u factors is recommended in areas where *S. dublin* (IX, XII: g, p), *S. rostock* (IX, XII: g, p, u), and *S. blegdam* (IX, XII: g, m, q) are present.

If the tested organism reacts with only one serum recommended for use in the particular group, the strain must be cultured in the presence of that serum (using the Edwards and Bruner or Hajna technic, see pages 1522 ff.) and then re-tested with the other sera.

If a complete diagnosis cannot be made by using this simplified schedule, the strain should be mailed, without delay, to a Salmonella typing center. There is no use in wasting time and sera with futile experiments. Delay in submitting cultures to a better equipped laboratory results in the cultures' turning rough, which in turn makes typing difficult or even impossible.

Simplified Schedule of Salmonella Typing

It must be emphasized that all organisms which cannot be easily classified in the laboratory must be forwarded to a typing center.

This simplified schedule does not contain Salmonella groups beyond E_3, since at least 95% of the Salmonellae frequently encountered in the United States belong to groups B, C, D, and E. The polyvalent sera do not contain ''O'' factors for further group testing, and thus the agglutination tests with this serum will be negative.

I. If the organism shows the biochemical properties of *S. typhosa*—is motile; forms only acid but not gas from dextrose and mannitol; forms some hydrogen sulphide; does not produce indol, urease, or methyl ethyl carbinol; does not ferment lactose or sucrose—test first with ''D,'' ''Vi,'' and ''d'' sera.

If there is no agglutination, test with Salmonella polyvalent serum, since it may be an anaerogenic Salmonella.

II. If the organism shows the biochemical properties of a Salmonella without producing hydrogen sulphide, test with polyvalent Salmonella serum first. Hydrogen sulphide-negative Salmonellae are rare in the United States. They are frequent in the Old World (*S. paratyphi*, *S. choleraesuis* biphasic variety, *S. sendai*, etc.). In animals, *S. abortus equi* is often present.

III. Organisms giving Salmonella biochemical reactions and which are nonmotile must be suspected of being *S. pullorum.* This will react with ‘‘D’’ serum. *S. pullorum* is rare in man.

IV. In all other cases—motile organism which forms hydrogen sulphide, acid and gas from dextrose and mannitol; no indol, urease, or methyl ethyl carbinol; does not ferment sucrose or lactose—test with polyvalent ‘‘O,’’ then ‘‘B_1,’’ ‘‘C_1,’’ ‘‘C_2,’’ ‘‘D,’’ and raw ‘‘E’’ sera.

If there is no reaction, repeat with alcoholized antigen.

If there is still no reaction, put organism into stock agar (M-6 or M-15) for eventual mailing; streak a purity plate; pick again and inoculate into: lactose, sucrose, salicin, dulcitol, and adonitol.

If lactose, sucrose, or salicin are not fermented, submit strain to a Salmonella typing center.

Arizona group paracolons usually do not ferment any of these five substances in one week; however, they usually break gelatin.

Ballerup group paracolons only exceptionally ferment dulcitol but will break (with one or two exceptions) one or more of the lactose-sucrose-salicin series, but not adonitol.

Bethesda group paracolons usually ferment dulcitol rapidly and will decompose one or more of the other substances except adonitol which is, however, usually attached by *Providence* paracolons. This latter group is usually anaerobic and mannitol negative. *Providence* organisms differ from Protei by their lack of urease.

V. If a strain is agglutinated with polyvalent ‘‘O’’ serum and produces hydrogen sulphide, the following procedure is recommended:

(a) Test with ‘‘B_1’’ serum. If agglutinated, test with ‘‘B_2’’ serum:
(1) If ‘‘B_2’’ negative, test with ‘‘b,’’ ‘‘i,’’ and ‘‘2’’ sera.
b+ 2+ : *S. schottmuelleri*
i+ 2+ : *S. typhimurium*
If b– i– : test with ‘‘fg,’’ ‘‘eh,’’ ‘‘mt,’’ ‘‘5’’ sera.
fg+ mt– : *S. derby*
fg+ mt+ : send to typing center (may be *S. california, essen,* etc.)
eh+ 2+ : *S. saint paul*
eh+ 5+ : *S. reading*
(2) ‘‘B_2’’ positive: test with ‘‘b,’’ ‘‘lv,’’ ‘‘7,’’ ‘‘enz_{15}’’ sera.
b+ enz_{15}+ : *S. abortus bovis*
kv+ 7+ : *S. bredeney*

(b) Agglutinated with ‘‘C_1’’ serum: test with ‘‘c,’’ ‘‘fg,’’ ‘‘mt,’’ ‘‘5’’ sera.
c+ 5+ : proceed according to Table 147
fg+ mt+ : *S. montevideo* (g, m, s)
fg– mt+ : *S. oranienburg* (m, t)
Confirm with absorbed sera.
If c– fg– mt– : test with ‘‘k,’’ ‘‘y,’’ ‘‘g,’’ and ‘‘z_{29}’’ sera.
k+ 5+ : proceed according to Table 147
y+ 5+ : *S. bareilly*
z_{29} : *S. tennessee*

(c) Agglutinated with ‘‘C_2’’ serum: test with ‘‘eh,’’ ‘‘d,’’ and ‘‘2’’ sera.
eh+ 2+ : *S. newport*
d+ 2+ : *S. muenchen*

(d) Agglutinated with ‘‘D’’ serum but not *S. typhosa* or *S. pullorum*: test with ‘‘fg,’’ ‘‘gms’’ sera. If positive either in one or in both, test single factors f, m, s, t:
fg+ gms+ f– m+ s– t– : *S. enteritidis* (gm) or *S. blegdam* (gmq) (in the Far East)
f– m– s– t– : send to Salmonella center (may be *S. dublin, S. rostock, S. moscow*)
t+ : send to Salmonella center (may be *S. pensacola* or *S. berta*)
If fg– gms– : test with ‘‘a,’’ ‘‘lv,’’ and ‘‘5.’’
a+ 5+ : *S. sendai* (Far East), *S. miami*
lv+ 5+ : *S. panama* (confirm with single factor ‘‘l’’ serum)

(e) Agglutinated with raw ''E'' serum. Use absorbed ''E_1,'' ''E_2,'' and ''E_3'' sera.
(1) E_1 positive: test with ''eh,'' ''lv,'' ''5,'' ''6,'' and ''7'' sera:
eh+ 5+ : *S. muenster*
eh+ 6+ : *S. anatis* (frequent)
eh+ 7+ : *S. nyborg* (rare)
lv + 5+ : retest with ''v.'' If negative, *S. uganda* (rare, lz_{13}–1,5)
lv + 6+ : *S. london*
lv + 7+ : *S. give*
eh+ lv+ : test with ''v'' and ''w.'' If v– w+ : *S. meleagridis* (e, h, – l, w).
(2) E_2 positive (rare): test with ''eh,'' ''6,'' and ''7'' sera.
eh+ 6+ : *S. newington*
eh+ 7+ : *S. selandia*
lv + 7+ : *S. new brunswick*
eh+ lv+ : test with ''v.'' If negative: *S. cambridge.*
(3) E_3 positive: test with ''s, t'' serum.
s, t+ confirm with ''g''; if +: *S. senftenberg.*

The use of this short method will establish the diagnosis of about 95 per cent of the strains found in man in the United States. Infrequently encountered organisms or those which do not fit into the established scheme must be mailed to a more completely equipped center.

Care should be exerted in the interpretation of the findings, because of the many cross reactions and ''minor antigens.'' As a rule, a higher dilution of the ''H'' antisera excludes ''minor antigens'' or those antigens which were not completely eliminated by absorption. The difficulties experienced with antigens I, VI, and XII have already been mentioned. Antigens VIII and XI also display a trend toward partial cross reactions. The problem is further complicated by the occurrence of Salmonella antigens in other organisms, mainly in closely related coliform and paracolon bacilli. Such organisms may show parts of Salmonella ''O'' or even ''H'' antigens, especially I, II, V to VII, XII to XIV, XVI, XIX, XXIII to XXX; VI; z_4, z_{23}, z_{24}, 1,5 . . .etc. No explanation has been found as yet for the occurrence of such serologic reactions. It is believed

E = *Sh. paradysenteriae* 4 c (rabaulensis and rio) does not ferment mannitol. N = negative, except *Sh. paradysenteriae* Flexner 6.

that these organisms could originate from Salmonellas possessing more complex antigens by loss of certain serologic factors. Salmonella antigens, however, were found not only in closely related Enterobacteriaceae. It was discovered that *Pasteurella pseudotuberculosis* contains part of IV, V, XII, *Pasteurella avicida,* the Vi, and *Pneumococcus* type 35 antigen XVII of the Salmonellas. There is, perhaps, a chemical relationship of haptens, similar to that existing between the antigens of OX protei and Rickettsiae.

Edwards described monophasic strains which greatly facilitate the production of single factor Salmonella sera.

Lederle, Inc., began the production of Salmonella typing sera on a commercial basis. These sera (polyvalent; group sera for groups A, B, C_1, C_2, D, and E; Vi and d sera) facilitate the typing procedure.

The phage typing of Salmonellae was attempted but is not being carried out as a routine diagnostic means.

AGGLUTINATION TESTS FOR TYPHOID AND SALMONELLA INFECTIONS

It is unfortunate that many physicians ask for an agglutination test for paratyphoid A in the Northern part of the United States, where this infection is practically nonexistent. Little attention is paid, as a rule, to agglutination tests for the most frequently found Salmonellae, as *S. typhimurium, S. montevideo,* or *S. oranienburg.* Most laboratories use typhoid, paratyphoid A and B antigens for the diagnosis of "enteric" infections. The preparation and use of such antigens is, therefore, given first.

The Macroscopic Widal Test

The example given below is for the diagnosis of typhoid fever. If any other disease is under consideration, the technic is the same, but a suspension of the bacteria causing the disease in question is used instead of a killed culture of typhoid bacilli.

Suspension of Killed Typhoid Bacilli

Use a culture of *Salmonella typhosa* that has been attenuated by at least several weeks' frequent transplantation on artificial culture media.

Inoculate bottles of nutrient broth with this culture and incubate at 37° C. for twenty-four hours (M-2).

To every 10 c.c. culture, add 0.1 c.c. of 10% solution of 40% formaldehyde. (Ten parts of 40% formaldehyde [Formalin] made up to 100 c.c. with distilled water.)

Place in the refrigerator and shake vigorously several times each day. Allow to remain in the refrigerator for at least four days. At the end of this time, the suspension is sterile. Remove any clumps by filtration through a layer of sterile absorbent cotton in a sterile funnel, catching the filtrate in a sterile bottle. This suspension will be useful as long as it shows no evidence of spontaneous agglutination.

Technic.—

Obtain clotted blood. Loosen the clot and centrifuge for 15 minutes at high speed. Decant the supernatant serum, placing it in a sterile corked test tube. Add 1 c.c. of this serum to 9 c.c. sterile physiologic saline. This is a 1:10 dilution of patient's serum.

Place Wassermann test tubes in a rack. Label them 1:10, 1:20, 1:40, 1:80, 1:160, 1:320, and control.

Add to tubes 2 to 7, inclusive, 0.5 c.c. saline solution. No saline is placed in tube 1.

Place in tubes 1 and 2, 0.5 c.c. of the 1:10 dilution of patient's serum. Mix the contents of tube 2 by drawing in and out of a pipette, withdraw 0.5 c.c., and place in tube 3. Mix the contents of tube 3, and remove 0.5 c.c. from this tube, placing it in tube 4. Continue through tube 6. When the contents of tube 6 have been thoroughly mixed, withdraw 0.5 c.c. and discard. Tube 7 is the saline control, and receives no serum. Add to each tube 0.5 c.c. of the suspension of killed typhoid bacilli (above). This makes the dilution of patient's serum in each tube as follows: 1:20, 1:40, 1:80, 1:160, 1:320, and 1:640.

Mix the contents of each tube by shaking thoroughly.

Place the rack in the incubator for eight to twelve hours.

A positive reaction is indicated by the formation of a sediment consisting of agglutinated bacteria. The supernatant liquid is clear. The control tube should remain cloudy without a sediment. All negative tubes will be cloudy without a sediment. Report the dilutions at which positive reactions are obtained. Killed suspensions of many bacteria may be purchased from most biological houses.

Rapid Agglutination Test in Typhoid and Salmonella Fever, Typhus, and Brucellosis

Comparative results of the rapid slide test technic with a standard test tube method have been reported by Welch and Stuart[1] and Welch and Mickle.[2] In general, it can be stated that the rapid slide method possesses advantages over the test tube method. Tests can be made and reported on the same day the specimen is received. This is very important where a rapid method is essential regarding disposition of cases in hospitals.

---

[1] J. Lab. & Cin. Med. **21**: 411, 1936.

[2] Am. J. Pub. Health **26**: 248, 1936.

Materials.—

Febrile Antigen Kit.*—The Lederle antigens contain droppers which deliver approximately 0.03 c.c. per drop.

Standard serologic pipettes. 0.2 c.c. capacity graduated in 0.001 c.c. These are the pipettes used in the Kahn test for syphilis.

Glass slides containing six rows of five each **wax rings** (see page 1007).

Technic.—

Use the first two rows of rings for ''O'' and ''H'' typhoid antigens, the third row for paratyphoid ''A,'' the fourth row for paratyphoid ''B,'' the fifth row for Proteus OX19, and the sixth for *Brucella abortus* antigen.

It is well to make both positive and negative controls on the antigens.

The same technic is used for each antigen.

Pipette serum into the various rings in the following quantities, beginning at the left and proceeding toward the right of the slide:

0.08 c.c., 0.04 c.c., 0.02 c.c., 0.01 c.c., and 0.005 c.c., using a Kahn pipette, 0.2 c.c. capacity, graduated in 0.001 c.c.

This gives serum concentrations, when mixed with the 0.03 c.c. of antigen of the following dilutions: 1:20, 1:40, 1:80, 1:160, and 1:320. If necessary, further dilutions may be made.

Add a drop of typhoid ''O'' antigen to each drop of serum in the first row, typhoid ''H'' antigen to the sera in the second row, paratyphoid ''A'' antigen to the third row, paratyphoid ''B'' to the fourth row, Proteus OX19 antigen to the fifth row, and Brucella antigen to the sixth row. Shake the antigens well but gently before using.

Using a separate toothpick, mix thoroughly each row of serum-antigen mixture, beginning with the smallest amount of serum and working from right to left.

Gently rock the glass slide back and forth 20 to 30 times and check the degree of clumping.

Record as ++++, complete clumping with no free antigen; +++, 75% clumping with 25% free antigen; ++, 50% clumping and 50% antigen; +, 25% clumping and 75% antigen; and ±, faint clumping. Absence of clumping is a negative reaction.

Clumping with ''O'' antigen differs from the typical small-flaking or granular agglutination obtained in the test tube method. ''O'' and ''H'' agglutination cannot be differentiated by appearance.

Interpretation of Results.—

A test may be positive for typhoid fever if it shows agglutination with either one or both of the typhoid antigens.

A positive agglutination with typhoid, paratyphoid ''A,'' or paratyphoid ''B'' antigens in a dilution of 1:80, if the patient has not had vaccine, is significant.

Cases of typhoid fever may show cross-agglutination with paratyphoid ''B'' antigen, but rarely with paratyphoid ''A,'' provided the patient has not had vaccine or previous infection with the Salmonella group of bacteria. If the patient has been vaccinated, or has history of previous infection, the results must be interpreted accordingly. In most vaccinated individuals, the results cannot be explained at all.

If the patient has been immunized with triple vaccine, agglutination with typhoid ''H'' and both paratyphoid ''A'' and ''B'' antigens will be expected for at least one year. ''O'' antigen may also show agglutination. ''O'' agglutinins usually disappear first; the ''H,'' ''A,'' and ''B'' agglutinins may persist even after three years.

Single specimens on an individual may be misinterpreted since cross reactions do occur with some sera.

Reporting the Results.—

Report to the physician the weakest concentration of the serum which causes agglutination of the antigen, and the antigen or antigens for which the reaction is specific.

---

*Febrile antigens for this test may be secured from Lederle Laboratories, New York.

The test may show agglutination with both "O" and "H" antigens, depending on the time the blood serum is obtained. "O" agglutinins often appear in the patient's serum before "H" agglutinins, and "H" agglutinins often remain longer than "O" agglutinins. After typhoid immunization, the "H" agglutinin may be present for three years, and during the first year, some "O" agglutinins will appear. "O" agglutinins are more likely to be present if the individual has received more than one series of inoculations. For the most part, all agglutinins disappear from the blood stream within 5 to 10 years after immunization unless the individual has more than one series of inoculation.

Other Technics

(a) Brumpt.[1]—

Brumpt used whole blood which is permitted to dry on a slide.

The antigens are prepared by the addition of 10% sodium citrate, 0.2% formol, and 1 to 2 drops of a saturated watery solution of methylene blue *or* Sabrazes blue.

Salmonella, Proteus, Brucella, and *Pasteurella tularensis* antigens may be used in this way.

One drop of antigen is mixed with the drop of blood, and the reaction observed.

If liquid blood is available, serial dilutions, similar to those used by Welch and Stuart, are used. Different amounts of the antigen are put on a glass plate or cardboard and drops of blood added directly from the finger or ear or from the vein. When blood and antigen are mixed, the plate is rocked and the reactions read.

(b) Bagilova.*—

One-tenth c.c. amounts of suspensions containing 80 to 100 milliards of Protei, Salmonellae, etc., per c.c. are dried on pieces of cellophane paper. The papers are kept in a refrigerator and just before use are dissolved in 1 c.c. saline.

Such antigens keep for 3 months.

Vi Agglutination

The Vi agglutination has attracted much attention. It is considered an excellent aid for the detection of typhoid carriers. Unfortunately, no two authors have performed this test alike. Brower divided the methods for the detection of the Vi antibodies in the serum into the following groups:

1. **Absorption technic,** used by Felix.—The serum is first absorbed with a *S. typhosa* strain rich in "O" and "H" antigens, then the Vi titer is determined by agglutination with a Vi strain.
2. **Direct titration of antibodies** with a strain which contains only Vi antigens; for example, the Bhatnagar strain of *S. typhosa.*
3. **Direct titration** with a strain from which the "O" antigens have been eliminated by growing in broth containing "O" serum and the "H" antigens separated by repeated centrifugation and washing, according to the method of Detre.
4. **Precipitation tests,** using antigenic extracts from Vi strains.

Because of technical difficulties involved in the other methods, the third method was found to be the most satisfactory. It requires, however, considerable work. The cultures must be tested and transferred frequently and their V—W variation cannot be prevented easily.

The technic of the Vi routine agglutination test is that of tube agglutination tests. The dilutions of the sera, however, are lower: 1:5, 1:10, 1:20, and 1:40. A suspension of the Bhatnagar Vi strain in 0.85% sodium chloride is used. The antigen is adjusted to tube 3 of the McFarland nephelometric standard (page 1477). The tubes are incubated for 2 hours at 37° C., and then left in the refrigerator overnight. A hand lens is used to facilitate the reading.

Gunther[2] devised an excellent modification of Desranleau's[3] technic.

Grow Bhatnagar Vi strain on veal infusion agar M-15, pH 7.6, for 24 hours.

---

*Zhurnal Mikrobiol. 1: 36, 1942.

[1] Bull. Soc. Path. Exot. 33: 390, 1940.

[2] Am. J. Clin. Path. 16: 293, 1946.

[3] Canad. Pub. Health J. 34: 502, 1943.

Wash off the growth with 10 c.c. of 75% alcohol per plate.

Keep in the refrigerator for 4 days, then centrifuge and wash with distilled water.

Suspend the sediment in 50% glycerol in 0.1% sodium chloride, buffered to pH 7.4 to 7.6.

Adjust the suspension to 10 times tube 1 of the nephelometer.

Dilute the serum 1:2 with saline.

Add to 0.05 c.c. of this dilution 0.05 c.c. of the antigen on a hollow slide.

Shake for 4 minutes on the Kahn shaker.

Read after 15 and 30 minutes using 150× magnification.

Most authors agree that the Vi agglutination test should be considered positive when agglutination occurs in tubes containing at least 1:20 dilution of serum. Positive tests were observed in a large proportion, about 80 per cent, of typhoid carriers, but agglutination is also found in about 5 to 10 per cent of the general population.

Shigella (Dysentery Bacilli)

Gram-negative, nonmotile, nonsporeforming rods, which do not give a Voges-Proskauer reaction; ferment dextrose with the formation of acid only; do not produce hydrogen sulphide. Do not utilize citrates as a sole source of carbon.

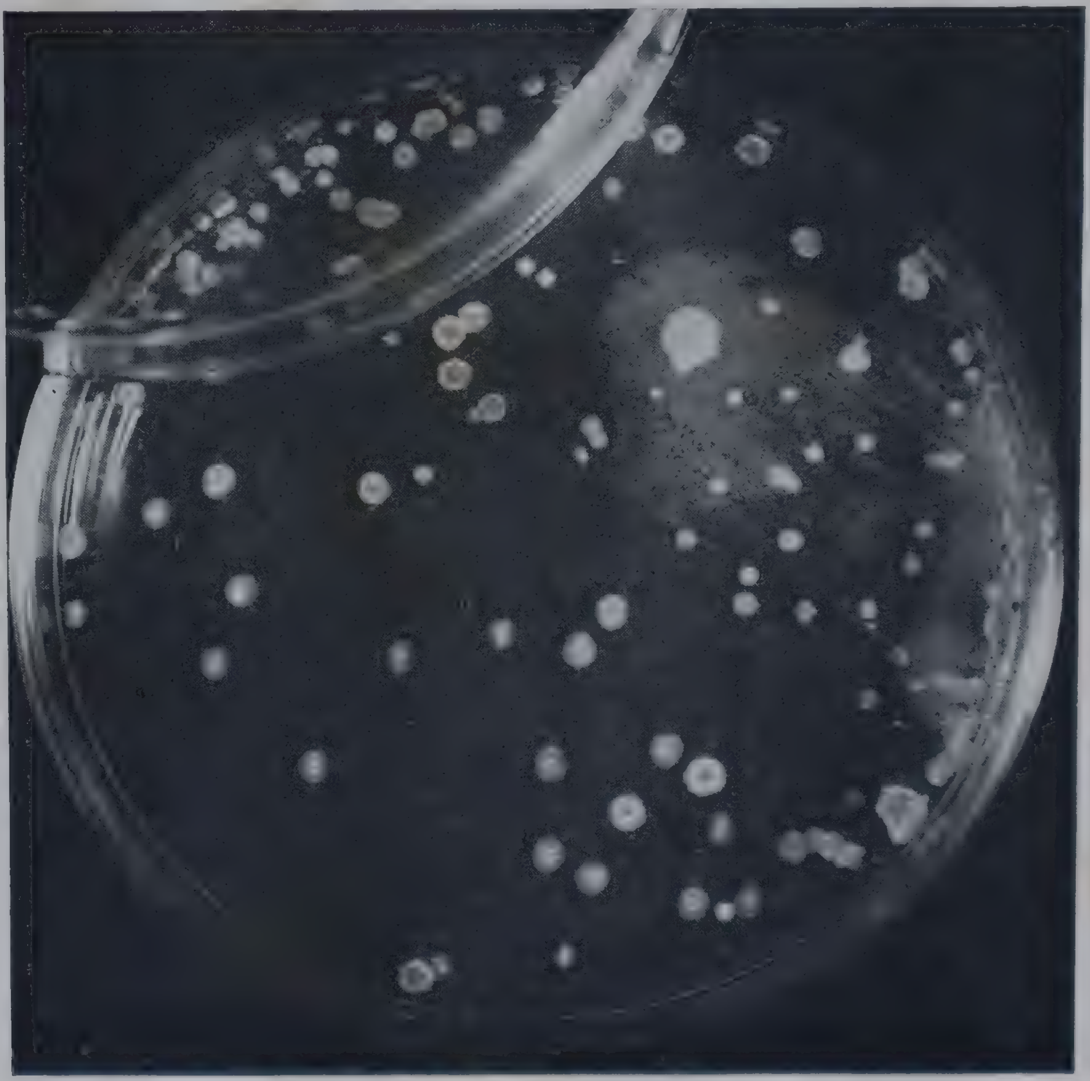

Fig. 363.—*Shigella sonnei* colonies isolated from stool specimen on SS agar. (Courtesy Dr. Oscar Felsenfeld.)

They grow well on the usual media, with the exception of a few strains which are fastidious (*Sh. dysenteriae*, rare members of the *Sh. paradysenteriae* group, very few *Sh. sonnei* strains).

The principal biochemical differences of strains important in human disease are given in Table 152.

Much information on the classification of Shigellae is contained in Neter's excellent review.[1] Other extensive articles were later published by Wheeler[2] and Weil.[3] The classification of the mannitol-negative strains was clarified by Wheeler and Stuart[4] who arrived at the following conclusions:

In the mannitol-negative, lactose-negative, and indol-negative group are *Sh. dysenteriae* Shiga-Kruse and Sachs' strains Q 454, Q 771 (identical with Gober's, ''8524'' and *Sh. arabinotarda* A, and Q 1167 (identical with *Sh. arabinotarda* B).

In the mannitol-negative, lactose-negative, and indol-positive group are the *Sh. ambigua* Schmitz, Sachs' strains Q 902 and Q 1030, and the new serotype 599-52.

The serologic classification of the strains is as follows:

Sh. dysenteriae, the true dysentery bacillus of Shiga-Kruse, is serologically homologous; one serum will agglutinate all strains. Serologically different strains (''Sachs'' strains), are, however, found. This is the only Shigella which forms a true exotoxin. It is rarely found in the United States of America.

Sh. ambigua, relatively rare in the United States, differs from *Sh. dysenteriae* in that it forms indol.

Sh. flexneri was formerly classified according to the schema of Andrewes and Inman as V, W, X, Y (= Hiss-Russell) and Z (= Strong), and combined forms, such as VZ, etc. Table 153 shows the more important forms according to the classification of Wheeler, Boyd, and Haden. *Sh. flexneri* is a frequent cause of dysentery.

Sh. alkalescens has at least 8 serologic types. It is one of the frequently found Shigellae.

Sh. sonnei is being reported in great numbers, principally in children and in inmates of asylums. It usually causes a short-term diarrhea, without frank blood in the stools. Two serologic types are recognized.

Sh. dispar has been differentiated into *Sh. ceylonensis* and *Sh. madampensis* on the basis of fermentation of dulcitol. Carpenter distinguished at least four serologic types. Recently it has been added to the alkalescens group under the name Alkalescens-Dispar.

SEROLOGY

It is not necessary to produce one's own sera since they are commercially available from Lederle Laboratories. These sera must, however, be used in strict adherence to the manufacturer's instructions. If sera are produced in the laboratory, smooth strains are selected and gown on extract agar slants M-13.

When injecting animals, give the first injection subcutaneously, the others intravenously. Inject the animals twice a week, for 5 weeks. Wash off the growth on the slants with sterile saline and kill by heating to 100° C. for 2 hours. Then add enough Formalin to make a 0.5% concentration. For the first injections, adjust to match tube 1 of the nephelometer; for later injections, adjust to tube 3.

Schedule of injections:

First injection: 0.1 c.c. of No. 1 density, subcutaneously.

Second to fifth injections: 0.1 c.c., 0.2 c.c., 0.5 c.c., 0.5 c.c. of No. 1 density intravenously.

Sixth to ninth injection: 0.5 c.c., 0.7 c.c., 1.0 c.c., and 1.0 c.c. of density No. 3 intravenously.

Bleed the animals after a 5 to 7 days' wait.*

The polyvalent serum for the A Group is prepared by pooling *Sh. dysenteriae* 1 to 7 type sera, according to Madsen,[5] and absorbing with Alkalescens-Dispar organisms.

The polyvalent serum for group B is prepared by pooling *Sh. flexneri* 1 to Y type sera and absorbing it with Alkalescens-Dispar 1, 3, and 4 organisms.

---

*Some authors recommend shorter schedules to avoid panagglutinating seras, e.g., 0.5, 1.0, 2.0, 4.0, and 4.0 c.c. amounts in 4- to 5-day intervals.

[5] Madsen: The Classification of the Shigella Types, Copenhagen, 1949, Ejnar Munksgaards Forlag.

The polyvalent serum for group C is prepared by pooling *Sh. boydii* 1 to 7 type sera and absorbing it with Alkalescens-Dispar 1, 3, 4 and *Sh. sonnei* II organisms.

The bivalent *Sh. sonnei* serum is a pool of sera against smooth and rough *Sh. sonnei* types.

The *Alkalescens-Dispar* group has at least 8 "O" groups and a polyvalent serum should represent the 5 most frequent types (*Sh. alkalescens,* I, II, III; *Sh. dispar* I, and Frantzen's strain 145 or 5513, the last being serologically identical with Kauffmann's *Escherichia coli* U 9/41).

Type-specific *Sh. flexneri* sera are not easy to prepare. In view of the diagnostic antigenic formulas of Madsen, the following absorptions are recommended:

Type 1 serum: absorb type 1a serum with type 2a, 5, and 6 organisms.
Type 2 serum: absorb type 2b serum with type 1a and X organisms.

†U.S.A.F. Far East M. Bull. 1: 101, 1953.

Type 3 serum: absorb type 3 serum with type 1b, 2a, and X organisms.

Type 4 serum: absorb type 4a serum with type 2a and X organisms.

Type 5 serum: absorb type 5 serum with 1a, 3, and X organisms.

Type 6 serum: absorb type 6 serum with 1a organisms.

Sh. boydii sera must be absorbed with *Sh. sonnei* 2 and Alkalescens-Dispar antigens.

Typing of Shigellae by use of polyvalent and monovalent sera has been simplified so that it may be easily performed even in small laboratories. The following points, however, must be kept in mind:*

1. Drops should not be too small.

2. The drops should contain enough bacteria that the saline control is definitely gray but not too dense. A few trials are necessary to determine the correct density. Material from solid media is definitely preferable. If for some reason broth cultures must be used, it is usually advisable to centrifuge and use the sediment for the tests.

3. It is better to use bacteria killed by heat, 100° C. for one hour.

4. Cultures which are negative when tested alive may need to be retested after half an hour's boiling because of the inhibiting, heat labile substance. Interference by this substance has been noted occasionally with *Sh. dysenteriae, Sh. ambigua, Sh. alkalescens,* and *Sh. flexneri.* In most cases the inhibition is not absolute in the sense that most of the strains which show inhibition are still slightly agglutinated after some delay.

5. The Sonne serum contains antibodies against both phases. Phase 1 (''smooth'') agglutinates strongly and promptly. Phase 2 (''rough'') agglutinates slowly and in small clumps. This is an inherent peculiarity of the phase 2 antigen and nothing can be done about it. Those who handle phase 2 of Sonne are apt to feel, quite understandably, that the serum is weak, which is definitely not the case.

6. Many individuals do not realize the advantage of using the polyvalent Flexner serum. Flexner types 1 to Y and Sonne comprise the great majority of all strains. Thus, if isolated bacteria are tested first with the polyvalent Flexner and the Sonne sera, most of the organisms can either be directly identified as Sonne, or subsequent testing may be restricted to the Lederle Flexner sera 1 to Y. Preferential use of the most prevalent sera Flexner 1, 2, 4, and 6 will further simplify the procedure.

7. Shigella antigens do occasionally occur in Enterobacteriaceae other than Shigella. Although this is a rare occurrence, it is imperative, because they do sometimes occur, to complement serologic identification by the classical cultural methods. There is little danger in issuing a preliminary report based on agglutination only, because the percentage of error

---

*We are indebted to Dr. A. J. Weil of The Bronx Hospital, New York, for this personal communication concerning use of the sera.

is small. Nevertheless, the final report must be based on serologic *and* cultural identifications. Practically all of the few troublesome cases with so-called unspecific reactions or failure of the sera were due to omission of old-fashioned bacteriologic control.

8. In this respect, the test for motility is one of the most important safeguards.

9. Both as a safety precaution and as a convenience, Weil makes his slide agglutinations on the inside of the cover of Petri dishes, which he divides into squares with a glass pencil. A piece of moist, dull black cloth, placed in the bottom of the dish, gives an excellent background for readings, and provides a simple moist chamber. Readings are most conveniently made in oblique light in a dimly lighted room. For instance, Weil reads his reactions in a small cubicle used for microscopic work, using the microscope lamp tilted at an appropriate angle.

Agglutination Test With the Patient's Serum

Agglutination phenomena do not occur in bacillary dysentery until about the twelfth day from the onset. The test, therefore, is not valuable for diagnostic purposes.

Protei

Morphology: Rods, 0.5 to 1.0 by 1.0 to 3.0 microns, occurring singly, in pairs, frequently in long chains, and in threads. Very motile with peritrichous flagella. No capsules; no spores.

Stain: Gram-negative.

Biochemistry: All Protei form urease which can be determined by the urease test R-15. They ferment dextrose, sometimes also sucrose. They may or may not produce indol. All strains, except *Pr. rettgeri,* form gas, and do not attack mannitol.

Pr. vulgaris spreads over the surface of moist media at incubator temperature. *Pr. morganii* spreads only on 1% agar at room temperature. It is thought that some protei may be pathogenic for children and others. Protei X19, X2, and XK are agglutinated by the sera of patients suffering from Rickettsial infections.

Characteristics of Protei are described in Table 152.

They are easily isolated on eosin-methylene-blue media M-71 or M-72. When *Pr. vulgaris* is present in wounds, it may make isolation of other organisms difficult. Spreading of its colonies may be stopped by using sodium azide (M-21), tellurite (M-42), or phenylethyl alcohol (M-23).

Coliform Organisms

Coliform organisms include the *Escherichia coli-Aerobacter aerogenes* group and the paracolon organisms.

Both main types of coliform organisms, *Esch. coli* and *Ae. aerogenes,* ferment dextrose, mannitol, and lactose with the production of acid and gas. Many strains ferment sucrose and salicin. *Esch. coli* is more often found in warm-blooded animals than *Ae. aerogenes,* which is more often present on the surface of plants.

These organisms may be differentiated according to Table 155.

TABLE 155.—THE "IMViC" REACTION

	Indol formation R-12	Methyl red test R-13	Voges-Proskauer reaction R-14	Utilization of citrate R-17
Esch. coli	+	+	0	0
Ae. aerogenes	0	0	+	+

In addition, *Esch. coli* grows on eosin-methylene-blue agar, M-71 or M-72, in dark purple colonies, with a metallic sheen, while *Ae. aerogenes* forms large moist, white or pinkish colonies with only a dark center. *Ae. aerogenes* is closely related to Klebsiella, and is classified with it.

Organisms which show atypical reactions and cannot be classified as typical *Esch. coli* or *Ae. aerogenes* are called "intermediates."

Paracolon Organisms.—

Paracolon organisms differ from *Esch. coli* and *Ae. aerogenes* by their slow fermentation of one or more of the following substances: lactose, sucrose, salicin. They cause considerable difficulty in the diagnosis of Salmonella infections. They are classified, according to their "IMViC" reactions as *Paracolobactrum coli, Paracolobactrum aerogenes,* and *Paracolobactrum intermediate.* In addition, "anaerobic" strains are known; these form only acid but not gas from fermentable substances.

Many coliforms have Salmonella or Shigella antigens. The occurrence of such antigens does not always signify pathogenic power.

Escherichiae.—

Escherichiae have "O" (somatic), "H" (flagellar), and "K" (envelope) antigens. "L" antigens are carried only by living organisms, and can be removed from antisera produced by injecting live bacteria only by absorption with boiled cultures. These antigens are, therefore, thermolabile somatic (envelope) antigens. "L" antigens are responsible for the "O"-inagglutinability of many live strains. "A" antigens are removed by heating for 2 hours at 120° C., while "B" antigens are destroyed by heating for only 1 hour at 100° C. Antigens "L," "A," and "B" are considered subdivisions of the "K" antigen.

At the time of writing this chapter, there are 128 recognized *Esch. coli* serotypes, belonging to 26 groups. Serotypes 26, 55, 86, 111, 112, 119, 124, 125, 126, 127 and 128 have been implicated in diarrhea. They are easily identified in slide-agglutination tests using 1:10 diluted rabbit sera prepared by injecting live cultures into rabbits. Most frequently types 55 and 111 are seen.

Since *Esch. coli* 111 does not ferment sorbose but breaks salicin within 4 days, while *Esch. coli* 055 has the opposite characteristics, colonies showing the appearance of *Esch. coli* on eosin-methylene blue agar (M-71 or M-72) may be streaked to a blood agar plate. Neither of these two *Esch. coli* types causes hemolysis. The cultures are then transferred to one Kligler (M-79) or T.S.I. tube (M-80), and to broth with sorbose (M-5) and with salicin (M-5). *Esch. coli* 111 and 055 do not form hydrogen sulphide, but will produce acid and gas in the Kligler or T.S.I. tubes. The surface growth may be used for agglutination, or a separate tube with agar (M-13, M-16, or M-17) is inoculated for this purpose.

Aerobacter (Klebsiella).—

Aerobacter (Klebsiella) organisms have capsular (K), smooth somatic (O), and rough somatic (R) antigens, as well as mucoid (M) antigens. Kauffmann* suggested an antigenic schema with 4 "O" and 14 capsular types, thus 17 antigenic combinations. Many Aerobacter strains form urease.

Aerobacters frequently occur in diarrheic stools of various etiology. They have been indicated as causing intestinal disturbances in children.

Paracolobactra (Paracolons).—

Paracolobactra (Paracolons) have complicated serologic structures. Three groups, belonging in the intermediate class, are rather well defined: the *Ballerup,* the *Arizona,* and the *Bethesda* groups (see page 1526).

The *Providence* group at present is somewhat confused. Members of this group may or may not be motile; may or may not form gas; do not produce hydrogen sulphide, but are indol positive. They grow on citrate agar; do not form urease or break gelatin; and may or may not attack mannitol. They are Voges-Proskauer negative. Of the nongasforming types belonging here, Stuart's 29911 strain is the best known.

Felsenfeld finds it expedient to call "transient" those anaerogenic paracolon organisms which ferment mannitol and produce urease, as well as those which lack both abilities.

Since the issue of Paracolobactra still needs much clarification, these organisms should be considered as the cause of diarrhea only if careful examinations have excluded other possible causes, especially parasitologic.

Kauffmann and Edwards consider *Pc. coliforme* as *Esch. coli,* and *Pc. aerogenoides* as Klebsiella-Aerobacter.

Typing sera for the Paracolobactra are available only in specialized laboratories.

---

*Kauffmann: Enterobactericeae, Copenhagen, 1951, Ejnar Munksgaards Forlag.

BRUCELLA

Brucella Melitensis

Morphology: Short, ovoid rods, 0.3 to 0.4 micron in length, occurring singly, in pairs, and in short chains and threads. Nonmotile, nonspore-forming, noncapsulated.

Stain: Gram-negative.

Colonies: On agar, they form ''ground glass'' appearing colonies, small, circular, convex, with dark center. They do not change litmus milk. They produce no change in the differentiating media for the colon group of organisms, since they do not ferment any carbohydrates. They are identified by their agglutination with immune sera. Cause brucellosis (Malta or undulant fever).

Brucella Suis

Morphology: Similar to *Brucella melitensis.*

Stain: Gram-negative.

Colonies: Culturally similar to *Brucella melitensis.* Isolated from genitourinary organs of swine. Chief host, the hog. Causes abortion in swine and frequently causes brucellosis (undulant fever) in man. Also infectious for horses, dogs, cows, monkeys, and laboratory animals.

Serology: *Brucella suis* can be differentiated from *Brucella melitensis,* but not from *Brucella abortus,* by the agglutinin absorption test.

Brucella Abortus
(Bacillus Abortus Bang)

Morphology: Rods, 0.4 to 0.5 micron by 0.6 to 1.5 microns, occurring singly. They are nonmotile, noncapsulated, and nonsporeforming.

Stain: Gram-negative.

Colonies: Very small, transparent, opalescent, lustrous, moist, entire. They do not change the differentiating colon bacilli media, since they do not ferment any carbohydrate. Cause contagious abortion in cattle, brucellosis in man.

Differential Characters of Species of Genus Brucella*

	INFECTIVITY FOR GUINEA PIGS	CO_2 TOLERANCE 10 PER CENT	H_2S FORMATION DAYS	DEXTROSE UTILIZED	AMINONITROGEN UTILIZED	EFFECT OF DYES

*Bergey: Manual of Determinative Bacteriology, ed. 6, 1948, Williams and Wilkins.

BRUCELLOSIS

Bruce,[1] investigating the disease known as Malta fever, Mediterranean fever, or undulant fever, discovered a bacterium in fatal cases of this disease which he called *Micrococcus melitensis.* This was a disease of goats transmissible to man. It was found on the Island of Malta, where British garrisons were often affected, and also on neighboring islands and shores of the Mediterranean. It was occasionally reported from Italy, Spain, Greece, Transcaucasia, Algeria, Tunis, Palestine, Arabia, India, South Africa, China, and various parts of South America. It was apparently brought to the United States about 1911. Bang[2] in Denmark, in 1897, isolated a bacterium responsible for contagious abortion in cattle. This disease was commonly known thereafter as Bang's disease; she termed the organism the *Brucella abortus.* MacNeal and Kerr[3] in 1910 first isolated and cultivated this organism in the United States.

---

[1] Practitioner 39: 161, 1887.

It was not until the work of Evans[4] was published in 1918 that these two diseases, one of goats and man, and the other of cattle, were found to be closely related because of the remarkably similar morphologic, cultural and serologic resemblances between the two bacteria. Traum,[5] in 1914, found in fetuses prematurely expelled from sows a bacterium which is related to Bang's disease and Malta fever. The bacteria, therefore, of Malta fever, of contagious abortion in cattle, and of sows, have well been given the generic name of Brucella and are designated as *Br. melitensis, Br. abortus,* and *Br. suis.* Infection with any of these bacteria is termed brucellosis.

Laboratory Diagnosis of Brucellosis.—The best method for the diagnosis of brucellosis is the cultivation and identification of the organism. The *melitensis* and *suis* varieties of Brucella grow readily under aerobic conditions, while the *abortus* variety requires an atmosphere containing 10 per cent carbon dioxide (see Fig. 380).

Morphology and Staining Characteristics of Brucella.—Brucella are small coccal or bacillary forms varying from 0.4 to 2.2 microns in length and from 0.4 to 0.8 micron in breadth. Both coccal and bacillary forms may be present. *Br. melitensis* is generally considered to be more coccal in form than *Br. abortus* but the difference in size and shape is so slight as to render it impossible to distinguish with certainty between individual strains. The bacteria appear singly, in pairs end to end, or in small groups; sometimes short chains of 4 to 6 members may be seen, especially in liquid media. These bacteria are nonmotile.

On semisolid media, the colonies are small, circular, convex, amorphous, smooth, and translucent. No pigment is formed. The growth of *Br. melitensis* becomes brown in older cultures and the browning extends down into the medium. *Br. abortus* may show this browning at times.

Brucella may be stained with the ordinary dyes. There is a tendency toward irregular staining and in some cases bipolar staining is present. They are gram-negative, nonacid-fast, and form neither capsules nor spores. The optimum temperature for cultivation of Brucella is 37° C. No acid or gas is produced. Growth in milk is accompanied by slowly increasing alkalinity. Indol is not formed. Optimum pH is 6.6 to 6.8. All three varieties of Brucella produce hydrogen sulphide. *Br. suis* produces it in abundance, *Br. abortus* less so, and *Br. melitensis* very slightly.

Br. melitensis and *Br. suis* may be grown under the usual aerobic conditions and, after a number of transfers, the *Br. abortus* adapts itself to ordinary aerobic growth.

It is interesting to note that *Br. abortus* and *suis* may be killed in three minutes at temperatures of 140° to 145° F. They persist in soil, water, and dust for several months, but disappear within ten days in milk, presumably as a result of the acid formed by other bacteria. These bacteria are able to survive two hours or more in milk mixed with gastric juice.

A Practical Method for Routine Blood Cultures in Brucellosis

A great deal of time has been lost in laboratories in attempts to justify isolation of Brucella organisms from blood. The use of large amounts of material and handling of many tubes provide sufficient opportunity for infection of technicians with Brucella strain. In order to cultivate these organisms successfully, M. Ruiz Castañeda, from the Department of Medical Research, Hospital General, Mexico, D. F., gave a practical method.[1] Dr. Castañeda's work is personally well known to the author, who considers a communication from his pen one that can be freely accepted by bacteriologists and clinical pathologists.

The medium suggested by him is as M-25.

Fifteen c.c. of the medium are placed in 100 c.c. flat-sided, rectangular bottles. The mouth of the bottle (about 1¼ cm. in diameter) is covered with thick paper and sterilized at 15 pounds for 15 minutes. The bottles are placed on their sides so that the agar sets on one of the narrow sidewalls forming an even, transparent layer. The paper is then lifted, using aseptic technic, and 10 c.c. of Castañeda broth are added. The flask is then closed with sterile rubber stoppers and the bottle again covered with the same paper cap. The air within the bottles can be replaced by suitable mixtures of CO_2 and air by any mechanical devise which avoids contamination of the double medium. This double medium should be tested for sterility before it is used. These tests are made at 37° C. for three or four days. The agar surface is wetted by the broth at 24-hour intervals.

The double medium may be inoculated with 10 c.c. of blood, the patient usually being bled with a 20 c.c. autoclave-sterilized syringe. The needle is inserted through the rubber stopper after the careful removal of the paper cap. The mixture of blood and broth is spread over the agar layer for a moment and the bottle incubated in a vertical position at 36° C. Every other day the broth is allowed to flow over the agar layer and the bottle replaced in the incubator, again in a vertical position, thus giving a series of inoculations.

Results.—When the agar layer shows colonies after 24 to 48 hours, it is likely that the culture has been contaminated. When the colonies appear 24 or 48 hours after the second inoculation, the cultivated organism has usually been found to be a Salmonella, less frequently Staphylococcus or Streptococcus, but it may be Brucella. Positive cultures of Brucella are detected more frequently after the third agar inoculation, that is, on the sixth day of cultivation. After 20 days the negative cultures may safely be discarded. The number of colonies and time of their appearance on the agar layer vary from one case to another and serve as a good indication of the intensity of the bacteriemia. Serial cultures performed twice a month have been of assistance in roughly estimating the course of the bacteriemia. During the acute phase of the disease the early appearance of innumerable colonies is the usual finding. In the chronic phase when positive, the culture shows few or sometimes a single colony in 10 or more days.

The colonies of Brucella are clearly seen through the agar layer and are easily transferred for further study. With some experience one may differentiate them from contaminants, Salmonella, and other organisms.

Castañeda's method reduces bacteriologic manipulation and material, avoids infection by technicians, and gives positive results. The rather high citrate content is intended not only to prevent clotting of the blood but also to reduce the phagocytic activity of polymorphonuclear leukocytes to a minimum. It is thought that the ease with which the Brucella colonies appear on the agar layer is due at least in part to the absence of plasma, thus reducing the bactericidal effect. This method avoids transfers and, as stated before, affords increased safety against accidental infection to the personnel.

---

[1] Proc. Soc. Exper. Biol. & Med. 64: 114, 1947.

Cultivation of Brucella.—

For the excellent method of Castañeda, see page 1540.

The cultivation of Brucella is carried out also by the method recommended by Poston[6] as follows: Obtain 15 c.c. of blood from each patient by venepuncture and place in a small flask containing 4 c.c. of sterile 2.5 per cent sodium citrate solution. Inoculate each of four flasks containing 100 c.c. of liver infusion broth of pH 6.8 with 2 c.c. of the citrated blood. Incubate the flasks at 37° C., two in the room atmosphere and two in atmosphere containing 10 per cent CO_2. (See page 1575, Fig. 380, for apparatus to produce 10 per cent CO_2 atmosphere for culture of Brucella.) After four days' incubation, make daily smears of the broth cultures and stain by Gram's method. If no organisms are seen in the smears after 10 days' incubation, transplant 5 c.c. of the original cultures to 100 c.c. of liver infusion broth every three days for two weeks. Incubate original cultures and transplants for three weeks before they are reported as negative.

Definitiveness in the diagnosis of the bacteriologic research is accomplished by means of guinea pig inoculation. Poston advises inoculation of three guinea pigs with blood from each patient; two injected intraperitoneally with 2 c.c. each of citrated blood; one inoculated in the groin with 1 c.c. of citrated blood. Observe the animals daily. Beginning two months after inoculation, make tests for specific agglutinins and for cutaneous reaction to Huddleson's brucellergin at intervals of a few days. When both tests become positive sacrifice the animals. Sacrifice animals which remain negative to the agglutination test and to the skin test 4½ months after inoculation. Plant tryptose broth M-24 with the guinea pig's blood and with pieces of organs and subject to the cultural procedures described above. The cultures may then be differentiated into *abortus, suis,* or *melitensis* varieties by the agglutinin-absorption technic, the bacteriostatic action of dyes, glucose utilization and hydrogen sulphide metabolism.[7] Prepare urine, stool, bile, or spinal fluid, or other materials for cultures according to standard methods. Inoculate such material on plates of liver infusion agar containing gentian violet in concentration of 1:200,000 (M-26a). Incubate one-half of the plates aerobically for ten days; place the other half in a container having 10 per cent CO_2 atmosphere and incubate at 37° C. for three days.

The blood may be collected directly into Huddleson's tryptose broth M-24. Trypticase soy broth M-3 is also a good medium for the culture of Brucella.

Borts emphasized the necessity of making large inocula in large amounts of fluid medium and the need for frequent plating to solid media. For such plating, liver infusion agar M-26 and tryptose agar M-16 are useful. It must be kept in mind also that the plates must be incubated in a carbon-dioxide atmosphere; this is indispensable for *Br. abortus* and does not harm the other types.

Plating is made with inocula taken from the interface of the blood-broth mixture. Contamination may occur from introducing a sterile capillary pipette too often into the blood culture. To avoid this, Felsenfeld recommends use of divided cultivation of blood samples in several tubes of trypticase soy broth M-3 or tryptose broth M-24.

It is good procedure to make subcultures every seven days for three weeks.

For further differentiation, liver agar M-26 with dyes is used. Page 1538 shows the difference between the strains.

Huddleson recently has recommended the addition of dead Brucella cells to the culture media. This method yields heavier growth.

SEROLOGY

Agglutination Test for Brucella.—In the absence of positive cultures, the most reliable indicator of Brucella infection is the agglutination test. This is particularly true in cases of acute brucellosis, in which a high serum agglutinin titer will be found in most cases. There is a progressive increase in the agglutinin titer upon repeated testing in suspected cases of acute brucellosis. Agglutinins may appear as early as the fifth day of illness, but ordinarily are not found until the second week after the onset. In some instances, specific agglutinins may not appear for several weeks. It is a very important fact, which is difficult to reconcile with our immunological knowledge, that agglutinins may be persistently absent or may be present in low titer in persons from whom Brucella has been cultivated. It must also be remembered about the agglutination reaction that the titer may remain at a high level for months or years after recovery. Again, certain people exposed to the infection may develop agglutinins without any apparent illness. Next, the level of the agglutinin titer may fluctuate widely on repeated testing. It is for this reason that keen judgment is necessary in interpreting the results of the agglutination test. A person suffering from some disease other than brucellosis may have a positive agglutination test merely as the result of a previous symptomatic or asymptomatic Brucella infection.

---

(2) Huddleson, I. F.: Tech. Bull. No. 100, Mich. State College, 1929.
(3) Huddleson, I. F.: Commonwealth Fund, N. Y., 1934.

In cases of chronic brucellosis, there are still more difficulties in interpreting agglutination tests. Many patients with chronic brucellosis give repeatedly negative agglutination reactions or positive tests in low titer. Attention is also to be called to the occasional cross agglutination of Brucella and *Pasteurella tularensis*. In cases of tularemia the relatively higher titer with the *P. tularensis* antigen and the usually typical history permit one easily to interpret the serologic findings. Vaccination against cholera also might give a positive titer.

The limitations of the agglutination test, as Simpson[8] so well pointed out, must be recognized; otherwise, errors will be made in two directions: first, the correct diagnosis of brucellosis may not be made because too much reliance is placed upon a negative test; or second, an incorrect diagnosis of brucellosis may be made in a person who has a residual agglutinin titer from a previous invasion by Brucella, but who is suffering from some other disease when the test is made.

Huddleson Rapid Agglutination Test for Undulant Fever of Man (Brucellosis) and Abortion Disease of Cattle

Materials Needed.—

1. Glass test tubes for collecting the blood sample. These are prepared in the manner described in the preparation of patient's serum. (See page 2031.)
2. 0.2 c.c. pipettes graduated in 0.001 c.c. These are the same as used in the Kahn test.
3. Glass plate ruled off with inch squares.
4. Huddleson antigen. This can be purchased from Sharp and Dohme, or Lederle, Inc.
5. Clean toothpicks for mixing serum and antigen.

Technic.—

Allow the patient's blood to clot. Loosen the clot from the side of the tube. Centrifuge at high speed for fifteen minutes to separate the serum from the clot. Remove the serum from the clot by means of a sterile dropper. The serum should be free of cells.

The apparatus used is a glass plate ruled off with inch squares and resting on a dark field illumination box.

---

[8] Ann. Int. Med. 15: 408, 1941.

Draw up 0.2 c.c. serum in the graduated pipette.

Remove any serum from the outside of the pipette with a clean cloth. Hold the pipette vertically when measuring the blood serum.

Place 0.08 c.c. blood serum in the first square.

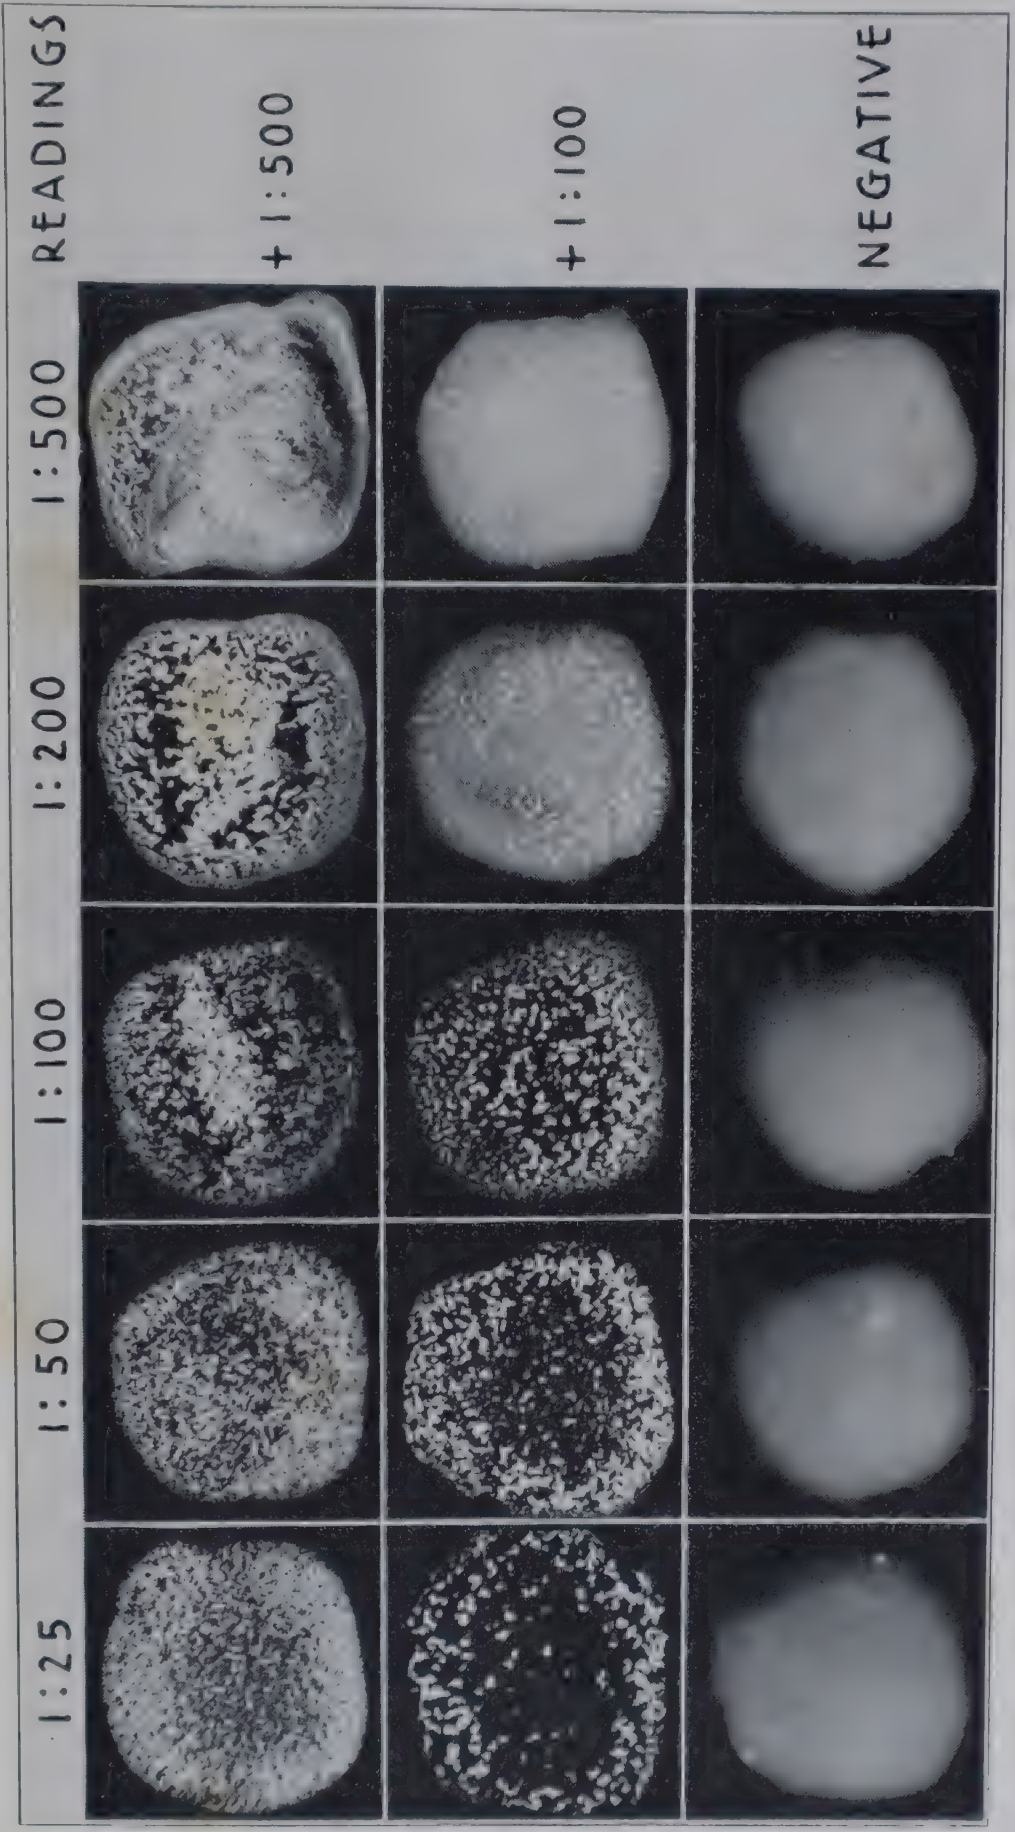

Fig. 364.—Rapid agglutination test for brucellosis. (From Gould and Huddleson: J. A. M. A., Dec. 11, 1937.)

Place 0.04 c.c. in the second square; 0.02 c.c. in the third; 0.01 c.c. in the fourth; 0.005 c.c. in the fifth.

Shake the vial of antigen thoroughly.

Remove a dropperful of the antigen. Hold the dropper vertically and add 1 drop of the antigen to each quantity of blood serum on the glass plate. Positive and negative controls should be made with the tests.

Using a clean toothpick for each quantity of serum, mix the serum and the antigen thoroughly.

Mix further by removing the glass plate from the box and tilting each back and forth 20 to 30 times. Check the degree of clumping after each 5 times. Replace the glass plate.

Examine at once for agglutination after turning on the light.

Reading the Test.—A negative result shows no change in the mixture of serum and antigen.

A trace of flocculence in the 0.08 c.c. amount of serum, with no flocculence in the other quantities, is to be disregarded, and the specimen reported as negative.

A positive reaction is reported if there is flocculence in any quantity of serum below 0.08 c.c.

Complete agglutination with the various amounts of serum used represents the following titers:

0.08 c.c.	1: 20 dilution of serum
0.04 c.c.	1: 40 dilution of serum
0.02 c.c.	1: 80 dilution of serum
0.01 c.c.	1:160 dilution of serum
0.005 c.c.	1:320 dilution of serum

With human sera, the positive reaction in a titer of 1:80 is considered diagnostic of brucellosis. With cattle sera a positive reaction in a dilution of 1:40 is suspicious of present or past infection, while positive reactions in 1:80 or higher are diagnostic.

One may expect to find the agglutinins in these cases after the blood has been infected for a week or longer.

Alternate Method of Agglutination Test for Undulant Fever of Man and Bovine Infectious Abortion

Cultivate several strains of *Brucella abortus* on liver infusion agar (M-26) for several days, wash off and suspend in 1 part carbolic acid to 200 parts normal saline solution. Make an even suspension. Filter this suspension through sterile paper and test for sterility. This sterile suspension is centrifuged and the clear supernatant fluid discarded. Pick up the sediment in a small amount of 0.4 per cent Formalin and keep the packed organisms in an ice box, making dilutions of the desired density at the time the agglutination tests are conducted.

Use unheated sera.

For each serum arrange four test tubes, adding to each one the following amounts of serum: 0.1, 0.04, 0.02 and 0.01 c.c. Add 2 c.c. of the antigen to each tube; this gives dilutions from 1:20 to 1:200. Now prepare control tube containing 0.1 c.c. of saline and 2 c.c. of antigen. Mix and incubate at 37.5° C. for twenty-four hours.

The readings are interpreted as follows:

Compare agglutination 1:50 or over implies positive result with cattle sera. With human sera, positive reaction requires agglutination at 1:100 or over.

A partial agglutination of 1:50 means a weakly positive with cattle sera.

No agglutination in 1:20 or over is negative with cattle sera.

The Brucellergin Test[9]

This intradermal test is used to determine hypersensitiveness to specific Brucella antigen. A positive allergic skin reaction is generally accepted as evidence of past or present invasion of tissues by Brucella. Most patients from whose blood Brucella has been recovered show a positive skin test, although occasionally the test is negative even though Brucella infection has been proved by culture. The chief sources of error in interpreting the significance of a positive skin test are: first, the test is frequently positive in exposed individuals with no history of an illness compatible with brucellosis; second, this hypersensitiveness, once acquired after symptomatic or subclinical infection, usually persists for many years. A positive skin test, therefore, does not mean that the symptoms from which the patient is suffering at the time of the positive skin test are necessarily due to brucellosis. Gould and Huddleson[9] believe that if the skin test is negative, brucellosis may be ruled out.

---

[9] Gould, S. E., and Huddleson, I. F.: J. A. M. A. **109**: 1971, 1937.

Making the Skin Test.—A number of antigens have been used for this skin test. The most commonly employed agents are (1) a heat-killed suspension of Brucella in physiologic saline solution and (2) a suspensoid of nucleoprotein isolated from Brucella by chemical separation, known as Brucellergin (Huddleson).

Technic of the Test.—Dilute the vaccine (which is commercially available) in the proportion of one part vaccine to nine parts sterile physiologic solution of sodium chloride and inject 0.1 c.c. of the diluted suspension intracutaneously in the ventral surface of the forearm. It is necessary to use properly standardized vaccines from a reliable source.

Interpretation.—A positive reaction is characterized by the development of a circumscribed erythematous, edematous, indurated area at the site of injection. In a positive test, the area of local reaction averages about three-fourths of an inch in diameter, but may vary from one-half inch to three or more inches. The reaction reaches its greatest intensity in 24 to 48 hours. Observe the test to get the best results 48 hours after injection. The presence of mild, transient erythema, without edema and induration, is of no significance. In frankly positive cases the induration usually persists for several days. In hypersensitive persons a positive test may be accompanied by a mild, or in some instances a severe systemic reaction. In such cases, the lymphatic channels above the site of inoculation may become red, thickened and painful, and the regional axillary lymph nodes may become enlarged and tender. An exacerbation of symptoms may follow the development of a positive skin test. Focal necrosis of the Arthus type occurs at the site of inoculation in a few cases.

It is interesting to note from the observations of Goldstein[10] and Elton[11] that the injection of heat-killed Brucella for the intradermal test stimulates the production of agglutinins. Evans[12] found that the intracutaneous injection of brucellergin in twelve volunteers caused the development of opsonins in seven and agglutinins in five; in one instance the agglutinins rose from zero to a titer of 1:320. Hence, blood specimens for serologic tests should be collected before the intradermal test is performed.

The Opsonocytophagic Test for Brucella

The opsonocytophagic test is partially described on page 1573. Owing to the inadequacies of the agglutination test and the intradermal test in certain cases to distinguish between present and past Brucella infection, Huddleson, Johnson, and Hamann[13] reintroduced the opsonocytophagic reaction, a modification of the Leishman-Veitch technic for determining the phagocytic activity of the blood in the presence of serum opsonins and homologous leukocytes. This test is employed in conjunction with the intradermal test or the agglutination test, or both, to determine the immunity status of an individual giving positive tests by either or both methods.

[10] J. Clin. Invest. 13: 209, 1934.
[11] Arch. Path. 30: 797, 1940.
[12] Pub. Health Rep. 52: 1419, 1937.
[13] Am. J. Pub. Health 23: 917, 1933.

Technic.—Mix 0.1 c.c. of the patient's citrated blood with 0.1 c.c. of a saline suspension of living Brucella which have been grown for 48 hours on liver infusion agar (M-26). The suspension should contain at least six billion organisms per c.c. of physiologic saline solution of a pH of 7.0. Incubate the mixture at 37° C. for 30 minutes, after which remove a small amount of the sedimented cells with a capillary pipette. Make a smear from a large drop of the cell suspension, dry rapidly, and stain with any good blood stain. The number of bacteria in 25 segmented neutrophilic leukocytes is classified according to the number of bacteria per neutrophile; the absence of phagocytosis indicates a negative result; 1 to 20 phagocytized bacteria indicates slight phagocytosis, 21 to 40 moderate, and 41 or more, marked phagocytosis.

Huddleson interprets the results as follows: The opsonocytophagic power of the blood is low during the active infective phase of the disease and becomes marked after recovery. On this basis, individuals have developed immunity to Brucella if 60% or more of the segmented neutrophiles show marked phagocytosis. If as many as 40% of the leukocytes show moderate to marked phagocytosis, the patient may be infected and has not yet developed any immunity, or he may be uninfected. According to Simpson,[8] while the contentions of Huddleson and his associates are strong in estimating the value of this test, it lacks confirmation. Studies by Calder[14] and Keller, Pharris and Gaub[15] provide support to Huddleson's thesis. On the other hand, Evans[16] regards the opsonocytophagic test as the least reliable of the diagnostic tests in cases of chronic brucellosis; she found strongly positive or immune reactions in four cases from which Brucella were cultivated, and weak or moderate reactions in recovered cases. Morales Otero and Gonzalez[17] found no correlation between cutaneous allergy to Brucella and the opsonocytophagic reaction. Lee Foshay[18] and Simpson,[8] working independently, have found that a significant proportion of patients yields aberrant and unexpected results in relation to the immunity status when the opsonocytophagic test is employed in conjunction with cultural methods, agglutination tests, and skin tests. High phagocytic titers or immune reactions occur in some patients with severe and uninterrupted brucellosis, proved by cultures. Certain recovered patients, asymptomatic for months or years, exhibit marked fluctuations from month to month, running the entire gamut from high to low phagocytosis, or sometimes none at all. Therefore, the results of the opsonocytophagic test should be interpreted with caution and with reservations.

Tovar[19] pointed out that it is necessary to use sodium citrate in a final concentration of 1% in order to eliminate "normal" opsonins. He recommended the use of formol-killed Brucellae for this test.

Testing Milk for Brucellosis.—See pages 1677 to 1680.

Hematology of Brucellosis

Leukopenia occurs in patients with acute brucellosis. In chronic brucellosis, either leukopenia, moderate leukocytosis, or normal leukocyte levels may be found. Lymphocytosis is a striking and constant feature of the blood picture in all of the manifestations of brucellosis. This is true in both percentage values and in absolute numbers of lymphocytes and there is unusually high proportion of immature lymphocytes. Mild anemia of the macrocytic normochromic type is present. The red cell sedimentation rate is usually not high, except when regional complications are present. Calder[20] believes that this combination of white blood cell and red blood cell abnormalities is distinctive for brucellosis and provides an additional confirmatory diagnostic aid.

BACILLI

Bacillus Anthracis
(Anthrax Bacillus)

Morphology: Rods, 1.0 to 1.25 by 5 to 10 microns long, with square to concave ends, occurring in long chains. Nonmotile. Spores central, 0.7 to 0.8 by 1.5 to 1.75 microns.

Stain: Gram-positive.

Colonies: Irregular, fringed, ''Medusa head,'' made up of interlacing chains which lie parallel along the margin. They produce a grayish, tough, spreading, fimbriate growth on agar. They form acid in dextrose. They are aerobic. Cause anthrax (malignant pustule). Flat, translucent, grayish colonies, showing granular surface with filaments (''medusa head''—visible often only under magnification) are characteristic. Capsulated forms are found only in tissues.

Stein[21] summarized the characteristics of *B. anthracis* as: (a) causes fatal septicemia in guinea pigs, (b) nonmotile, (c) methylene blue not reduced in 48 hours, (d) salicin not fermented (M-5), (e) slow action upon gelatin (M-84), (f) slow peptonization of milk (M-11), (g) broth (M-2) is clear or shows slight turbidity, (h) sheep blood cells (R-3) are only exceptionally and very slightly hemolyzed, (i) on nutrient agar (M-13 to M-15) growth shows tenacious texture, comes off in threads when touched with the needle.

For the isolation of *B. anthracis* use nutrient agar plates (M-13 to M-15).

It is recommended that poured plates be prepared. The deep colonies of *B. anthracis* are loose and ragged, which permits differentiation from the colonies of several other of the Bacillus species. Surface colonies in transmitted light often have a ''ground-glass'' appearance.

The excretions and secretions of infected animals and man are examined. In man, the stools, urine, and pus from pustules are usually selected for the test, although the organisms may be found in the skin, intestines, and lungs. Since bacteriemia is a common complication of anthrax infection, the blood is the material of choice.

In animals, the modus of infection is considered in the selection of material. In living animals, the hair, food, and soil on which they graze are important. In dead animals, the cadaver is examined for evidence of infection, the inner organs being selected for cultures. In advanced decomposition of animals, where cultures would be almost impossible, the precipitin method of Ascoli is used. This method is a mixing of immunized rabbit serum with an extract of organs under examination for the production of a precipitate.

Ascoli Precipitin Test

Grind up the organs or blood of suspected animals.

Suspend in saline.

Boil for 5 minutes.

Filter through filter paper and allow to cool.

Carefully stratify 0.5 c.c. of this extract on 0.5 c.c. of immune serum in a small test tube.

Allow to stand 15 minutes at room temperature.

---

[20] J. A. M. A. 112: 1893, 1939.

[21] Am. J. Vet. Research 5: 38, 1944.

Definite ring-like precipitate forms at the junction of the two fluids in positive cases.

Always run controls with (1) known anthrax extract; and (2) with a normal serum.

The examination of blood of infected animals will usually show typical anthrax bacilli even in a stained smear. Cultures on dextrose agar may be made for definite diagnosis.

Bacillus Subtilis

(Hay Bacillus)

Morphology: Rods, 0.365 by 1.5 to 2.5 microns, occurring singly and in chains. Motile by means of peritrichous flagella. Spores central or excentric, 0.875 micron in thickness.

Stain: Gram-positive.

Colonies: Spreading, grayish, ameboid, with crenate margin. They grow abundantly on any medium, producing a thin, grayish white membranous, glistening, spreading, adherent growth. They alkalinize and peptonize milk. They form acid, but no gas, in dextrose and sucrose. They are aerobic. Nonpathogenic. This is a frequent laboratory contaminating organism.

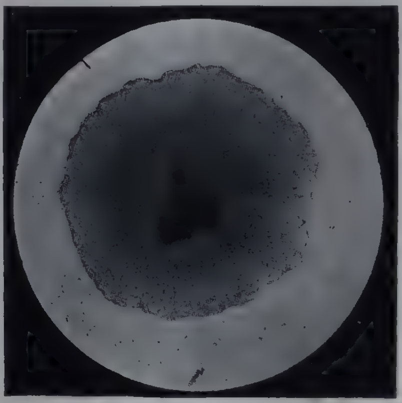

Fig. 365.

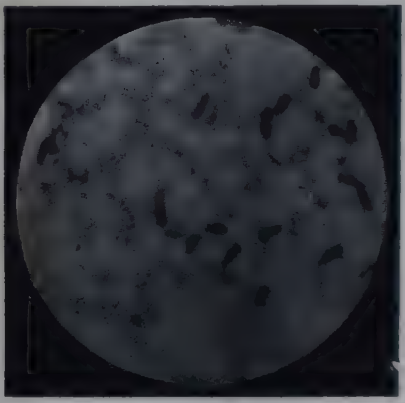

Fig. 366.

Fig. 365.—Colony of *Bacillus subtilis* (hay bacillus) on dextrose agar.
Fig. 366.—Spores of *Bacillus subtilis.* (×950.)

Bacillus Megatherium

Morphology: Rods, 1.6 to 2.0 by 3.5 to 4.0 microns, occurring singly, in pairs, and chains. Motile by means of peritrichous flagella. Spores are central or slightly excentric, and are 0.75 to 1.25 by 1.5 to 2.0 microns.

Stain: Gram-positive.

Colonies: Circular, thick, white to cream color, entire. They produce a dirty white, smooth, glistening, slimy growth on agar, browning the medium. Old cultures become yellowish red with pellucid spots over the surface. They do not coagulate milk. They peptonize the milk. They form acid in dextrose and sucrose. They are aerobic. Nonpathogenic.

Bacillus Cereus (Mycoides or Anthracoides)

Morphology: Rods, 1.3 to 1.4 by 3.0 to 5.0 microns, occurring in long chains. They are motile by means of peritrichous flagella. The spores are central, and are 0.8 by 1.4 to 2.2 microns.

Stain: Gram-positive.

Colonies: Grayish, spreading, rhizoid. They grow on agar with a whitish, soft, glistening, rhizoid growth, the growth becoming dull. They do not coagulate milk, but peptonize it slowly. They form acid in dextrose and sucrose. They are aerobic. Nonpathogenic.

GENUS CLOSTRIDIUM*

The salient features of this genus include the following characteristics:

1. Gram-positive in young cultures.
2. Catalase negative.

---

*See footnote, p. 1554.

3. Sporeforming bacilli, filamentous and plectridial forms often occurring.

4. No demonstrable cytochrome system.

5. Motile, with the exceptions of *Cl. perfringens, Cl. filiforme,* occasional unclassified microaerophilic strains, and some nonproteolytic, nonsaccharolytic types.

6. Nonencapsulated, except *Cl. perfringens, C. butyricum,* and *Cl. fallax.*

7. Anaerobic, with the exception of the listed microaerophilic types: *Cl. tertium, Cl. carnis,* and *Cl. histolyticum.* Additional unclassified microaerophilic strains occur in soil and have been isolated from wounds.

The classification presented here, like that of Reed and Orr, is primarily based upon the reaction obtained in iron-milk. Four categories are evident, although, properly speaking, stormy fermentation differs from a condition of "acid, clotting, with gas" only in time and intensity.

Clostridia are predominantly saccharolytic, proteolytic, or neither. Pathogenicity is not limited to any one of these three divisions, nor is it excluded from any.

The size of the Clostridium is not a diagnostic feature inasmuch as various media alter morphology by promotion or depression of growth.

The location of the spores should not be heavily relied upon as a strong differential characteristic in presumptive identification.

The isolation and identification of Clostridia demand that critical media be employed and that they be evaluated within a reasonable time limit. Forty-eight hours' incubation at 37° C. is considered optimal for most physiologic reactions, and the present key is prepared on this basis.

Clostridium Tetani
(Tetanus Bacillus)

Morphology: Rods, 0.4 to 0.6 by 4.0 to 8.0 microns, occurring singly. They are rapidly motile by means of peritrichous flagella. Spores are spherical and terminal.

Stain: Gram-positive.

Colonies: Colonies are small, transparent, villous to fimbriate margins.

Cl. tetani is one of the strictest of the anaerobes, and is most notable for the powerful exotoxin produced. A characteristic type of death is observable in a test animal: an opisthonic convulsion is diagnostic.

It is still questionable whether there is any proliferation of the organisms in tissue, but a toxin, lethal to man in a dosage of 0.25 mg., is produced; this causes tetanus or lockjaw.

Physiologically, *Cl. tetani* is nonsaccharolytic and is a proteolytic species. Reports vary on two rather important criteria for physiologic differentiation: iron-milk and the production of indol. Normally (this may be a geographic difference), no change occurs in iron-milk (M-5), although rarely a strain will be encountered which will form a soft clot. Indol might not be produced, particularly with fresh isolations (R-12).

The Gas Gangrene Group

With each new war wound study, another evaluation of the Clostridia of the gas gangrene group is usually advanced. Members incriminated in this infection are derived from all four categories of our differential charts. It has been usual to consider as causative agents those pathogens isolated from gangrenous infections, using the term "contaminating or concomitant species'' for the nonpathogenic species which have been isolated. It is not clear what role some of the nonpathogenic proteolytic species play, but their appearance often seems to indicate more than saprophytic opportunism.

Three groups of Clostridia can be outlined which will comprise most Clostridia isolated from war wounds or cases of gangrene:

I. Proteolytic Clostridia which include *Cl. novyi* and *Cl. sporogenes, Cl. sordelli,* and *Cl. bifermentans, Cl. histolyticum,* and *Cl. lentoputrescens.*

II. Saccharolytic types of pathogenic Clostridia which include *Cl. perfringens, Cl. carnis, Cl. fallax, Cl. septicum, Cl. feseri,* and perhaps *Cl. aerofoetidum,* although the last mentioned is but slightly, if at all, toxigenic.

III. Other Clostridia often found are:

(a) Those species probably representing fecal contamination, such as *Cl. tetanomorphum, Cl. cochlearium,* etc.

(b) Those species which probably are soil contaminants: *Cl. paraputrificum, Cl. multifermentans, Cl. capitovale,* etc.

(c) In the Far East, the Armed Forces Laboratories have consistently found ''unclassified'' microaerophilic types in many wounds and have confirmed their identity from soil samples taken from the immediate area of wounding. These types are usually of slight toxicity.

Clostridium Perfringens (Welchii)
(Bacillus Aerogenes Capsulatus)

(Gas Bacillus)

Morphology: Rods, short, thick, 1.0 to 1.5 by 4.0 to 8.0 microns, occurring singly and in pairs, less frequently in short chains. They are nonmotile. They form capsules. Spores are oval, central, or excentric.

Stain: Gram-positive.

Colonies: They are obligate anaerobes. They form acid in litmus milk, coagulating it with profuse gas formation. Colonies are circular, moist, slightly raised, opaque center, entire.

Several types are differentiated according to their toxins; one of them (F) is nonhemolytic, and is supposed to cause food poisoning.

Clostridium Sporogenes (Bacillus Oedematis Maligni)

Morphology: Rods, occurring principally in long chains. They are large with rounded ends. They are motile by means of peritrichous flagella. Spores are oval and excentric.

Stain: Gram-positive.

Colonies: They are obligate anaerobes. Colonies are delicate, spreading, semitransparent, becoming grayish, crenated. They acidify and coagulate milk with gas formation.

Clostridium Feseri (Chauvei)

Morphology: Rods, large, occurring singly and in short chains. Usually show a dark chromatic point near each extremity. Motile by means of peritrichous flagella. Spores are oval, central, or excentric.

Stain: Gram-positive.

Colonies: They are obligate anaerobes. Colonies are small, grayish, semiopaque, filamentous. Cause symptomatic anthrax (blackleg).

Clostridium Botulinum

Morphology: Rods, large, with rounded ends, occurring singly and occasionally in short chains. They are motile by means of peritrichous flagella. Spores are oval and subterminal.

Stain: Gram-positive.

Colonies: They are obligate anaerobes. They grow only at temperatures below body temperature. Colonies are flat, grayish, irregular, mottled. They form an exotoxin which is pathogenic. The organisms, themselves, are nonpathogenic.

Cl. botulinum, by type being synonymous with *Cl. parabotulinum,* occurs in soil, and has been isolated from the feces of animals. Occurrence of *Cl. botulinum* seemingly tends toward a definite geographic distribution. As a point of interest, although several descriptions of cases of suspected *Cl. botulinum* intoxication exist in Japanese literature, it was not until 1950 that the exact identity of *Cl. botulinum,* type A, was undeniably confirmed from soil isolates. Type E, however, also occurs.

It is difficult to correctly identify the *Cl. botulinum* by physiologic reactions and by morphology in the absence of toxin neutralization or protection testing. On primary isolation, the organisms frequently are slow carbohydrate fermenters. The inherent pattern of physiologic reactivity, apart from the toxin, is that of the "acid-digestion" group of proteolytic Clostridia.

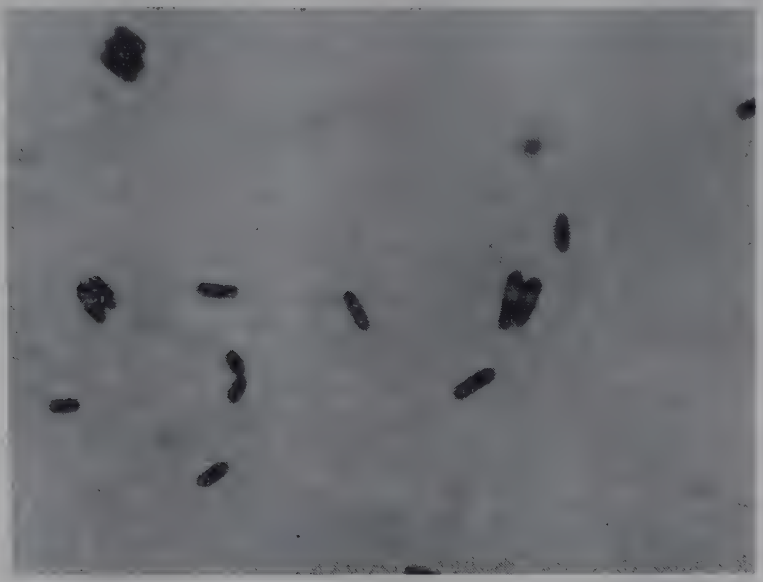

Fig. 367.—Impression smear from experimental gas gangrene, showing sporulating organism, *Clostriduim histolyticum.* (Photomicrograph from slide of T. F. Wetzler.)

Cl. botulinum is a saprophyte and probably does not proliferate in the tissue of the host.

The toxin is lethal to man in a dosage of 0.0084 mg. (crystallized).

Cl. botulinum, as a group, is divisible into some 5 types by serologic-toxigenic differentiation. Types A and B are those found in food poisoning of man; type C (often further subdivided into "alpha" and "beta") is incriminated in forage poisoning of horses, limberneck of chickens, etc. Type D has been the causative agent of a type of cattle poisoning, whereas type E may be analogous to type C.

The Butyricum Group

Since this group is useful in commercial enterprises, the manufacture of solvents and dairy products, etc., it has been well studied as a group, the notable feature of many members being "stormy fermentation" in iron-milk. Frequently, members of this group give delayed types of reactions, thus being easily separated from *Cl. perfringens.*

It has been pointed out elsewhere that the reaction termed "stormy fermentation" is a condition of "acid, clotting with gas." Fermentation of carbohydrates demonstrates the close relationships of the two categories, both of which include most of the saccharolytic types of Clostridia described.

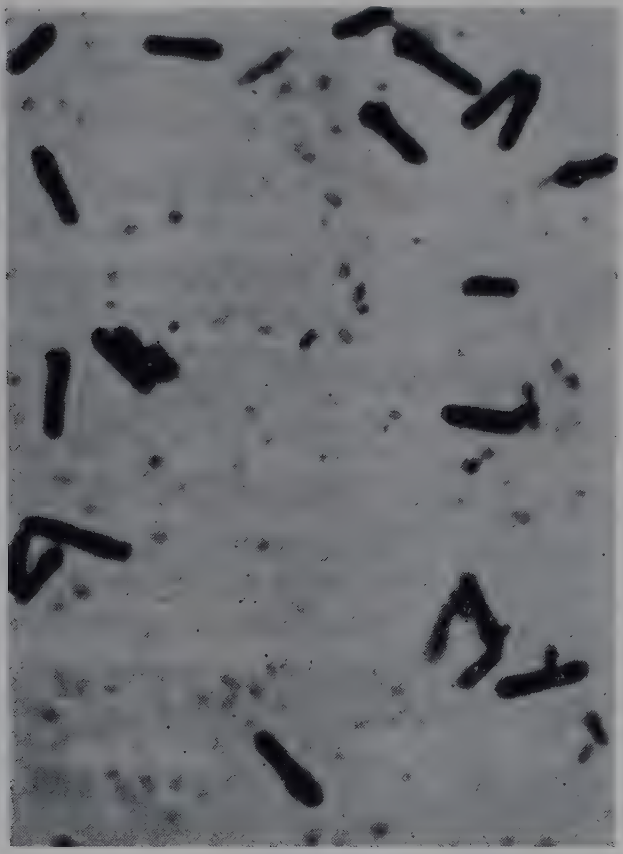

Fig. 368.

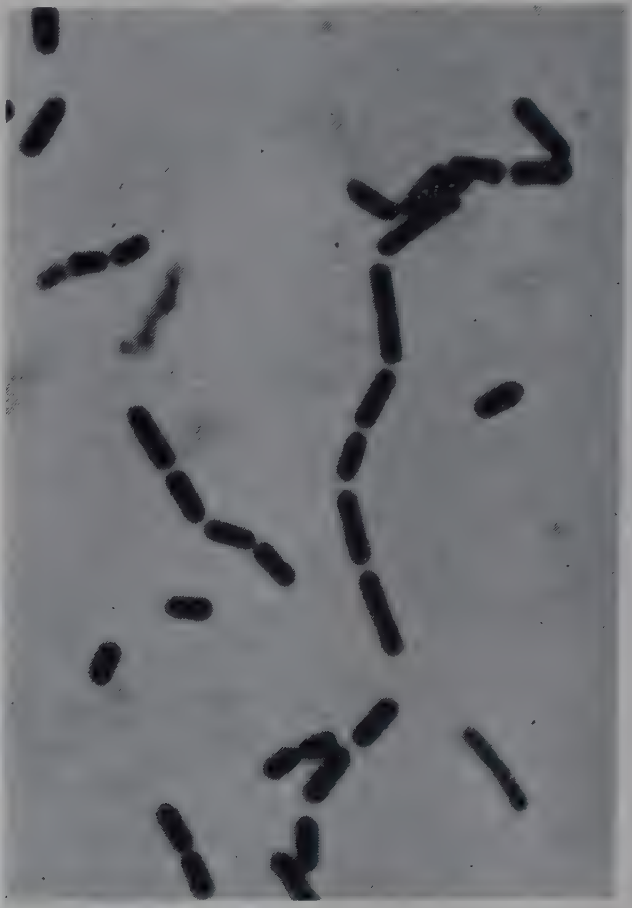

Fig. 369.

Fig. 368.—An 18-hour culture of a proteolytic Clostridium with early sporulating forms. *Clostridium sporogenes.* (Photomicrograph from slide of T. F. Wetzler.)

Fig. 369.—A typical 18-hour culture of *Clostridium perfringens*, demonstrating uniform cell size and a tendency to form short chains. (Photomicrograph from slide of T. F. Wetzler.)

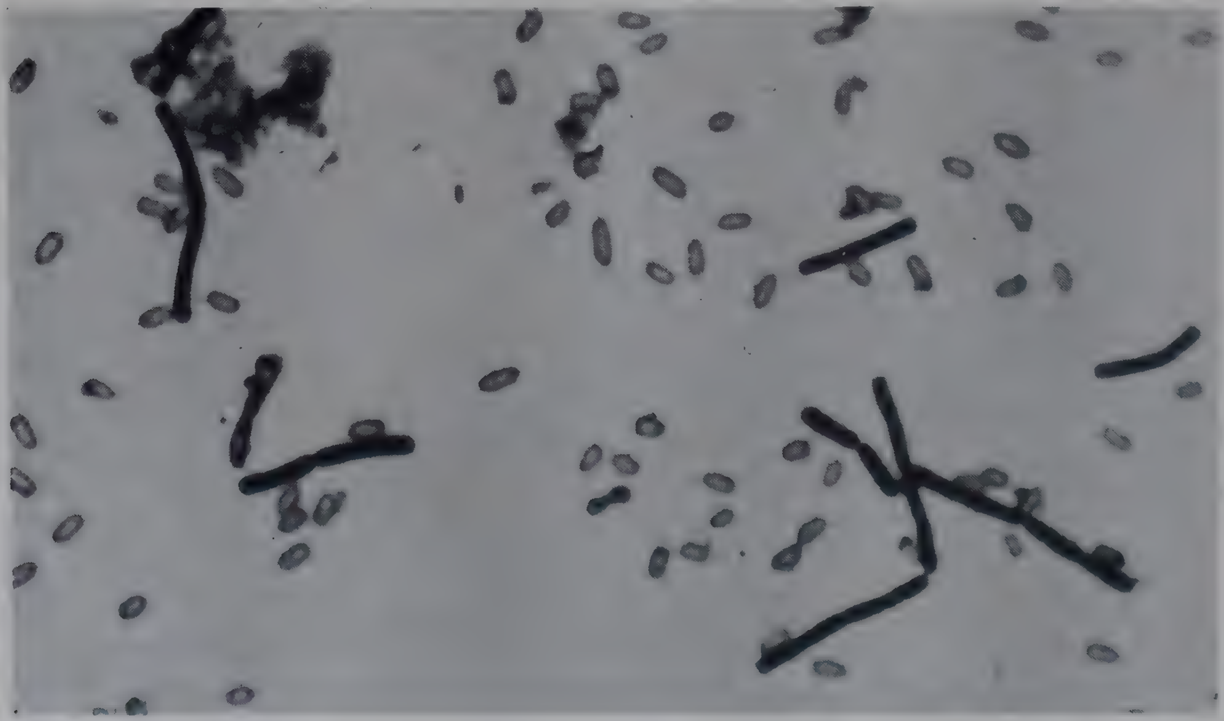

Fig. 370.—A 48-hour culture of a sporulating anaerobe. Note the relative abundance of extracellular spores. *Clostridium bifermentans.* (Photomicrograph from slide of T. F. Wetzler.)

Though it may be convenient to group all the members into a general category "*Clostridium butyricum* group," this is a haphazard approach. Many members of this group are well described: *Cl. pasteurianum, Cl. multifermentans, Cl. beijerinckii, Cl. acetobutylicum,* among others.

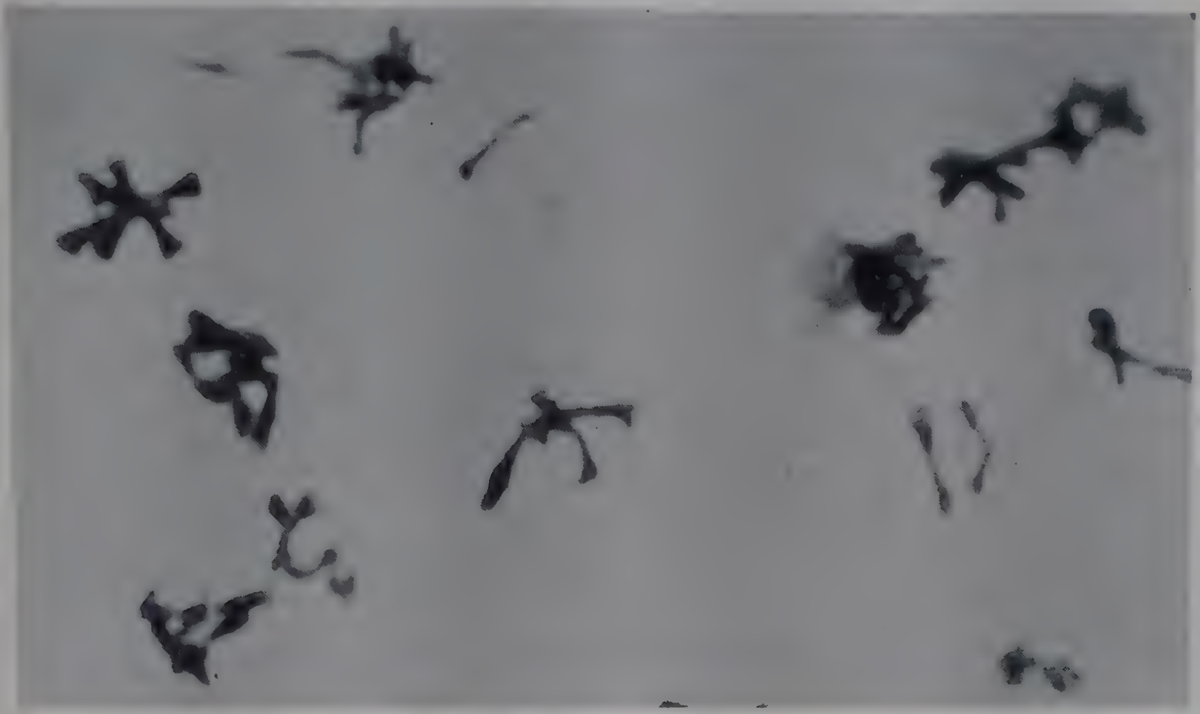

Fig. 371.—An example of pleomorphism and involution forms. A microaerophilic Clostridium. (Photomicrograph from slide of T. F. Wetzler.)

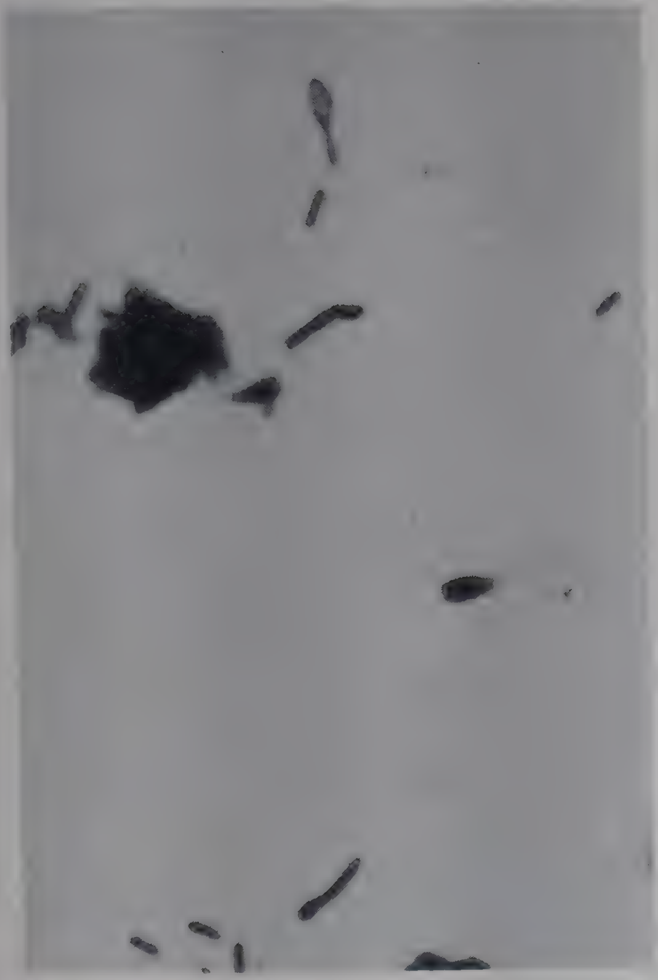

Fig. 372.

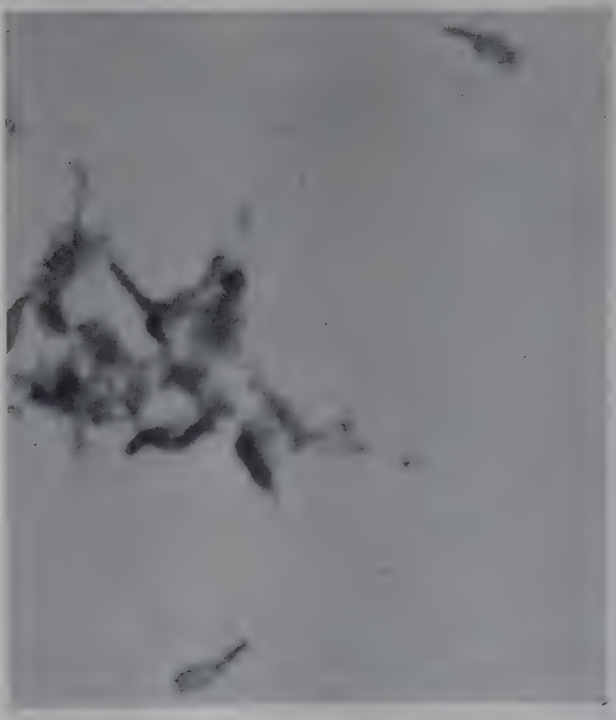

Fig. 373.

Fig. 372.—A typical microaerophilic Clostridium. Spores are not formed aerobically. (Photomicrograph from slide of T. F. Wetzler.)

Fig. 373.—Typical swollen, elongate, terminal spores of a microaerophilic Clostridium. (Photomicrograph from slide of T. F. Wetzler.)

With the exception of *Cl. multifermentans,* none of the species in this group are hemolytic.

For practical purposes, differentiation is based largely upon specific carbohydrate fermentation, the final acidity achieved being lower than pH 5.2.

There is no more difficult task for the bacteriologist than to differentiate Clostridia, particularly if they occur in mixed cultures. Much progress was made possible by the introduction of thioglycollate media by Brewer and the great contributions of McClung, Reed and Orr, and others in this field.

CLOSTRIDIA*

Introduction

Diagnostic identification of the clostridial flora always involves a three-step procedure: elimination of the concomitant aerobic flora, separation of the individual anaerobic species, and identification of the anaerobic species.

It is well to keep in mind that the members of this genus are notable for their proteolytic or saccharolytic activity or both. Reagents and media must be uniformly prepared—indiscriminate substitution frequently results in observations differing from those described.

There is no substitute for repetitious plating and exact following of procedure. There are virtually no easy tests in this field of bacteriology.

If a laboratory is not equipped to employ the various methods described for differential diagnosis, it is recommended that the clostridial isolates be forwarded to a laboratory which is prepared to use these methods.

Collection of Specimens

The source of the specimen will determine the method of collection and mode of shipment. Specimens will usually come under one or more of the following headings:

1. Material from animal sources, such as tissues from biopsy and autopsy, swabs, blood specimens, aspirated fluids, urine, feces, gastric contents, sputum, fragments of skin, fur, hair, or feathers.

Such materials are inoculated into screw-capped tubes containing chopped heart medium (M-12), or, if not available, into thioglycollate broth tubes (M-48), containing at least 20 c.c. of the medium in 50 c.c. tubes.

Specimens, particularly tissue blocks, may be shipped in the frozen state.

About 1 gm. of the following specimens is required:

2. Food specimens including raw, pasteurized, processed, or frozen materials.

Canned and pasteurized products should be submitted in original containers, regardless of the size of the container.

Frozen foods should be shipped in the frozen state.

Raw foods may be forwarded in sterile, dry containers, or, if possible, in thioglycollate broth tubes (M-48).

Samples from opened containers may be submitted for anaerobic investigation in deep thioglycollate broth tubes (M-48). One gram is a sufficiently large specimen.

Sterile, dry, screw-capped tubes are the containers of choice for:

3. Soil samples.

---

*This method has been described in the *Annual Reports*, Technical Section, of the 406 Medical General Laboratory of the U. S. Armed Forces in Tokyo, Japan. We are indebted to Captain John D. Marshall, Jr., MSC, from the 406 Medical General Laboratory, and to Mr. Theodore Wetzler, now at the Vestal Laboratories, St. Louis, Mo., for details, tabulations, and photomicrographs appearing in this section.

4. Clothing specimens. A fragment approximately 1 by 2 inches is desirable.

5. Material enclosed in tissue is usually considered analogous to a tissue specimen, and is handled as such. Such materials include cloth, shell fragments, soil, etc.

6. Drugs, solvents, diluents, antibiotics, chemical preparations, etc., should be submitted in their original containers, if practicable.

Procedure

A. Preliminary Processing.—

At least one medium must retain the entire bacterial flora until all the species have been isolated and identified. The loss of a bacterial population due to faulty technic, lack of anaerobiosis, overuse of selective inhibitors, etc., occurs frequently.

I. Specimens arriving in chopped heart medium or thioglycollate broth are immediately incubated and kept at 37° C. for 24 hours. Blood specimens are incubated for 5 or more days.

II. Specimens mailed without specific media are handled in the following manner:

1. Blood specimens are thoroughly mixed by inverting several times. A 5 c.c. quantity is aseptically withdrawn and inoculated into a chopped heart medium tube (M-12) and incubated at 37° C. for 7 to 10 days.

2. Food specimens are aseptically opened. A 1 gm. quantity is inoculated into a thioglycollate broth tube (M-48).

3. Drugs, solvents, diluents, antibiotics, chemical preparations, etc., are aseptically pipetted into chopped heart medium (M-12), using 2 to 4 c.c. Solids or dry specimens may be directly inoculated into chopped heart medium.

III.

1. After this initial incubation from all tubes, 1.0 to 1.5 c.c. are aseptically withdrawn with a pipette (after thorough shaking) and inoculated into thioglycollate broth tubes (M-48) containing 6 c.c. of broth.

2. The thioglycollate broth subcultures are incubated at 37° C. for 24 hours.

3. The original tubes are kept at room temperature serving as holding media.

B. Separation of the Aerobic and Anaerobic Flora.—

1. After the incubation of the thioglycollate subculture, a Gram stain is made. Any method is acceptable, using absolute alcohol or 95% alcohol alone for decolorization. A careful check for gram-positive bacilli, particularly for those with spores, is made. Note relative position of any spores and swelling.

2. Prepare an acrolein test (R-19).

Magenta indicates positive, pink to rose is doubtful, yellow or colorless is negative.

The production of acrolein (acrylic aldehyde) from glycerol is considered specific for the aerobic *Bacillus amaracrylus,* and for the anaerobic *Clostridium perfringens.* Doubtful readings may occur with strains of *Cl. tetani, Cl. botulinum,* and *Cl. sporogenes.*

3. Inoculate solid media from tube B (1) for aerobic and anaerobic growth: (See also "Wound Infection," page 1603.)

(a) Aerobic
    (1) Bood agar with yeast extract (M-14)
    (2) Eosin-methylene blue agar (M-71 or M-72)
    (3) Tellurite blood agar (M-41 or M-42)
(b) Anaerobic
    (1) Blood agar with yeast extract (M-14)
    (2) Blood agar with sodium azide and chloral hydrate (M-22)
    (3) Nagler plate (M-57)
(c) Incubate the aerobic plates at 37° C. for 24 hours.
(d) Incubate the anaerobic plates at 37° C. for at least 40 hours, but no longer than 60 hours.
(e) Anaerobiosis is best accomplished in the Brewer anaerobic jar under positive hydrogen pressure, which is supplied by using mossy zinc and 30% hydrochloric acid in a generator. Powdered chromium and sulphuric acid may be used, too. Illuminating gas can be substituted for hydrogen, as in the Gradwohl-Drucker jar.

(f) Indicators of anaerobiosis must be employed. A glucose-methylene blue tube is preferred for this purpose.

4. Growth on the aerobic plates is noted and recorded.

5. The anaerobic plates are examined after 40 to 60 hours' incubation and processed as follows:

(a) Check the anaerobic controls, dismantle the jar, and remove the plates.

(b) Observe colony formation.

No test adequately describes colostridial colony morphology on the plates. Competence is acquired only through practice and familiarity with the media employed. Before attempting to pick colonies, compare the yeast extract blood agar plate with the sodium azide-chloral hydrate plate. Most mesophilic bacteria grow as well as Clostridia on the anaerobic plates, but Staphylococci, Bacilli, and most Enterobacteriaceae do not grow on the sodium azide-chloral hydrate medium.

The Gram stain will easily demonstrate the inhibition effected.

All gram-positive spore-bearing bacilli which do not grow well on aerobic plates are suspected of being Clostridia.

In general, the following colonies are picked:

All hemolytic colonies
All transparent colonies
All flat, grayish, translucent colonies
All colonies with emanating dryish spreading growth.

6. The colonies are picked and transferred into thioglycollate broth (M-48), incubated overnight at 37° C., and the growth examined with the aid of slides, stained according to Gram.

7. All gram-positive bacilli, regardless of sporulation pattern, are streaked out on yeast extract blood agar plates (M-14), and incubated for 48 hours. Should minute colonies arise within this time, not to exceed 1 mm. in diameter, a Gram stain must be made on them. Gram-positive bacilli showing such colony formation are probably microaerophilic Clostridia. It has been reported that microaerophilic Clostridia do not sporulate on aerobic plates.

8. Any questionable findings encountered require that the thioglycollate broth culture be replated anaerobically and colonies picked anew.

9. All findings are to be duly entered on the work sheets.

10. One of the more difficult points to be emphasized in anaerobic work is the necessity for constant checking of an isolated strain for contamination. The isolation of but a single species of Clostridium from an incoming specimen is a rare occurrence. As a rule, when one species is isolated, it is the practice to repeat the isolation technic to find others. If Clostridia are recovered from a specimen, at least 5, and usually 10, pickings of each should be employed for taxonomic study. If no growth is observed, the initial tube should be subcultured again, in order to avoid false negative results.

Taxonomic Classification of Clostridia

A. Introduction.—

Clostridia may be roughly classified into three general patterns, none of which is mutually exclusive: pathogenic and nonpathogenic, toxogenic and nontoxogenic, proteolytic and saccharolytic.

The needs of clinical bacteriology are usually met by the rough division into pathogenic and nonpathogenic types. Pathogenicity varies with the type of laboratory animal used. For uniform results, the guinea pig is the animal of choice.

A table listing differential characteristics is included. Geographic distribution of clostridial species may result in occasional variations, perhaps in carbohydrate fermentation, liquefaction of gelatin, or in the rapidity of hydrogen sulphide production.

B. Differential Criteria.—

Differential criteria are shown in Tables 156 to 159, which follow mostly that of Reed and Orr.

1. All differential media used in this work are to be inoculated with 0.2 to 0.3 c.c. of an 18-hour-old thioglycollate broth culture. Such inoculation (except for plates) is done with pipettes. Stabbing of the semisolid and the solid tube media is performed with a flamed wire.

2. All differential media used for classification data are to be incubated at 37° C. for at least 40 hours. None should be incubated at that temperature for more than 60 hours unless otherwise specified.

3. Only carbohydrates listed in the tables are inoculated in a small laboratory. A sugar-free thioglycollate broth (M-54) must be used as a control.

4. A 0.5 c.c. amount of a 0.04% brom cresol purple solution is pipetted into each carbohydrate tube, in order to determine the result of the fermentation after incubation. No indicator should be employed directly with the basic carbohydrate broths because they are often irreversibly reduced. The indicator must be added, therefore, after incubation.

5. Nagler plates (M-57), or any modification thereof, should be avoided in small laboratories. The lecithovitelline reaction is of diagnostic value only in the hands of those well experienced with it.

6. The ability of Clostridia to produce hydrogen sulphide is checked in three media simultaneously employed: iron-lactose-trypticase agar (M-56), iron-gelatin (M-52), and iron-litmus milk (M-51). The first and third of these media are incubated aerobically, the second anaerobically. Darkening or blackening of media other than these three is not considered an index of hydrogen sulphide production.

7. The reduction of nitrates to nitrites is determined in 48-hour cultures in thioglycollate nitrate broth (M-50).

8. Tryptone broth (M-1) is inoculated and incubated anaerobically for 48 hours for indol production.

9. Iron-litmus milk tubes (M-51) and all liquid media with thioglycollate are incubated aerobically.

10. The tables of differential reactions (Tables 156 to 159) contain 48-hour readings. This should explain some of the disparity between these and some other tabulations listing reactions recorded at time intervals other than 48 hours.

11. In vivo demonstration of bacteriemia and toxemia:

A chopped heart tube (M-12) is inoculated with approximately 0.5 c.c. of an 18-hour thioglycollate broth culture. This medium is then incubated aerobically according to the following outline:

Organism	*Time*	*Temperature*
Cl. tetani	3 to 5 days	37° C.
Cl. botulinum	5 to 7 days	30° C.
Cl. fallax	24 to 36 hours	37° C.
Remainder	48 hours	37° C.

(a) Traumatize the thigh muscles of a guinea pig by using slight pressure with a pair of large forceps or a hemostat.

(b) Denude the area of approximately 1 sq. cm. of hair.

(c) Cleanse with tincture of iodine, followed by absolute alcohol or acetone.

(d) Using a 20 gauge needle and a 5 c.c. syringe, inject 0.5 to 0.8 c.c. of the culture fluid into the thigh muscles.

(e) For *Cl. botulinum*, an intraperitoneal injection may be made using 0.5 c.c. of culture fluid. Forced feeding of the animal can be tried directly with cell-free filtrate, but is most dangerous.

(f) Hold all animals at least 7 days before declaring the result negative.

For *Key*, see Table 156.

All data obtained from differential reactions should be systematically entered on the work sheet. Comparison is then made with the tables of reference.

Occasional deviations from the tables will be encountered; in such cases, refer to the outstanding characteristics of the species in question, since individual, single enzymatic reactions may be at variance.

Malleomyces Mallei
(Glanders Bacillus)

Morphology: Small, slender rods, 0.25 to 0.4 by 1.5 to 3.0 microns, occurring singly, but they may grow into long threads. Nonmotile.

Stain: Gram-negative, irregular staining, often bipolar.

Colonies: On Loeffler's blood serum, they are moist, opaque, slimy, with yellowish brown tinge. On glycerin veal agar, they are whitish, transparent. They acidify and coagulate milk. Cause glanders.

The medium of choice is glycerin potato veal agar formula M-38.

Slimy, tenacious colonies are characteristic. They develop in about one week. The principal characteristics of the organism are:

(a) No fermentation of carbohydrates, except occasional slight action on dextrose.
(b) Very unevenly staining, granular, gram-negative organisms. Use methylene blue stains.

SEROLOGY

Agglutination Method of Povitsky

(1) **Preparation of the Culture.**—Use a forty-eight-hour culture of *Malleomyces mallei* (the causative organism of glanders) on glycerin-potato-veal agar formula M-38.

Wash off the growth with a small amount of sterile physiologic saline. This gives a milky suspension.

Pour off the suspension.

Heat for one hour at 70° C.

This suspension may be kept in the ice box for two or more months.

To use, add enough sterile physiologic saline to make it only faintly cloudy.

This suspension should be tested against a known positive and a known negative serum before use.

(2) **Agglutination test** using patient's blood serum.—Dilute the serum to be tested 1 to 40 with sterile physiologic salt solution; that is, 1 part of serum to 39 parts of saline.

Place 3 c.c. test fluid (described above) in each of 5 test tubes.

Place in the first tube 0.1 c.c. of the 1:40 serum, making the dilution of serum in this tube 1:1,200.

Place in the second tube 0.075 c.c. serum diluted 1:40, making the dilution of serum in this tube 1:1,600.

Place in the third tube 0.06 c.c. serum diluted 1:40, making the dilution of serum in this tube 1:2,000.

Use positive serum in the fourth tube, and negative serum in the fifth tube.

Shake.

Place the tubes in a water-bath at 37-40° C. for two hours.

Very active reactions may be read at the end of one hour.

Place in the ice box overnight.

If a reaction occurs, the upper part of the liquid is clear, while a veil-like sediment is found. A negative reaction shows the sediment in a definite "button" at the bottom of the tube, the fluid above being cloudy.

Glanders occurs in man as an acute or chronic systemic infection and as a cutaneous disorder. Most of the cases reported in the past have been due to direct or indirect contact with infected horses. Accidental infections have been recorded among laboratory workers. Agglutinin titers higher than 1:320 are considered diagnostic. The complement fixation test is a less sensitive index, but is more specific. When positive in dilutions of 1:20 or higher, it is diagnostic of infection with *M. mallei.*

Mallein Test

Another diagnostic aid found quite useful is a modification of the mallein skin test, permitting its safe use in human beings. One-tenth (0.1) c.c. of commercial mallein in a dilution of 1:10,000 is injected intradermally into the skin of the forearm. The test is read at 24 and 48 hours. Specific positive tests reach maximum erythema, 10 to 20 mm. in diameter, after about 18 to 24 hours and fade only slightly if at all by the end of 48 hours.

ANIMAL INOCULATION

Straus Test

Inoculate several male guinea pigs with increasing amounts of the culture. A swollen, red, and tender scrotum on the second or third day is a sign of a positive reaction.

MELIOIDOSIS

The synonym of this disease is Stanton's disease which is caused by *Malleomyces pseudomallei.* It occurs in Burma, the Malay States, and Ceylon. It bears many resemblances to tularemia because both are diseases of rodents which accidentally attack man. It closely resembles glanders. It was reported by Stanton and Henessy in 1917, although earlier Whitmore, in 1912, found the bacterium in autopsies of babies in Rangoon. Krishnaswami found 200 cases in Rangoon. Other cases have been reported in Singapore.

The first case reported in the Western Hemisphere is that by McDowell and Varney,[1] showing ulcers and sinuses of the buttock and thigh of eight years' duration.

The *Bacillus whitmori (Malleomyces pseudomallei)* closely resembles *M. mallei.* The bacillus is small and occurs in very large numbers in all acute lesions of the disease. With Leishman's stain, bipolar staining is commonly seen. It resembles the glanders bacillus in colonies but is more actively motile.

Bacteria from rough colonies average 2 by 0.6 microns, from smooth colonies, 5 to 6 microns. They show parallelism and are usually arranged in an irregular network. Growth is strictly aerobic. The organisms grow rapidly and profusely on all commonly used media at 24° to 37° C. Colonies of the smooth form are entire, convex, and mucoid, and often grow to a diameter of 8 mm., are initially grayish white, but change to a deep brown. They are surrounded by a narrow inner zone of complete hemolysis and a larger zone of diffuse hemolysis on blood agar plates (M-28 and M-29).

Differential Diagnosis

Miller and associates[2] recommend the following procedure for the isolation of *Malleomyces mallei* and *pseudomallei:*

(a) Cultivation on eosin-methylene blue agar (M-71 or M-72) with 4% glycerol.

(b) If more heavily contaminated, collect specimen, before plating, in saline with 1,000 units of penicillin per c.c., and incubate for 3 hours at 37° C.

[2] J. Bact. 55: 115, 1948.

(c) Agglutination which, however, does not differentiate the two species.
(d) Animal inoculation, especially of hamsters.
(e) If feasible, oxidase reaction (R-18).

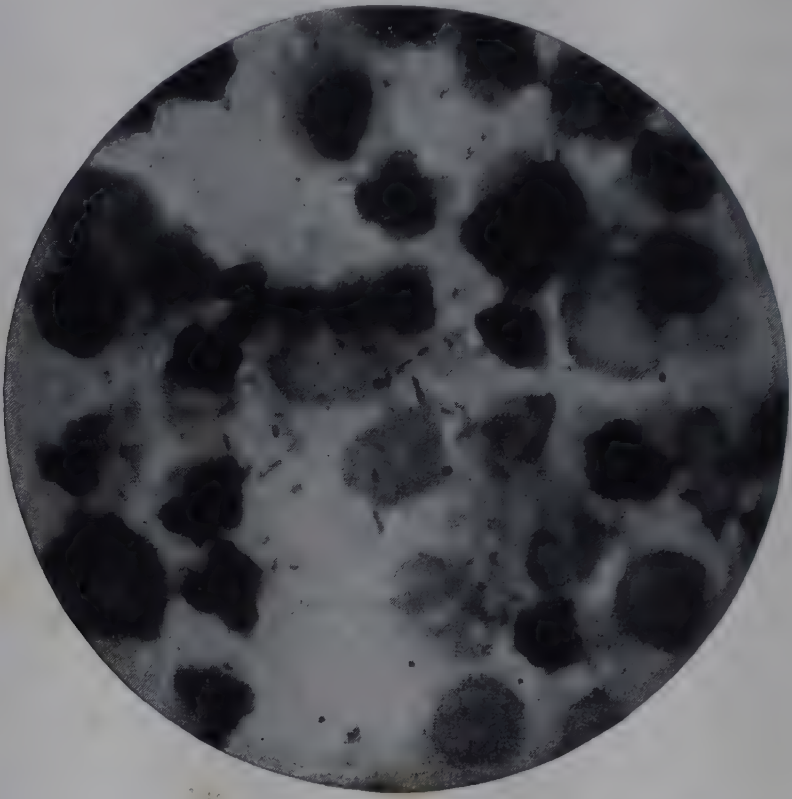

Fig. 374.—Photomicrograph showing direct smear from cerebrospinal fluid of case of influenza meningitis.

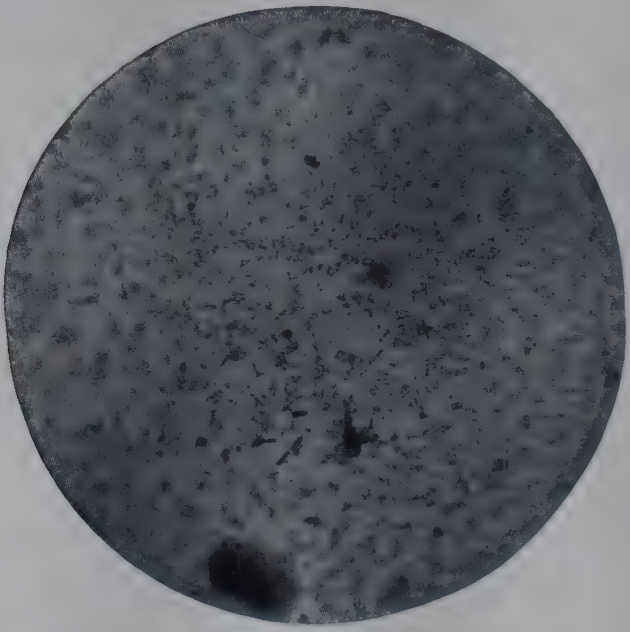

Fig. 375.—Photomicrograph of pure culture of influenza bacilli. (From Levinson: Cerebrospinal Fluid in Health and in Disease, ed. 3, St. Louis, 1929. The C. V. Mosby Co.)

HEMOPHILUS

The hemophilus group is a rather heterogeneous mixture of gram-negative microorganisms. In human diseases, *H. influenzae* and *H. pertussis* are important, while *H. haemoglobinophilus* and *H. hemolyticus* may cause diagnostic difficulties.

H. influenzae requires chocolate agar M-31, but grows well also on blood agar with human or rabbit blood M-28, M-29. It is differentiated from *H. hemolyticus* in that the latter grows on media containing yeast but no hemoglobin.

H. pertussis requires glycerin potato blood agar M-39, for its growth. It forms hemolytic, pearly, small colonies in 48 hours. It is easily differentiated from *H. para-pertussis* and *Br. bronchiseptica* by its inability to grow on agar without blood.

Hemophilus Influenzae

Morphology: Rods, very small 0.2 to 0.3 by 0.5 to 2.0 microns, occurring singly and in pairs, occasionally in short chains, and at times in long thread formation. Frequently show a marked tendency to bipolar staining. Nonmotile.

Stain: Gram-negative.

Colonies: On blood agar, they are small, circular, transparent, homogeneous, entire. Cause meningitis, pleurisy, and other inflammations.

Hemophilus Pertussis

(Bacillus of Bordet and Gengou)

Morphology: Short, oval rods, 0.2 to 0.3 by 0.5 to 2.0 microns, occurring singly, sometimes in pairs, frequently showing tendency to bipolar staining. Nonmotile.

Stain: Gram-negative.

Colonies: On blood agar, they are small, transparent, entire. Causes whooping cough.

Agglutinating antisera can be prepared against *H. pertussis* by injecting rabbits twice a week with 0.5 c.c., 0.7 c.c., 1.0 c.c., 1.0 c.c., 2.0 c.c., and 2.0 c.c. quantities (in that order) of a suspension of the density of tube 4 of the nephelometer (page 1477). The suspension is prepared by washing 48-hour-old cultures on glycerin potato blood agar formula M-39 with 1:10,000 Merthiolate in saline.

Mix 0.1 c.c. doses of serum dilutions with 0.1 c.c. amounts of the antigen, shake for 3 minutes, then add 0.5 c.c. saline to each tube and read the results. Look for agglutination or lack of agglutination. Only 3 plus agglutination is considered positive.

Agglutination and complement fixation tests are carried out with the serum of the patient. They are not widely used.

OPSONOCYTOPHAGIC INDEX

Kendrick and associates[1] described this test, using 20 billion *H. pertussis* preserved in 1:10,000 Merthiolate containing saline.

The performance and reading of the test are the same as in the Huddleson opsonocytophagic test for the diagnosis of brucellosis, pages 1546 and 1573.

Hemophilus Conjunctivitidis

(Koch-Weeks Bacillus)

Morphology: Rods, small, 0.2 to 0.3 by 0.5 to 2.0 microns, with rounded ends, occurring singly. Nonmotile.

Stain: Gram-negative.

Colonies: On blood agar, they are small, transparent, entire. Cause infectious, contagious conjunctivitis.

According to *Bergey's Manual of Determinative Bacteriology* (1948), this is the same organism as *H. influenzae.*

Hemophilus Duplex

(Diplobacillus of Morax and Axenfeld, Moraxella Lacunata)

Morphology: Short rods, 0.4 to 0.5 by 2.0 microns, occurring singly and in pairs and short chains. Ends rounded or square in the chains. Nonmotile.

Stain: Gram-negative.

Colonies: On blood agar, they are small, circular, transparent, entire. Cause catarrhal conjunctivitis.

Hemophilus Ducreyi

(Bacillus of Soft Chancre)

Morphology: Small rods, 0.4 by 1.5 microns, with rounded ends, occurring singly and in short chains. Nonmotile.

---

[1] J. Infect. Dis. 60: 302, 1937.

Stain: Gram-negative.

Colonies: On blood agar, they are small, grayish, glistening, showing a slight zone of hemolysis around the colony in three or four days. Best growth on clotted rabbit, sheep, for human blood, heated to 55° C. for fifteen minutes. Cause "soft chancre."

TABLE 160.—DIFFERENTIAL DIAGNOSIS OF HEMOPHILUS*

	BLOOD AGAR PLATE (X)	SATELLITE PHENOMENON (V)	INFUSION AGAR

*Strains cultivated in the laboratory for at least 3 subcultures.

Summary of Methods of Laboratory Diagnosis of Chancroid

The methods commonly used in the laboratory diagnosis of chancroid are biopsy, cultures, and skin tests. Small lesions do not permit biopsy. Culture results are useful in the majority of cases. Smear methods are also useful. Skin tests are dubious. Autoinoculation has been suggested but it is, in our opinion, too dangerous to be used. Emphasis, too, in this diagnosis must be placed upon the results of staining of smears by Pappenheim and Sellers' method. The Ducrey bacilli show a tendency to bipolar staining which gives some of them the "closed safety-pin" appearance. Greenblatt and others have stressed the "school of fish" arrangement in which the bacilli are grouped in long parallel columns between cells or shreds of mucus.

The Skin Test as a Method of Diagnosis of Chancroid

The Ito-Reenstierna[2] Reaction

It has been shown that individuals having chancroid infection are sensitive to the intradermal injection of killed cultures of *H. ducreyi.* This phenomenon is known as the Ito-Reenstierna reaction. Sterilized, diluted bubo pus from chancroid patients has been used by Cole and Levin,[3] and others, but in comparative studies by Greenblatt and Sanderson,[4] it has been shown that this material is much less reliable than an antigen made from a killed suspension of *H. ducreyi.* Dulaney[5] has substantiated the findings as to the value of the test with a bacillary antigen in diagnosis.

The skin reaction does not become positive until 10 days to 2 weeks following the appearance of the initial lesion, and remains positive for many years and perhaps for life. These facts must be given consideration in the interpretation of the findings. In the differentiation of chancroid from other venereal ulcers and buboes, it is well to remember that the appropriate procedures to rule out granuloma inguinale, lymphogranuloma venereum, fusospirochetosis, gonorrhea, and carcinoma should be performed.

Preparation of Antigen for Skin Tests.—Some strains of *H ducreyi* will grow on the surface of infusion blood agar slants (0.1% glucose, and 3 to 5% whole blood) in CO_2 atmosphere as advocated by Hunt.[6] When the transplant has been made, the side of the tube is gently heated in a Bunsen flame, and the tube immediately stoppered with a rubber stopper. After 48 hours' incubation at 37° C. the growth is removed from the slant with saline and centrifugated. The supernatant fluid is removed, and the sediment resuspended in saline and killed by heating at 60° C. for 40 minutes. Phenol 0.3% or Merthiolate 1:10,000 can be added as a preservative. The antigen should be vigorously shaken to break up the clumps.

Method of Sanderson and Greenblatt.—All the strains of *H. ducreyi* isolated by these authors grew poorly or not at all on the surface. To obtain a satisfactory antigen, the following method was employed: To each slant of beef infusion agar M-15 is added *onto the surface* 1 c.c. of human defibrinated blood, inoculum of culture is made into the blood, following which the tube is gently heated on the side and then stoppered with a rubber stopper to reduce the oxygen tension. After 3 days' incubation at 37° C., the blood is removed and laked in 25 c.c. of sterile distilled water and centrifugated. The sediment is rewashed until free of hemoglobin—usually twice is sufficient. The sediment from each culture tube is then added to 10 c.c. of physiologic saline, killed at 60° C. for 40 minutes and preserved with 0.3% phenol or Merthiolate 1:10,000.

A *positive* reaction to an intradermal injection of 0.1 c.c. of antigen is manifested by an area of induration surrounded by an erythematous halo at the site of injection. The induration should measure 7 mm. in diameter in positive cases. Greenblatt and Sanderson* have noticed that occasionally the induration may be minimal, but that in such cases the erythema must measure at least 14 mm. before the reaction may be considered as positive. Any smaller reaction is a doubtful test and in such cases the injection should be repeated after a few days. Strong reactions sometimes have a central pustular area. Generalized reactions have not been observed. Frank negatives show nothing but traumatic effect of the injection.

PASTEURELLA

Pasteurella Avicida

(Bacillus Cholerae Gallinarum)

Morphology: Small rods, 0.25 to 0.4 by 0.5 micron, with rounded ends, occurring singly. Nonmotile.

Stain: Gram-negative.

Colonies: Transparent bluish, becoming semiopaque. The slant is thin, white, glistening. They cause fowl cholera.

Pasteurella Suilla

(Pasteurella Suiseptica)

Morphology: Rods, 0.4 to 0.5 by 1.0 to 1.5 microns, occurring singly. They are nonmotile.

Stain: Gram-negative.

Colonies: Scant growth on agar, growth becoming slimy. They cause swine plague.

---

*Greenblatt and Sanderson: J. M. A. Georgia 27: 218-219, 1938; ibid. 27: 320, 1938.

[6] Proc. Soc. Exper. Biol. & Med. 33: 293, 1935.

Pasteurella Bollingeri (Boviseptica)

Morphology: Rods, 0.5 by 0.6 to 1.0 micron, occurring singly. They are nonmotile.

Stain: Gram-negative.

Colonies: Grayish white, slightly raised, undulate. They cause hemorrhagic septicemia in domestic cattle, hogs, and horses.

Pasteurella Pestis
(Bacillus Pestis)

Morphology: Rods, 0.5 to 0.7 by 1.5 to 2.0 microns, occurring singly. Nonmotile.

Stain: Gram-negative.

Colonies: Grayish white, translucent, iridescent, undulant. Growth on agar is grayish, viscid, thin, moist, translucent.

They cause plague in man, rats, and ground squirrels. Transmitted from rat to rat and from rat to man by the infected rat flea.

Devignat[1] classifies plague bacilli as:

	GLYCERIN	NO_2 PRODUCTION
Oriental tyye	0	+
Antic type	+	+
Medieval type	+	0

Human material suspected of containing Pasteurella must be handled with extreme care. In fact, many State laws forbid the handling of such material in other than Public Health laboratories. The following procedure is recommended[2]:

> "To the Officers of the Public Health Service and State and Local Health Officers:
>
> "Owing to the appearance of plague in several American ports it is important that all cases of suspected plague, both in man and animals, be subjected to a bacteriologic examination.
>
> "1. The following material from persons or rodents suffering from plague may be sent to laboratories:
>
> **Human Cases (Living)**
>
> "(a) Pus or gland fluid from buboes aspirated by syringe or collected after incision, on agar slants.
> "(b) Portions of tissues affected, removed at operation, in sterilized bottles, securely stoppered.
> "(c) Blood specimens, in sterilized sealed glass ampules or test tubes.
> "(d) Cultures of suspected organisms, on agar slants.
>
> **Human Cases (Necropsy)**
>
> "(a) Portions of the affected tissues—preferably bubo, lung, and spleen—in sterilized glass bottles, securely stoppered.
>
> **Rodents**
>
> "(a) The whole rodent carcass, in fruit preserving jar.
>
> "2. Do not place tissues or rodents in a preservative. The bacteriologic diagnosis of plague rests upon the production of the disease in laboratory animals, and the isolation and growth of the causative organism, *Bacillus pestis*. Any preservative that kills this organism will defeat the purpose of the exami-

[2] Pub. Health Rep. 35: No. 37.

nation. If decomposition of the specimen is feared, it may be placed in a tight container and this in turn surrounded by ice in a larger container, preferably of wood. Every specimen should be plainly marked, preferably by ordinary pencil, showing the date and the exact location from which it was taken.

"3. The shipper must make certain that the specimen is packed in such manner as to prevent possible danger to those handling the same, provided the package is properly handled.

"In this connection it is necessary that specimens be wrapped in sufficient cotton, or other absorbent material, to prevent leakage of fluid from the container should the glass be broken.

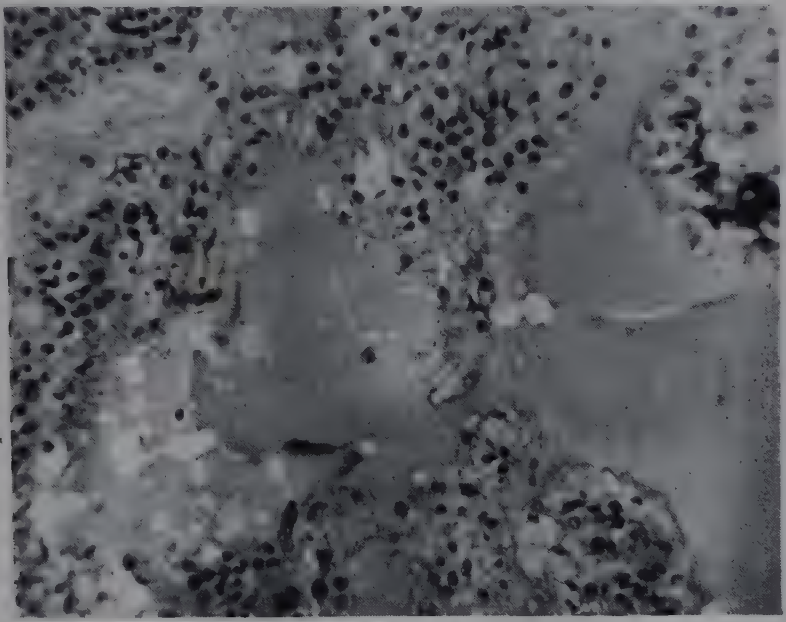

Fig. 376.—Plague bacilli in lung lesion (×300). (Courtesy Dr. Oscar Felsenfeld.)

"The following Instructions should be **explicitly observed.**

"1. **Ship by express**—Federal laws prohibit the shipping of plague-infected material, or cultures, by mail.

"2. Do not make packages too small, as small packages are more likely to be lost in transit, or overlooked.

"3. Each package should be marked as follows:

Notice
This package contains perishable specimens
for bacteriological examination
Please Expedite."

Laboratories carrying out tests for *Past. pestis* base their examination on the following properties of the plague bacillus:

(a) Bipolar, short, ovoid, gram-negative bacilli.

(b) Growth on agar (M-15) with 3 to 3.5% sodium chloride.

(c) Acid in dextrose, mannitol, salicin; no action on lactose, sucrose, dulcitol, or sorbitol.

(d) Indol negative.

(e) Does not reduce methylene blue.

(f) No motility at 22° C. in 18 hours.

(g) Animal inoculation tests.

The above reactions are carried out in media with fermentable substances M-5, tryptone water M-1, or cystine trypticase medium M-6.

SEROLOGY

There are capsular and somatic antigens.

Precipitin tests with animal tissue, similar to Ascoli's test for the diagnosis of anthrax (page 1547), are used.

The agglutination test is difficult to do because of the self-agglutinating qualities of most strains.

Specific phages are used to differentiate types of plague bacilli.

Plague phage, dried on paper strips, may also serve to identify plague bacilli (Cavanaugh and Guan*) when put on plates inoculated with the suspected strain.

Pasteurella Tularensis

Morphology: Small rods 0.2 by 0.3 to 0.7 micron, occurring singly. They are nonmotile.

Stain: Gram-negative.

Colonies: They grow on media containing egg yolk, blood, blood serum and dextrose. Sterile rabbit spleen, fresh, aids the growth.

They are agglutinated by immune tularemia serum. Cause tularemia or "rabbit" fever.

Past. tularensis does not grow on ordinary media. Cystine agar M-30 and, to a certain extent, egg media may be used for its cultivation.

Tularemia is an acute, often fatal disease of rodents caused by *Pasteurella tularensis.* It is highly infectious and is transmitted to man from rodents by the bite of a flea or tick, or by contamination of the skin or conjunctiva with tissues or body fluids of infected rodents, flies or ticks. The site of infection in man is usually marked by a necrotic, punched-out ulcer, which is associated with a regional lymphadenitis that tends to chronicity. The disease begins with a sudden chill, followed by an irregular fever, lasting two or three weeks. Convalescence is prolonged.

McCoy and Chapin in 1912 found the causative organism in squirrels, and named it *Bacterium tularense,* cultured it, transmitted the infection to various rodents by feeding, nasal inoculation, and injection of blood, and reported positive complement fixation and agglutination for human sera. Francis identified, in 1919, the deer-fly fever of Utah with the plaguelike disease of rodents of California, and in 1921, gave the name of "tularaemia" to the disease on account of the bacteriemia. He isolated *Past. tularensis* from fly-bitten human cases, wild jack rabbits, and one ground squirrel, and demonstrated agglutinins in human cases, and transmitted infections in laboratory animals with the deer fly, *C. discalis.* Since that time many cases have been described in the United States.

The occurrence of this disease in man depends on the presence of the disease in wild rodents, especially rabbits, and is often known to be associated with the discovery of sick and dead rabbits in the vicinity. Scratches, abrasions, thorn punctures, etc., have been reported at the site of infection. Infection is acquired from infected tissues or body fluids, and may occur in connection with dressing or handling rabbits, woodchucks, or laboratory animals or with the handling of ticks or flies. Infection from man to man has not been reported either by contact, operative procedures, or insects. The disease is found especially in rural districts, among those exposed to ticks and flies and especially those handling wild rabbits, such as hunters, marketmen, housewives, and cooks. Laboratory infections are frequent.

*Am J. Clin. Path. 23: 619, 1953.

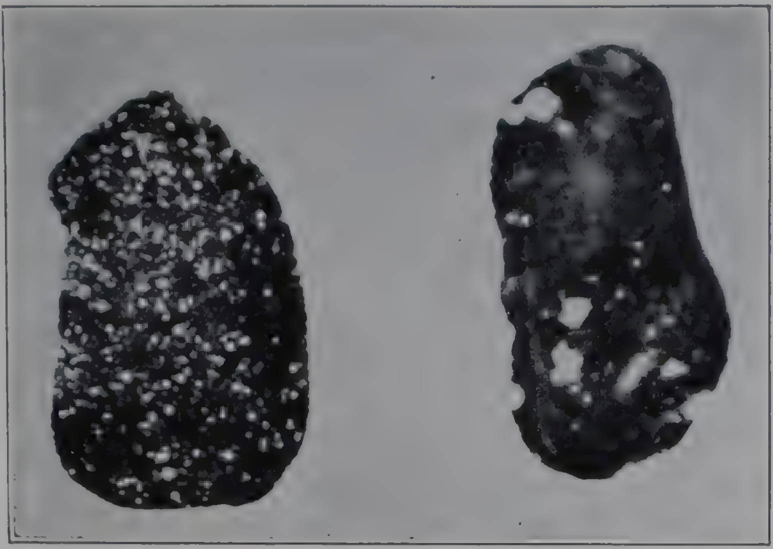

Fig. 377.—Guinea pig spleens, showing acute (left) and subacute (right) lesions of tularemia. (Francis.) (Army Medical Museum No. 40325.) (From Simpson, W. M.: Tularemia, Paul B. Hoeber, 1929.)

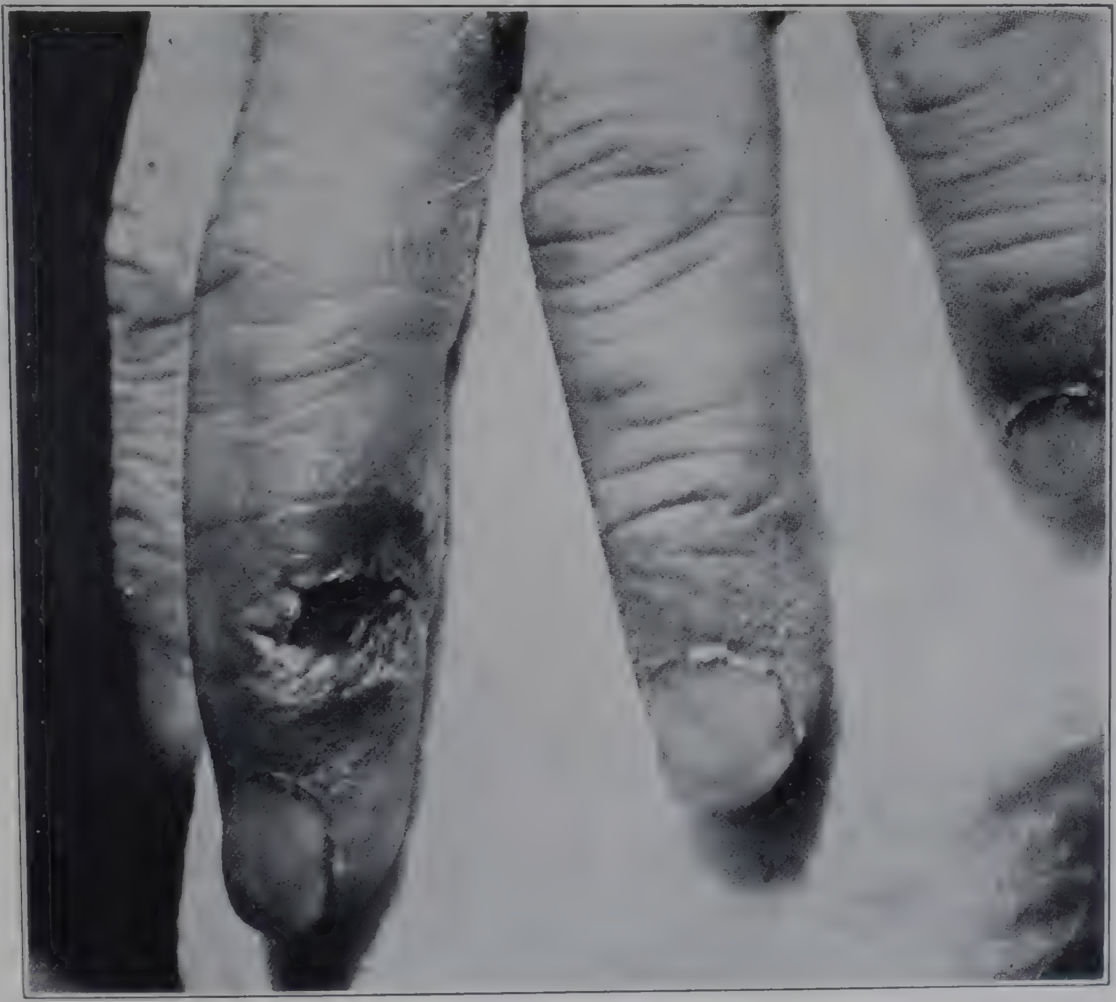

Fig. 378.—Ulcer of finger nineteen days after onset in a market man who dressed rabbits. (Brown and Hunter.) (Stitt: Diagnosis and Treatment of Tropical Diseases, P. Blakiston's Son and Co.)

Immunity is lasting in man and may be connected with the long persistence of agglutinins. There is no record of a second attack. Francis described five types of this disease: *ulceroglandular tularemia, oculoglandular tularemia, glandular tularemia, typhoidal tularemia,* and *ingestion tularemia.*

Diagnosis.—In connection with the agglutination test, which will be described below, it must be remembered that cross-agglutination between the sera of tularemia and undulant fever and their causative organisms is important. There is a marked difference in titer for *Past. tularensis* and the *melitensis-abortus* group. Blood of tularemia patients has the higher titer. Practically equivalent titers necessitate agglutinin-absorption tests.

The rabbit is the animal of choice for the development of an antiserum. Antigen is a 72-hour culture washed off with physiologic saline containing 0.2 per cent commercial Formalin, then centrifuged and the sediment suspended in physiologic saline containing 0.2 per cent commercial Formalin.

The *Pasteurella tularensis* cannot be successfully demonstrated in stained smears or sections of pathologic tissue of man, so that this method of identification is not practicable. The usual method of isolation of the organism is by animal inoculation, as described below.

In connection with the diagnosis, attention is called to the Schilling dif-ferential blood counts of three cases reported by the author.[1] (See pages 798, 799.)

Intradermal Test

A successful intradermal reaction was reported by Foshay.[2] This reaction has the appearance of a positive tuberculin reaction. It shows up in about 48 hours. Foshay test solution is made from virulent strains of *Past. tularensis.* This suspension is oxidized for about five hours with nitrous acid and then adjusted to a turbidity equivalent to 100 p.p.m. of fuller's earth. The standard test dosage of this suspension is 0.05 c.c. The proper time to read the response is at the forty-eighth hour after administration. Hypersensitivity of the skin is a notable feature of tularemia; therefore, caution must be used in selecting an antigen which affects the toxicity of heat-killed organisms for skin testing.

Bacteriologic Diagnosis by Animal Inoculation

This is accomplished by injecting a guinea pig intraperitoneally with blood obtained by venous puncture. This blood is defibrinated and mixed with an equal volume of physiologic saline solution. Inject about 5 c.c. of this defibrinated diluted blood. If *Pasteurella tularensis* is present, the guinea pig dies between the fourth and sixth day and the autopsy will show lymph nodes in the groin, enlarged, soft, and caseous. Spleen and liver are studded with multiple areas of white necrosis. Splenic and hepatic lesions sometimes so minute as to require hand lens for identification will be present. If no lesions are detected in animals which die in the usual time, transfers should be made to fresh animals.

In the case of other material, such as pus from the site of the fly bite or tick bite, or from the patient's suppurating glands, or tissue from a wild rabbit's spotted spleen or liver, this should be injected subcutaneously on the abdomen of guinea pigs or rabbits. These animals will die within a week if *Pasteurella tularensis* is present. They will show the same lesions as noted in the case of injection of blood into guinea pigs.

It is noteworthy that material from the dead animal's lymph nodes, spleen, or liver, rubbed upon the shaved abraded skin of another guinea pig or rabbit, will cause death within a week with the same typical lesions in the lymph nodes, spleen, and liver, and thus the infection may be propagated for an indefinite number of passages through guinea pigs or rabbits.

[2] Foshay, Lee: J. Infect. Dis. 51: 286: 1932.

Agglutination Test

Agglutination tests are highly successful in the diagnosis of tularemia. These tests will be worthless in the first week, but constantly positive in the second week. The test remains positive for seven weeks, the titer gradually increasing from the fourth week to the seventh, with a maximum of 1:1280 or 1:2560. It begins to fall in titer in the eighth week; but agglutinins persist for many months after recovery has occurred. Francis states that the agglutinins fail to disappear entirely in any case, even for ten to thirty years after recovery. At the end of the first year, the average titer is about 1:160. The final titer-level to which all cases seem to fall, even after ten, fifteen, or twenty years is 1:160, 1:80, or 1:40. Cross agglutination of *Brucella abortus* and *Brucella melitensis* may be found in many human tularemia sera. Also note that human brucellosis sera may show cross agglutination of *Pasteurella tularensis.* Therefore, if tularemia is suspected, agglutination should be made not only for *Pasturella tularensis* but also for *abortus* and *melitensis.* The titer with *Pasteurella tularensis* will be higher than with *abortus* and *melitensis* antigen in a case of tularemia.

One attack of tularemia confers permanent immunity, the agglutinins remaining in the blood serum. The titer acquired by the original attack does not become elevated by exposure to the disease.

If the blood serum of the case is diluted according to the figures given above for the length of time of infection, an agglutination test may be performed in the usual manner. (See pages 1528 ff.)

The antigen, or killed culture of *Pasteurella tularensis,* is made as described above. The patient's serum is diluted with physiologic saline. The test is performed by adding 0.5 c.c. of the patient's diluted serum to 0.5 c.c. of the antigen. Mix thoroughly and place in the incubator for eight to twelve hours. A positive reaction is indicated by the formation of a sediment consisting of agglutinated bacteria. The supernatant liquid is clear. A control of a mixture of saline and the antigen, and one containing diluted serum only, should also be made. It should show no sediment. Negative results are cloudy with no sediment.

Opsonocytophagic Test for Tularemia and Brucellosis
(Method of George A. Hunt)

Hunt[1] uses the following procedure in the diagnosis of tularemia. This procedure is similar to the opsonocytophagic test described by Gould and Huddleson[2] and Evans.[3] (See page 1545.)

Five c.c. of blood are added to 0.2 c.c. of 20% sodium citrate in a sterile tube. A mixture of equal parts (usually 0.1 c.c.) of this citrated blood and a saline suspension of *Br. abortus* or *Past. tularensis* organisms (living 48-hour culture or Formalin killed and washed free from Formalin just before use) equivalent in turbidity to 500 parts per million of kaolin in water, is incubated 30 minutes at 37° C. and the sedimented cells spread on a slide and stained according to Huddleson's or Evans' technic or any good blood stain. (See page 1545 for a second method.)

Hunt states that on several occasions he has been unable to obtain fresh citrated blood specimens before the polymorphonuclear leukocytes had disintegrated. In these instances it is possible to obtain results comparable to the opsonocytophagic test if one employs one volume (0.1 c.c.) of fresh citrated blood from a normal individual (5 c.c. blood added to 0.2 c.c. 20% citrate), one volume of plasma or serum from the patient, and one volume of the saline suspension of *Br. abortus* or *Past. tularensis* equivalent to 500 p.p.m. kaolin in turbidity. Controls are made using equal volumes of the normal citrated blood and the bacterial suspension to be certain that no phagocytosis takes place in the normal blood.

---

[1] Hunt, George A., formerly Bacteriologist of the Laboratory Department of the St. Louis City Hospital: Personal communication.

[2] J. A. M. A. **109**: 1971, 1937.

[3] Pub. Health Rep. **52**: 1419, 1937.

Parallel tests were made as follows: (1) fresh citrated blood from the patient plus bacterial suspension, (2) plasma of patient plus normal citrated blood plus bacterial suspension, and (3) serum of patient plus normal citrated blood plus bacterial suspension. Results of tests made on sera and plasma of 25 patients all gave results comparable to the tests made using the technic described by Huddleson.

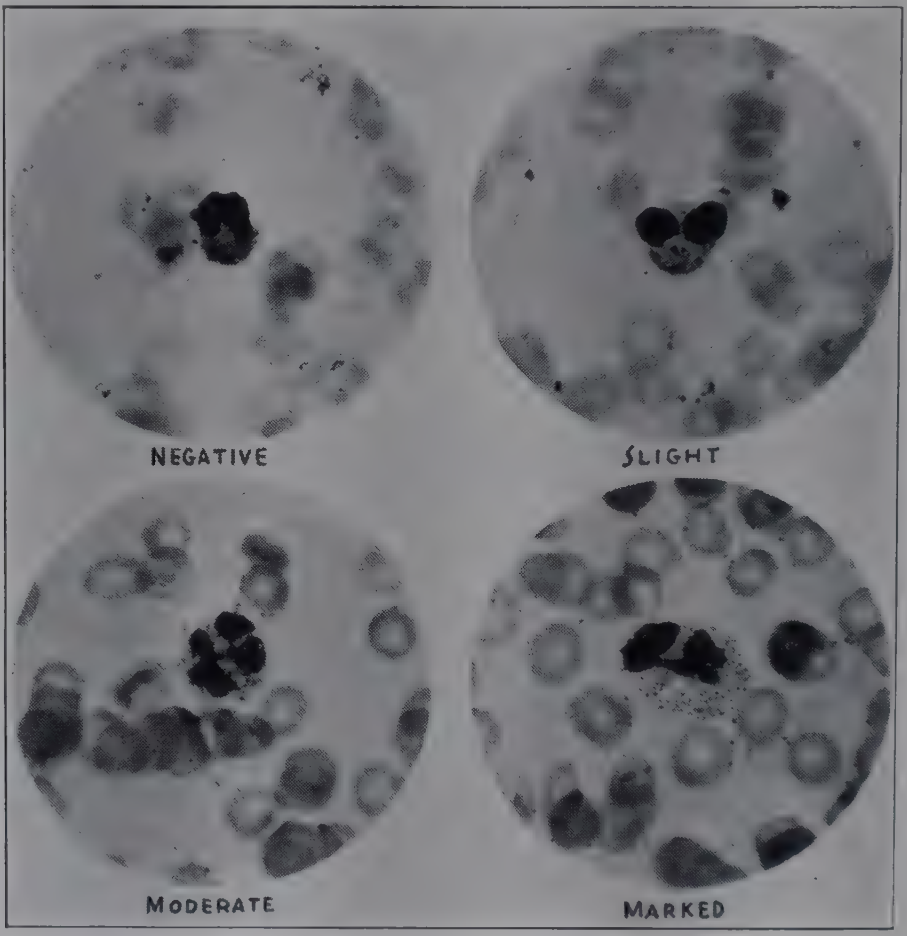

Fig. 379.—Positive and negative opsonocytophagic tests for tularemia and brucellosis.

Hunt has used this modified procedure only when it was impossible to obtain fresh citrated blood from a patient. It is difficult, however, for some laboratories to obtain fresh samples when most of their specimens are received by mail. The modified procedure may prove of value to central state laboratories.

For normal blood he has employed volunteers of the O-Group (Group IV Moss). He has not encountered hemagglutination and hemolysis and does not know whether this would interfere with the test. A few tests using fresh citrated rabbit blood in place of fresh citrated human blood gave satisfactory results.

Attention is called to the test because of the fact that many seem to have forgotten the work of Wright and the principle of opsonization and consequently hesitate to utilize it.

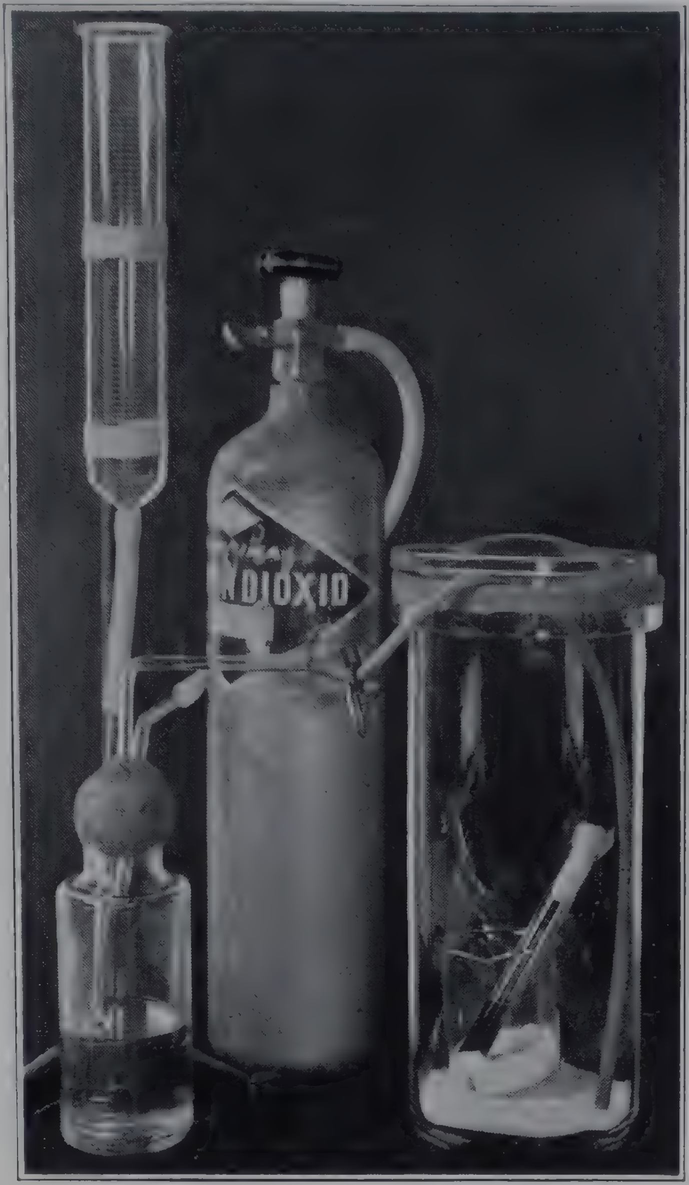

Fig. 380.—Apparatus used to produce a 10 per cent carbon dioxide atmosphere for culture of Brucella. (From Gould and Huddleson: J. A. M. A., Dec. 11, 1937.)

Pseudomonas Aeruginosa

(Bacillus Pyocyaneus)

Morphology: Rods, 0.5 by 2.0 microns, occurring singly, in pairs, short chains, and occasionally in thread formation. Motile by means of one to three polar flagella.

Stain: Gram-negative.

Colonies: Large, spreading, grayish with dark center and translucent edge, irregular. The medium becomes a greenish color, later turning brown. The blue color can be shaken out with chloroform. Dextrose is the only common sugar fermented, with acid production only. They may cause green pus formation.

The medium of choice for *Ps. aeruginosa* is the blood agar plate. Transfer colonies to agar slants M-13 for observation of pigment production.

Serratia Marcescens

(Bacillus Prodigiosus)

Morphology: Rods, 0.5 by 0.5 to 1.0 micron, occurring singly and occasionally in chains of 5 or 6 elements. Motile, with two to four peritrichous flagella.

Stain: Gram-negative.

Colonies: Circular, thin, granular, gray becoming red, first in the center, and later spreading to the periphery. The entire growth takes on a fuchsin-red color with a metallic luster. Nonpathogenic. They form a small amount of CO_2 gas in dextrose.

VIBRIO

Vibrio Comma

(Vibrio Cholerae)

Morphology: Slightly curved rods, 0.4 by 2.0 microns, occurring singly and in spiral chains. Motile, possessing one to two polar flagella.

Stain: Gram-negative.

Colonies: Circular, whitish, brown, moist, glistening, translucent, slightly raised, entire. Turn litmus milk alkaline at the top and slightly acid at the bottom; do not coagulate the milk, but peptonize it. They form acid in dextrose. They are found in the intestinal contents of cholera patients and carriers.

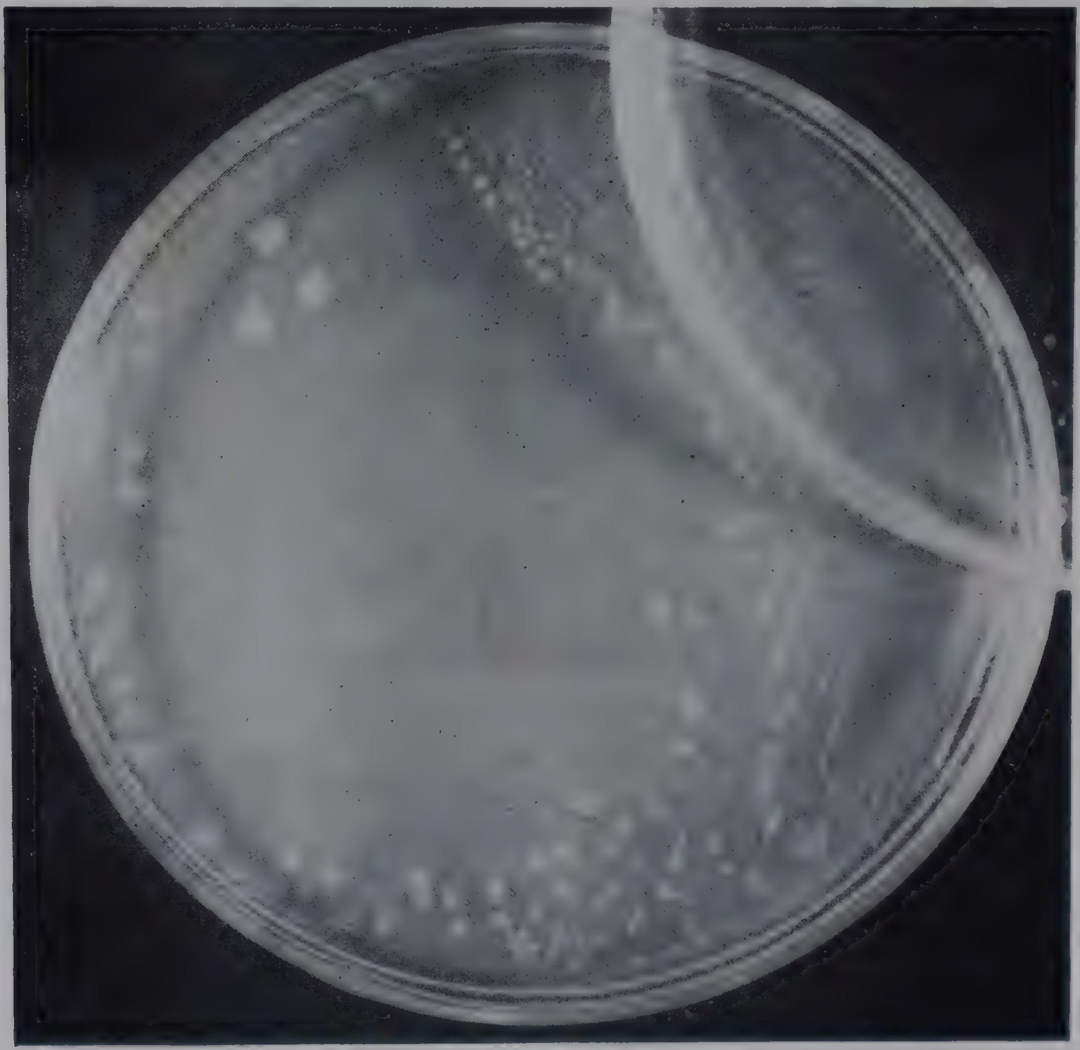

Fig. 381.—*Vibrio comma* colonies on D.E.C. plate of Panja and Ghosh. (Courtesy Dr. Oscar Felsenfeld.)

Cholera vibrios grow well on alkaline media. The true *V. comma* has the following properties:

(a) Fermentation of mannose and sucrose, but not arabinose, with the production of acid, but no gas.

(b) Indol and cholera red positive (R-12) and R-16).

(c) Voges-Proskauer negative (R-14).

(d) No beta-hemolysis of goat cells (R-3).
(e) Agglutination with specific sera.

Media for the preservation, isolation, and identification are given in the section on "stool examination." The same media are used to test milk and water for the vibrios.

The El Tor vibrio differs from the true cholera vibrio in that it is hemolytic and gives a positive Voges-Proskauer test. The Celebes strain of El Tor is pathogenic, while the Mecca strain is not (Felsenfeld).

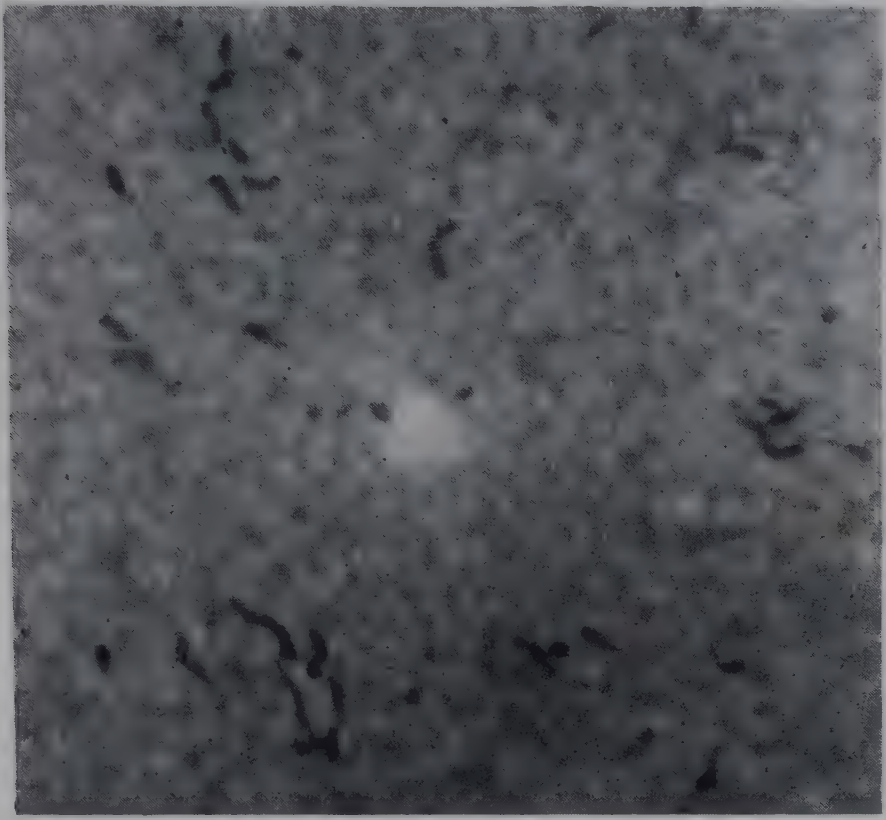

Fig. 382.—*Vibrio comma*, broth culture (×2,000). (Courtesy Dr. Oscar Felsenfeld.)

SEROLOGY

The entire group of cholera vibrios have a common H antigen, while the true cholera vibrios (types Inaba and Ogawa) have a common O antigen, called O-I formerly. Now it is designated as "A" antigen. Formol does not destroy the O antigen of the vibrios.

H + O sera.—Grow the vibrios in infusion broth M-4, pH 8.0. After 24 hours kill by the addition of 0.3% of formol. Inject 1 c.c. doses of this antigen 3 to 4 times at weekly intervals into rabbits.

O sera.—Monovalent sera are obtained by growing the organisms in the presence of antisera and transferring the growth to an agar plate. Wash the growth from the agar with saline and keep in the boiling water bath for 2 hours. Standardize to tube 5 of the nephelometer (page 1477) and inject at weekly intervals 0.1 c.c., 0.2 c.c., 0.5 c.c., 1.0 c.c., 1.0 c.c., 2.0 c.c., and 2.0 c.c., respectively, into rabbits.

Burrows has grouped cholera vibrios according to their "O" antigens. As stated above, the "A" antigen is common to all types. The Ogawa type has the basic antigenic structure A,B . . .; the Inaba A,C . . .; the Hikojima A,B,(C) . . . The most important diagnostic antigens seem to be B and C. Useful and specific sera may be prepared by cross-absorbing Inaba and Ogawa strains. Burrow's work has been confirmed and expanded by Kauffmann, Galut, and others. Pandit and Felsenfeld showed that the "H" antigen of cholera vibrios is not homogenous and cannot, therefore, be used as a means of identifying the genus.

Patient's serum can be used for diagnostic agglutination tests. Use the same technic as suggested for the macroscopic Widal test, using the proper antigen.

Use suspensions of boiled vibrios for the determination of O agglutinins, and 0.2% formolized cultures for the detection of H-O antigens.

The agglutinins are detectable on the fourth day of disease, and usually reach their maximum on the seventh day of the disease.

Paracholera Vibrios

Morphology: Curved rods, often shorter and thicker than *V. comma.* Motile, possessing a polar flagellum.

Stain: Gram-negative.

Colonies: They frequently produce a gray, plumose, moist, glistening growth on agar. They do not coagulate litmus milk. They are found in fowl diarrhea and in stools of man. Their pathogenicity is questioned.

LACTOBACILLUS, LISTERIA, ETC.

Lactobacillus Boas-Oppleri

Morphology: Rods, 1.0 by 6.0 to 8.0 microns, occurring in pairs and in chains. Nonmotile.

Stain: Gram-positive.

Colonies: No growth on agar. Milk agar colonies are small, gray, and granular. Litmus milk is acidified with coagulation. They form acid in dextrose and lactose. They form levorotatory lactic acid in milk. They are found in normal gastric contents, but particularly in gastric carcinoma and other diseases causing stagnation of the stomach contents.

Lactobacillus Bulgaricus

Morphology: Rods, 1.0 by 2.0 microns, often occurring in long chains. Nonmotile.

Stain: Gram-positive, older cultures show gram-negative forms.

Colonies: On whey agar, they form circular to irregular, grayish white filamentous colonies. They acidify litmus milk, with a soft creamy curd in twenty-four hours. They form acid in dextrose, lactose, galactose, levulose, and mannitol. They form 2.7 to 3.7% lactic acid in milk. The lactic acid formed is either inactive or levo-rotatory. They also form a small quantity of volatile acid. They are microaerophilic.

Fig. 383.—*Lactobacillus acidophilus.* (×950.)

Lactobacillus Acidophilus

Morphology: Rods, rather slender, frequently with tapering ends, 4.0 to 5.0 microns in length occurring singly and in short chains. Nonmotile.

Stain: Gram-positive, although older cultures may also show gram-negative forms.

Colonies: Thin, irregular, translucent, fimbriate margin. They form acid in litmus milk, usually with a soft coagulum after forty-eight hours. Acid formed in dextrose, maltose, lactose, sucrose, and raffinose. Some cultures also ferment mannitol. Cultures give off odor of acetic acid.

L-agar (M-14) is recommended for the growth of Lactobacilli.

Listeria Monocytogenes

Morphology: 0.5 micron broad, 1 to 5 microns long, small organisms, occurring as single cells, in V-shaped pairs, or in short chains. Gram-positive. Nonsporulating, noncapsulated, motile with a single flagellum. Pathogenic for mice.

Colonies: Aerobic and facultative anaerobic. Small, transparent, hemolytic colonies on blood agar M-28, M-29. Acid from dextrose, rhamnose, and salicin. Indol, gelatin, and nitrate negative.

Four serologic types are known.

Causes meningitis in man and listerellosis in ruminants. Plating to tryptose agar with 0.05% potassium tellurite greatly facilitates its isolation.*

Bacteroides

Small, slender rods, gram-negative, nonmotile, nonsporeforming. Anaerobic. No proteolytic action; no hemolysis. The genus has not as yet been completely described.

ERYSIPELOTHRIX RHUSIOPATHIAE

Small, slender, nonmotile organisms, appearing in chains which branch freely; often resembling Actinomycetales. They are gram-positive. They grow best under anaerobic conditions, forming alpha-hemolytic, granular colonies. They produce hydrogen sulphide and do not form indol. After adaptation to aerobiosis, the colonies are smooth when grown in oxygen-containing atmosphere.

Dextrose broth with 10% serum is favorable for primary isolation. Subcultures are made on blood agar plates with 1% dextrose.

Inoculation of mice helps to confirm the diagnosis.

PLEUROPNEUMONIA ORGANISMS

These are small, pleomorphic organisms which are often invisible through the ordinary optic microscope. They are gram-negative, and stain well with Wayson's method (S-37).

For primary isolation, thioglycollate broth (M-48) and Norman and Kuhn's broth (M-116) are the media of choice. Since the growth of pleuropneumonia organisms does not cause visible turbidity in all cases, blind daily subcultures are made to further thioglycollate broth tubes and to Norman and Kuhn's plates (M-117). It is necessary to cut out pieces of the solid medium and examine under the microscope to see the colonies.

Frequently such pieces are put into thioglycollate broth for subculture. After several inoculations from broth to broth, visible turbidity will develop.

BARTONELLACEAE

Bartonella Bacilliformis

Morphology: Pleomorphic, coccuslike, ring, oval, rod-shaped (straight, or more or less curved), and granular forms are found. In red blood cells, they form a short chain of cocci or a chain of rods, or they may resemble Chinese letters or a circumflex accent. In endothelial cells lining blood and lymph channels of viscera from fatal Oroya fever, they are sometimes discrete and rod-shaped, but commonly granular or amorphous round masses, distending the cells. In cutaneous nodules, they appear within endothelial cells as rod-shaped organisms or in clusters. Very slowly motile in fresh preparations of blood in Oroya fever. Motile in young cultures. Three to five unipolar flagella. Nonmotile spirals seen in dark-field examination, up to 50 microns in length.

Stain: Gram-negative; reddish-violet with Giemsa and Wright stains. Bipolar staining frequently observed.

Cultivation: They have been grown in Noguchi leptospira medium and in Geiman semisolid and solid media. Growth in Noguchi medium appears in 5 to 15 days, as a nebulous zone 5 to 10 mm. below the surface of the medium. Granular colonies sometimes observed. Tissue cultures have been successful, the organisms developing within the cytoplasm of cells. Beef infusion agar containing cystine, glucose, and rabbit blood have been used, and also chorioallantoic fluid of the developing chick.

---

*Gray, M. L., Stafseth, H. J., and Thorp, F., Jr.: J. Bact. 59: 443, 1950.

The general consensus is to classify *Bartonella bacilliformis* as a bacterium. It is the cause of human bartonellosis, Carrión's disease, or Oroya fever.

Human Bartonellosis, Carrión's Disease, Oroya Fever

Distribution.—Human bartonellosis occurs only in certain regions of western South America, from approximately 2 degrees north to 13 degrees south latitude. The disease is observed in two regions in Peru: one, the Pacific watershed; the other, the Marañon watershed. It is seen near the Peruvian border in Ecuador, and in the southwestern part of Colombia, in a large area around the city of Pasto.[*]

Transmission.—Transmission is by the sandfly, Phlebotomus. The mechanism of transmission is through feeding.

The only known reservoir of virus in human bartonellosis is man. Man and the insect vector are the only living beings known to be naturally infected. The incidence of asymptomatic human carriers in infected areas is 10% or higher.

Diagnosis.—The organism must be demonstrated in the peripheral blood. This can be accomplished by examining films, both thin and thick, after staining with Wright or Giemsa stain. When the organisms are not demonstrable in the films, blood cultures must be made. Early in the disease the blood cultures will be positive before the organisms can be found in the blood films.

When the disease is well established, there is irregular fever, rapid and severe anemia, high erythrocytic sedimentation rate, pains in the joints, enlargement of the lymph nodes, and, coupled with history of the environment in which the patient has recently lived, all serve to make the diagnosis.

During the eruptive stage, diagnosis is established by the characteristic appearance of the verrugas, and confirmed by demonstration of the Bartonellae in the lesions. Sections should be fixed in Regaud's fixative and stained with Giemsa stain.

The blood picture is discussed on page 733.

The verruga may resemble an angioma, an angiofibroma, or a botryomycoma,[†] but these tumors are always single and congenital. The subctuaneous nodules, when they have not eroded the skin, may resemble fatty tumors, fibromata, and similar pathologic conditions. However, the coexistence with typical miliary verrugas, the localization near the joints, and the course of the disease furnish the diagnosis. In doubtful cases, bacteriologic and histologic studies of the lesions should be made. In this period blood cultures are often positive.

The disease is not transmissible to the usual laboratory animals. Even monkeys are difficult to infect.

BORRELIA[‡]

Relapsing Fever

The etiological agent of relapsing fever is a spirochete belonging to the genus Borrelia. Many "species" have been described as the causative agent of relapsing fever, including *Borrelia duttonii, Bor. hispanicum, Bor kochii, Bor. novyi, Bor. obermeieri, Bor. recurrentis,* etc. At the present time, it is not definitely known whether these so-called species or races are true, separate taxonomic species or whether they merely represent strains or varieties of one or two species. Morphologically, all of the so-called species and strains are identical. Likewise, the diseases produced are similar clinically. These strains or variants differ from each other principally in their serologic characteristics. It is claimed that in a patient or animal any given strain of Borrelia assumes different serologic characteristics during each relapse.

---

[*] For further details, the reader is referred to Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, The C. V. Mosby Company, 1951.

[†] H. Groot, in Clinical Tropical Medicine by Gradwohl, Benitez Soto, and Felsenfeld, St. Louis, 1951, The C. V. Mosby Co.

[‡] Revised from A. A. Packchanian in Clinical Tropical Medicine by Gradwohl, Benitez Soto, and Felsenfeld, St. Louis, 1951, The C. V. Mosby Co.

Morphology: The spirochetes which cause relapsing fever are cylindrical or slightly flattened, with pointed ends, and measure from 8 to 20 microns in length and 0.2 to 0.3 micron in diameter. Each spirochete has about 3 to 7 large, wavy, irregular, inconstant spirals, each spiral having an amplitude of 1.5 microns. These microorganisms are highly motile and divide by transverse fragmentation.

Stain: Borrelia stain readily with Wright, Giemsa, and other common bacteriologic stains.

Cultivation: The spirochete of relapsing fever probably has never been successfully cultured in vitro. Because of their flexibility and small diameter, relapsing fever spirochetes can be passed through a thin-walled Berkefeld filter.

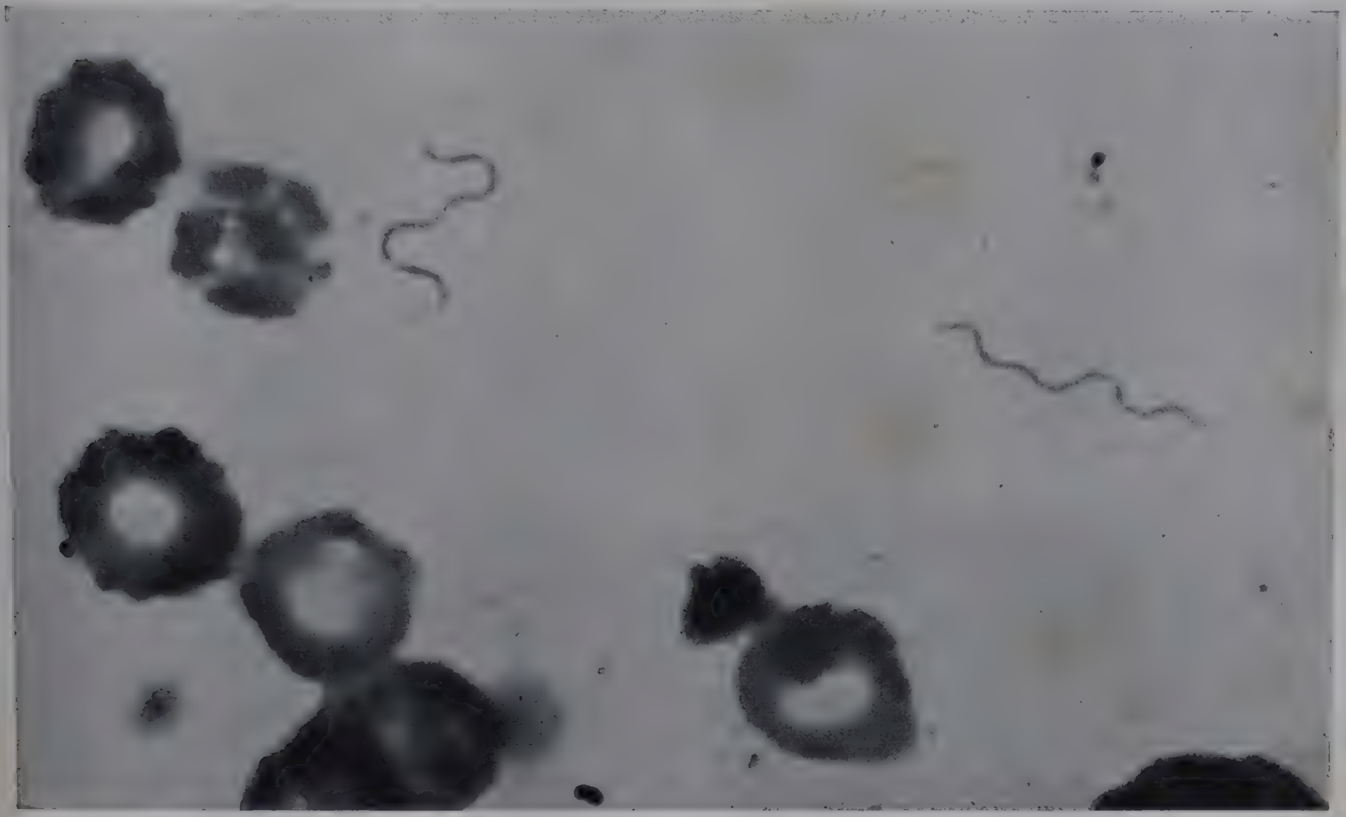

Fig. 384.—Thin blood film showing spirochetes of relapsing fever. Wright stain. (×2,700.) (From Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, The C. V. Mosby Co.)

During the febrile period, the motile spirochetes with lashing movements may be demonstrated in a fresh wet preparation of the patient's blood by dark-field examination, preferably with a high-power, dry objective.

Stained thin or thick blood films are valuable for detection of the microorganisms in the blood.

When the central nervous system is involved, the spirochetes can be demonstrated at times in the cerebrospinal fluid.

Inoculation of laboratory rats with the patient's blood is also a valuable method of diagnosis. Place about 5 to 10 c.c. of the patient's blood, taken during the febrile period, in a sterile test tube containing a few glass beads, and defibrinate by shaking.

Inoculate each of two rats with 1 or 2 c.c. of the defibrinated blood.

From the third to the twelfth day, examine the rat's blood each day for the presence of spirochetes.

The sample of defibrinated blood may be refrigerated for several weeks before inoculation of the rats, if necessary. Defibrinated blood containing Borrelia, stored in an icebox for 2 or 3 months, still retains its power to infect susceptible test animals.

Borrelia have never been cultured successfully in vitro. There are no successful serologic tests.

Distribution of Relapsing Fever.—

Both tick-borne and louse-borne relapsing fevers are widely distributed and found in most parts of the world. The louse-borne disease is found in cold as well as in warmer climates, while the tick-borne relapsing fever occurs chiefly in warmer regions.

Louse-borne relapsing fever appears usually in the form of small or large outbreaks or epidemics, although occasionally sporadic cases are encountered. The infection apparently is not transmitted to man by the bite of the infected louse; however, if the louse is crushed and the material is rubbed into abraded skin as by scratching, infection may take place. It is believed that the spirochetes do not pass through the louse egg.

Louse-borne epidemics are frequently associated with poverty, unhygienic conditions, and troop movements. The disease is often found in close association with louse-borne typhus, and in some cases mixed infections of typhus and relapsing fever coexist. Apparently there is no reservoir host other than man in the louse-borne relapsing fever, and therefore delousing of people and of their clothing is an effective means of limiting the spread of the disease.

Tick-borne relapsing fever occurs usually sporadically. Infected ticks transmit the spirochetes by biting man. The soft ticks which are known to be naturally infected are *Ornithodorus parkeri, O. hermsi, O. rudis, O. talaje, O. turicata, O. erraticus, O. moubata, O. savignyi, O. asperus, O. tartakovski, O. tholozani,* and *O. verrucosus.*

The soft tick remains infected for life and passes the infection through its egg. It therefore seems that Ornithodorus is the principal reservoir host of *Borrelia recurrentis,* although mammals such as monkeys, chipmunks, prairie dogs, rats, and squirrels may acquire the infection from ticks and serve as reservoirs for a shorter period.

Crab lice (*Phthirus pubis*) and bedbugs (*Cimex lectularius*) apparently play no role in transmitting relapsing fever.

The spirochetes may be demonstrated in the spleen, brain, and other organs.

Laboratory Findings.—

During the febrile period, albuminuria is usually present. The leukocyte count is elevated to about 10,000 to 20,000 while there is fever. The Wassermann reaction is said to be positive in a small percentage of cases.

TREPONEMA

Treponema Pallidum

(Spirochaeta Pallida)

Morphology: Cylindrical, 0.25 to 0.3 by 6 to 14 microns, with pointed ends. Spiral amplitude, 1.0 micron, regular. Spiral depth, 0.5 to 1.0 micron, very constant. Waves, one or more slight, undulating curves may be present. Axial filament doubtful. The whole seems to consist of a spirally wound axial filament. Chambered structure absent. Membrane doubtful, if there is one present, it must be flexible. Crista absent. Terminal finely spiral filament present, and easily seen in cultures. Flagella absent. Highly motile end portion absent. Division transverse or possibly also longitudinal.

Stain: Diagnosis is usually made by means of the dark-field microscope, where the organisms may be observed alive. In this way they can be identified by their movement. They stain pink with the Giemsa stain. They are disintegrated in bile salts in the proportion of 1:10. The Krajian method of staining is recommended. (See pages 2138 and 2141.)

Cultivation: They have been cultivated under strict anaerobic conditions in serum-water containing fresh tissue.

T. pallidum is the microbic agent that causes syphilis.

Treponema Microdentium

Morphology: They are less than 0.25 micron in thickness in the center, and taper toward each extremity, which is pointed. The length varies with age, although they may reach 8 microns with 14 curves. Sometimes a long, thin flagella-like projection is observed at each extremity.

Cultivation: Strict anaerobes, cultivated on serum-water with fresh tissue. Nonpathogenic. They are normal inhabitants of the oral cavity. They may be stained with the Giemsa or the Krajian stain.

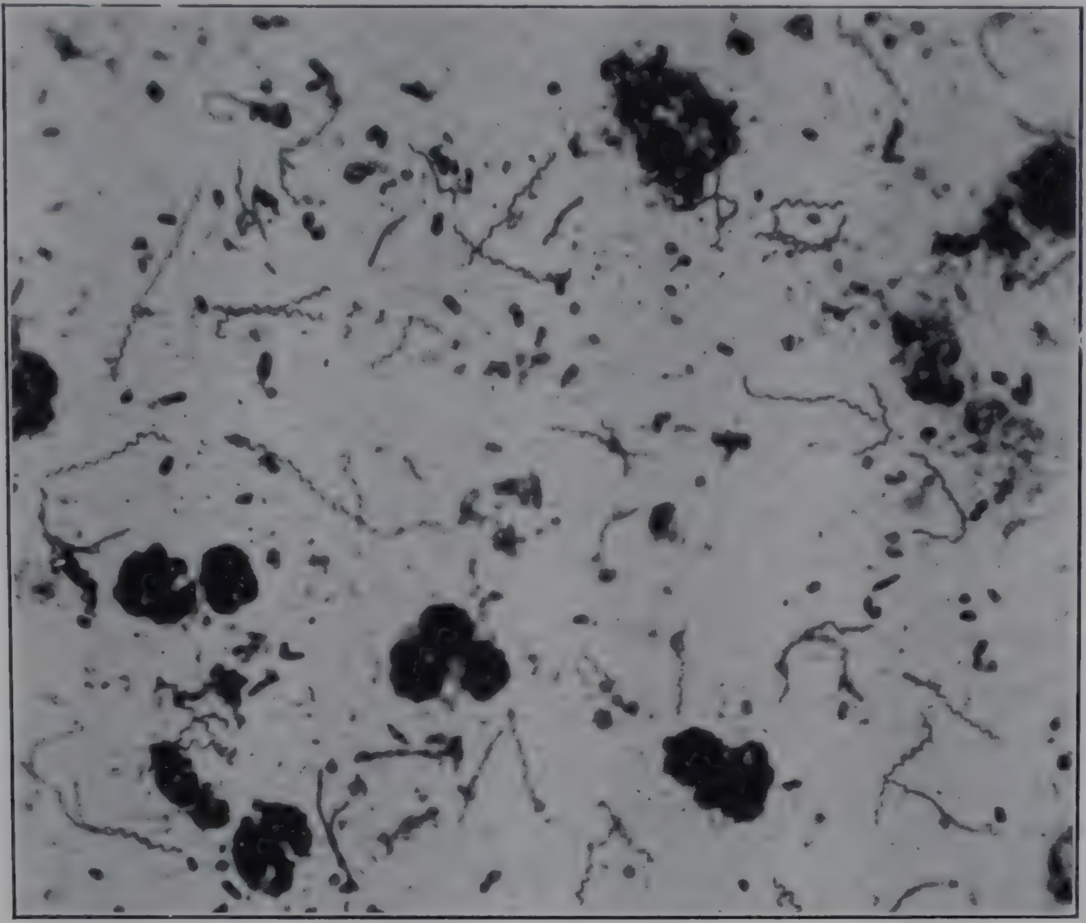

Fig. 385.—*Treponema pallidum* in a biopsy specimen of penile sore. Stained by the Krajian 20-minute method. (From Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, St. Louis, 1952, The C. V. Mosby Co., by permission.)

Treponema Macrodentium

Morphology: Spirals with abruptly tapering extremities. They are 0.7 to 1.0 by 3.0 to 8 microns, with 2 to 8 curves.

Stain: They may be stained with the Giemsa or the Krajian stain.

Cultivation: They are obligate anaerobes, and are cultivated in serum-water containing fresh tissue. They are normal inhabitants of the oral cavity. Nonpathogenic.

Treponema Carateum*

(Treponema Herejoni)

Morphology: In dark-field illumination, they appear as brilliant cylindrical filaments, coiled along the long axis. The coils are tight, regular, and rigid, especially in the center. At times, these coils relax and separate, to return to their original position. Length, 7 to 22 microns; thickness, 0.2 to 0.3 micron; depth of spirals, 0.8 to 1 micron; number of spirals, 7, 15, to 29. Very highly motile, turning rapidly about the long axis. Bipolar movements of progression. When stationary, in addition to the spinning or drilling movements, there are movements of torsion and flexion, arching, and assuming shapes of letters O, P, and S. They have undulant and creeping movements, so that they move in and out of focus. Movement is lost in 1 to 6 hours. They cause mal del pinto, or pinta.

---

*Revised from F. León-Blanco in Clinical Tropical Medicine by Gradwohl, Benitez Soto, and Felsenfeld, St. Louis, 1951, The C. V. Mosby Co.

Stain: They stain well with Giemsa stain and especially well with the Krajian spirochete stain.

Cultivation: They have not been successfully cultivated.

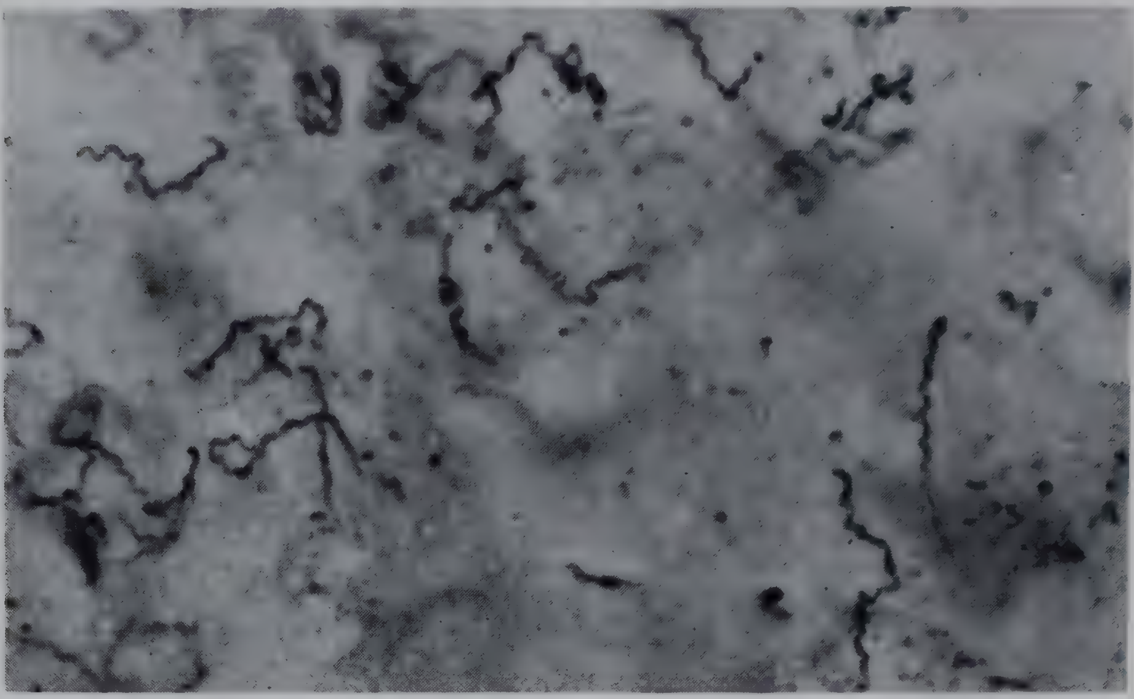

Fig. 386.—*Treponema carateum* in skin in a case of mal del pinto. Service of Dr. Pequeño. (Stained with Krajian spirochete stain; ×950; reduced ⅕.)

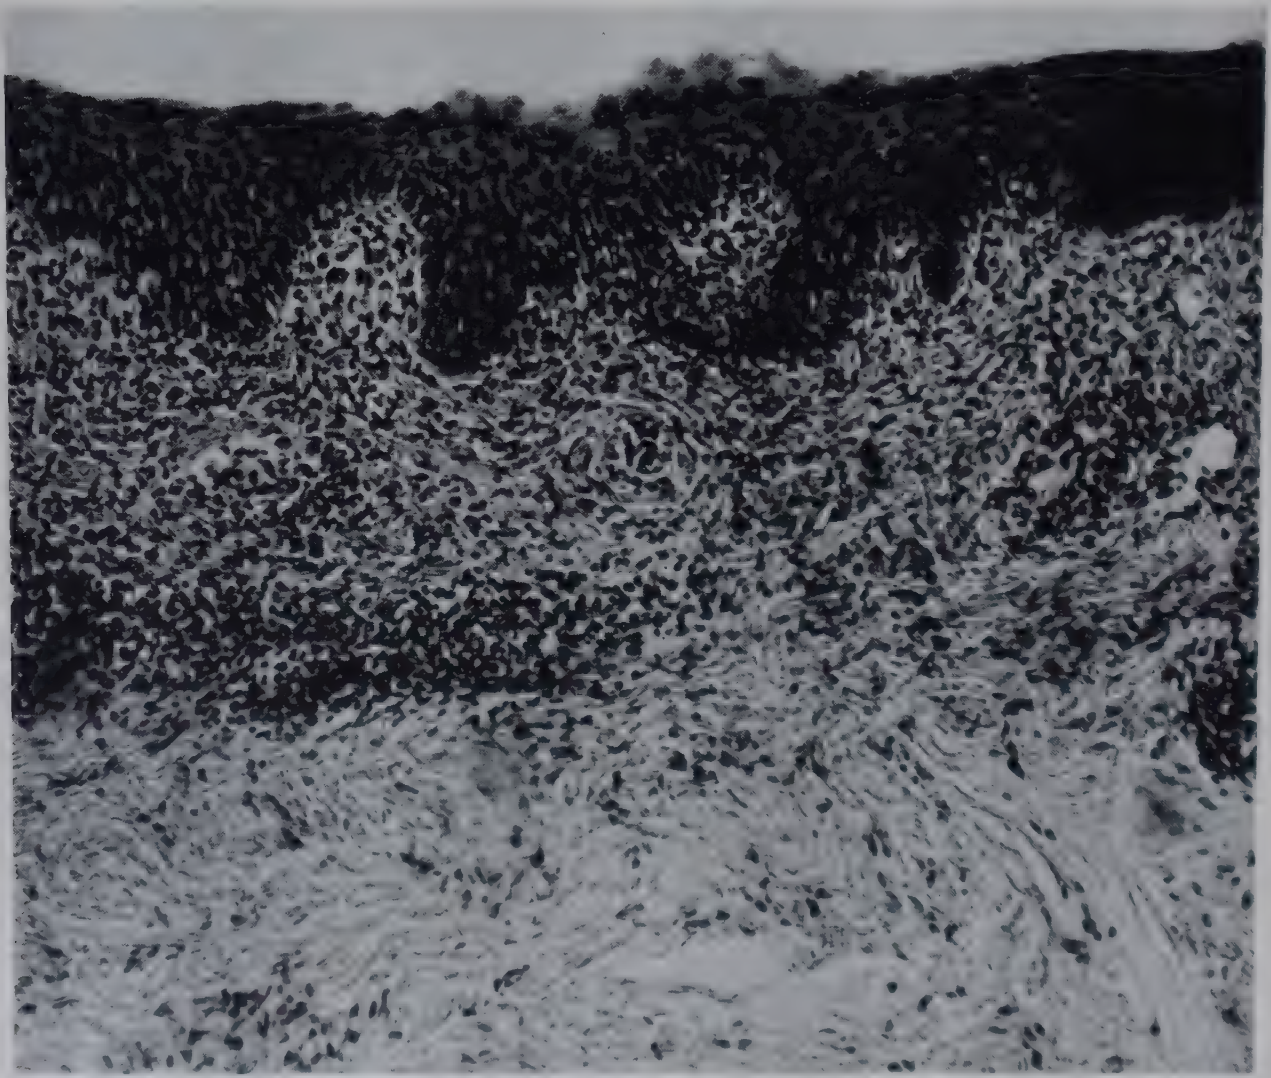

Fig. 387.—Section of skin in mal del pinto. (Service of Dr. R. B. H. Gradwohl.)

According to León-Blanco, the distribution of the treponemata in cutaneous lesions in man varies for the initial lesions of mal del pinto (carate) and pintids, and also for lesions of the later phase. In the initial lesions and in the pintids, treponemata are particularly abundant in the epidermis and in the intercellular spaces of the rete mucosum, especially in the acanthotic interpapillary crests, as well as in the epithelial portion of the pilosebaceous follicles. In the dermis they are localized especially in the portion occupied by the inflammatory infiltration, and they are abundant near the blood vessels. It is not exceptional to see them as they traverse the walls of these vessels. In the later phases, they have been seen only in the rete mucosum and in the epithelial portion of the pilosebaceous follicles.

Distribution of Mal del Pinto.—

Mal del pinto (pinta) is endemic in rural or suburban areas, stopping at the outskirts of large cities, particularly in countries with a high epidemic index. Where the disease is sporadic, it can be found in large urban centers.

In the intertropical regions of the Americas, the disease is most widely distributed in villages situated in the valleys of large rivers, at an altitude which varies from sea level to 2,570 meters. In some areas in this zone, incidence reaches 50 to 90%, while in localities a short distance from these zones, only 1 to 2% of the population is affected. Apparently there is no relationship between the disease and geographic conditions. Infection is more frequently seen among inhabitants of villages and small towns situated between mountainous zones and the sea than among residents of towns which lie near the coast. In coastal zones, rural towns and villages show a higher index of infection than less urbanized areas.

In villages with high incidence of the disease, it is found in family foci, although intimate contact with pintous patients is not the sole prerequisite for infection. It is frequently observed that in marriages of one to twenty-five years, one marital partner may be ill with the disease while the other has remained healthy (León-Blanco).

Where the infection is sporadic, pinta is not transmitted to those who live with infected individuals.

When members of the Caucasian race live under conditions similar to those of Indians, Negroes, and mestizos, they are as easily infected. There is no special susceptibility to pinta on the part of certain races when the mode of life is identical. Sex has no bearing on incidence of the disease. Pinta can occur at any age, although the initial lesions are most frequently seen between the ages of 5 and 20 years.

Diagnosis.—Examination for treponemata in cutaneous lesions and in glands may be carried out by silver impregnation of biopsy material. We recommend the method of Krajian. The dark-field examination may be made of serous matter obtained by puncture of the glands or by erosion and expression of cutaneous lesions. This method is the most rapid and the easiest.

Technic.—With a bistoury or curette, make a very superficial abrasion in the skin of the suspected lesion.

Apply pressure with a pair of forceps. A few drops of serous matter will be expressed from the lesion.

If the first drops contain many red blood cells, discard until a clear drop is obtained.

Mount the drop on a slide under a cover glass, and examine by means of the dark-field microscope.

If desired, make a smear and stain by the Krajian spirochete method.

Treponema Pertenue*

Morphology: 12 to 20 microns long, with 8 to 20 small, broad turns in the spiral. Morphologically indistinguishable from *Treponema pallidum*. Motility by translation in the direction of the long axis, a rotary movement of the spirals, giving the impression of a corkscrew turning on its own axis, and a waving or twisting movement from side to side.

Stain: They require special methods of staining. They stain easily with the Krajian spirochete stain.

---

*Revised from A. J. Sheldon in Clinical Tropical Medicine by Gradwohl, Benitez Soto, and Felsenfeld, St. Louis, 1951, The C. V. Mosby Co.

Cultivation: Cultivation is difficult, if not impossible.

They cause yaws or frambesia.

The organisms are readily killed by drying and cannot withstand exposure to air and light more than 24 hours in a moist medium.

The spirochetes are present in large numbers in primary and secondary lesions and have been demonstrated in lymph glands, spleen, and bone marrow. They have not been found in the blood stream, but Castellani successfully infected apes by injecting blood from frambesia patients. Further evidence of their presence in the blood stream is the dissemination of the secondary lesions over the entire body. Organisms have never been demonstrated in deep organs other than those mentioned above, nor in the nodular, ulcerative, scaling, or gummatous lesions of the tertiary stage of the disease. Monkeys and rabbits, as well as apes, can be experimentally infected with frambesia. Hamsters are also susceptible.

Transmission (Yaws or Frambesia).—

Treponema pertenue is readily transmitted from infected persons to others by direct contact. Indirect contact with contaminated clothing, bedding, sleeping mats, utensils, furniture, soil, etc., is probably a less important means of spreading the disease because the organisms are quite fragile. Mechanical transmission by the "gnat" fly, *Hippelates papillipes*, is possible within seven hours after feeding on open frambesia lesions, by regurgitation of ingested material containing spirochetes. Venereal transmission does occur but is only incidental. Autoinfection may occur during the early course of the disease. Lesions frequently spread locally and to opposing contiguous surfaces, particularly the mouth, anus, and vagina. It is not believed that congenital infection occurs, although interstitial keratitis has been found among frambesia patients in Samoa where syphilis does not exist among the native population.

Trauma plays an important role in the transmission of frambesia. It seems likely that the organisms must come in contact with an abrasion in the skin in order to initiate successful infection. It is questionable whether or not they can penetrate the intact skin. It is generally accepted that the location of the primary lesion is also the site of infection. Primary lesions occur most frequently on exposed regions of the body which are most likely to be traumatized: the feet and legs. Crowded, unhygienic living conditions foster spread of infection in family groups so that frequently all of the children and sometimes the adults in a family develop lesions.

Persons of all ages are susceptible to infection with this organism, but the disease occurs most commonly in children.

Immunity.—

It is believed that one attack of yaws confers protection against another in regions where the disease is endemic, the immunity developing slowly and over a period of years. This immunity is not always complete or constant.

Distribution.—

The disease is seen mostly among Negroes, although it has been found in Polynesians, Melanesians, yellow-skinned races, Indians, and European races. A few cases have been found among the Caucasoids in the United States following residence in or visits to tropical areas where frambesia is endemic. If racial immunity exists, it plays a secondary role to unhygienic environmental conditions in the dissemination of frambesia.

Diagnosis.—Yaws must be differentiated from syphilis, particularly in the tertiary stages. Little aid can be obtained from the laboratory, since the etiological agents are indistinguishable, and specific serologic tests are reactive in both diseases. Spirochetes can be readily demonstrated by dark-field microscopic examination of serum from primary and secondary frambesia lesions after removal of the crusts. The usual serologic tests for syphilis, complement fixation, flocculation, and other specific tests are reactive in over 99% of patients with early frambesia. The tests become reactive two to three weeks after the appearance of the primary lesion. The titer increases rapidly and becomes strongly reactive during the fifth or sixth week. The tests remain reactive for months or years, occasionally becoming nonreactive in the tertiary stage.

LEPTOSPIRA*

Morphology: Leptospirae belong to the family Spirochaetaceae. They are characterized by a flexible threadlike structure consisting of a large number of regular spiral coils. The amplitude of each coil is approximately 0.5 micron. The length of the entire Leptospira varies between 8 and 12 microns. Degenerative forms may reach a length of 40 microns. The width is constant and approximately 0.25 micron.

Multiplication is by transverse fission, which may be seen under the microscope.

Leptospiras are visible under the dark-field microscope. They look like strings of very closely packed small beads. The ends are hooked, the center part rather rigid, and they move only slowly through the field, with rapid rotation on the long axis. In viscid media they seem to have some traction and acquire some speed, the middle part appears flexible, the movement becoming snakelike. The ends at times exhibit a whipping motion.

Do not confuse them with so-called ''pseudoleptospiras,'' which are threadlike fibrin structures expelled from blood cells in blood specimens; these show Brownian movement and movement caused by currents in the liquid, and are often mistaken for true leptospiras.

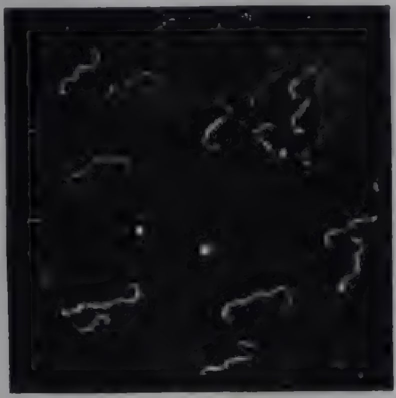

Fig. 388.—*Leptospira icterohaemorrhagiae* (×950). (Kolle-Wassermann: Handbuch der pathologischen Mikro-organismen, Band VII, 1, Table III.)

Staining: Leptospiras are not stained with simple dyes like gentian violet. They are stained readily by the Giemsa method in blood films, and in tissue sections by the Krajian 20-minute method. The primary coils are invisible with the usual fixatives.

To stain with Giemsa stain, use a strong solution, with faintly alkaline water, and stain at 37° C. for 30 minutes. Pour off, and re-stain with dilute Giemsa at 37° C. for another 30-minute period. Wash and examine. Victoria-blue may also give good results.

Take care that the slides are clean and fat-free. Wash the stain off carefully by allowing the water to drip on the stain-covered glass, and rinsing the precipitate with the water. Leptospiras stain violet, and the separate coils can be seen distinctly.

In tissues, the method of Krajian for staining spirochetes is recommended. See page 2138.

Leptospiras are able to pass through the pores of various filters. Their great flexibility, their extreme thinness, and their actively boring movements permit them to pass through the pores.

Cultivation: Leptospiras have no complicated growth requirements, but will grow in simple solutions as follows.

Buffered Peptone Solution

Peptone Difco or BBL	0.1%
Phosphate buffer, pH 7.2	10 %
Distilled water	1,000 c.c.

---

*From A. C. Ruys in Clinical Tropical Medicine by Gradwohl, Benitez Soto, and Felsenfeld, St. Louis, 1951, The C. V. Mosby Co.

Sterilize in an autoclave at 15 pounds pressure for 30 minutes.

Usually an enriched medium is preferred, since the leptospiras grow better in such media.

Vervoort Medium

(Modified by Wolff and Schüffner)

Peptone Difco or BBL	1 gm.
Ringer's solution	200 c.c.
Sörensen's phosphate buffer, pH 7.2	100 c.c.
Tap water	1,000 c.c.

Boil until the phosphates have been precipitated and filter after cooling. Distribute into small tubes.

Sterilize at 100° C. The pH is 6.9 to 7.0.

Add 10% sterile rabbit serum and inactivate at 56° C. for 30 minutes. Some rabbit sera agglutinate the leptospiras and cannot be used in the medium, so that each rabbit serum must be previously tested.

Korthof Medium

Peptone Difco or BBL	400 mg.
Sodium chloride	700 mg.
Sodium bicarbonate	10 mg.
Potassium chloride	20 mg.
Calcium chloride	20 mg.
Monobasic potassium phosphate (KH_2PO_4)	90 mg.
Dibasic sodium phosphate ($Na_2HPO_4 . 2H_2O$)	480 mg.
Distilled water	500 c.c.

Heat the mixture for 20 minutes at 100° C. Cool and filter.

Sterilize at 100° C.

Add 8% of sterile fresh rabbit serum.

Tube the mixture and inactivate at 56° C. for 1 hour.

Noguchi Medium

Rabbit serum	1.5 parts
Ringer's solution	4.5 parts
2% agar	1.0 part

Paraffin oil to cover the surface.

Noguchi used this medium also in combination with a fluid medium consisting of 1.5 parts of rabbit serum and 4.5 parts of Ringer's solution poured over the solid medium, the whole covered with paraffin oil. A drop of rabbit hemoglobin—1 part of defibrinated rabbit blood and 3 parts of distilled water—may be added to improve the results.

Savino Medium

Monobasic potassium phosphate (KH_2PO_4)	2 gm.
Sodium chloride	3 gm.
Magnesium sulphate	0.05 gm.
Calcium chloride	0.01 gm.
Distilled water	1,000 c.c.

Add, as activator, 0.1% of yeast extract
0.5% of caseine hydrolysate
and 0.005% of hematin.

Adjust the reaction to pH 7.1 with hydrochloric acid.

Sterilize at 115° C. for 15 minutes.

Add 10% sheep serum sterilized by filtration.

Leptospiras must be cultivated under aerobic conditions. The optimum temperature for rapid growth is 37° C., but lower temperatures are necessary to keep the cultures alive. Incubation is mostly between 28° and 32° C.

To obtain rich cultures, it is necessary to seed with large amounts of material. For subculturing, nearly 0.5 c.c. of the old culture is transplanted into the fresh medium.

Viability and Resistance: Leptospiras show remarkable viability in cultures. Cultures in Vervoort's medium kept in the dark at room temperature without subculturing sometimes remain alive for years. In the semisolid medium of Noguchi, a thick layer of leptospiras grows 10 to 12 mm. below the surface, and these organisms may remain fully virulent for years.

Leptospiras are very sensitive to acid reaction. They are killed very quickly in acid urine. To isolate them from urine, it is advisable to alkalinize the urine by keeping the patient on appropriate diet for some days before collecting the specimen. They are not very sensitive to salts. They may remain alive in sea water for several hours, but disappear more quickly from salt and brackish water than from fresh water.

They are killed at 50° to 55° C. in 30 minutes. They tolerate low temperatures well. They can be kept alive in tissues for several months when frozen at –20° C. In culture fluid at this temperature, however, they survive no more than five days. They cannot be preserved by lyophilization.

They have little resistance against the various disinfectants. Bile kills them quickly. They are not susceptible to sulfa drugs. Of the antibiotics, penicillin is active; it has been used successfully in animal experiments. Good results have been reported in a few patients.

Antigenic Structure

Soon after the discovery of leptospiras as the etiological agent of various infections, the question arose as to whether those strains which differ serologically are independent species or whether they are mere variants of the same species. This problem has not been solved to date, and both theories have their adherents. The first strains recognized as differing from the classic Weil strains were *L. hebdomadis, L. akiyama* A in Japan, and *L. pyrogenes* in Sumatra, all of which cause an acute febrile disease, but mostly without jaundice, and with a much lower death rate than Weil's disease.

When still more serologically different strains had been isolated, a more elaborate study of the antigenic structure became necessary, especially since the various strains cause almost the same clinical picture in man, the differences being unimportant and only in degree. In addition, the virulence for animals is not a reliable means of differentiation either.

Antisera from patients or sera prepared by injection of cultures into rabbits agglutinate cultures of leptospiras often in a high titer.

Because of the faint visibility of the leptospiras in ordinary light, the **agglutination** is poorly visible macroscopically. Pot[1] reported that concentrated Formalin-killed cultures may show agglutination visible to the naked eye, but unfortunately with these antigens the titers are lower and a much greater quantity of cultures is needed.

This method and others based on the same principle have found only few followers, so that the serologic tests must be controlled by the dark-field examination. Serum dilutions made with a buffer solution are mixed with equal quantities of a rich culture and kept at room temperature. After two hours, the results can be read provisionally, but the titer is not determined until the next day.

In the lower dilutions of a strongly active serum, agglutination is clearly visible; in the higher dilutions, lysis complicates the picture. The conglomerates of agglutinated leptospiras begin to show signs of lysis, until, at the end, only shapeless balls can be found, and finally nothing is seen except a few freely floating single leptospiras. The titer end point is the last dilution of the serum which shows some difference in number with the control.

Attention must be called to the fact that sometimes ''nests'' of leptospiras grow in rich cultures. These may resemble agglutinated leptospiras. In the ''nests,'' however, each leptospira is entire and actively moving; in agglutinated conglomerates, the leptospiras have a damaged appearance and the movements finally cease.

To avoid the danger of working with living leptospiras and to be able to have a stock of antigen ready at hand, some laboratories use Formalin-killed cultures. It is necessary to use chemically pure Formalin and no more than 0.5%. Impurities may cause nonspecific acid agglutination.[2] When dead cultures are used, however, the lysis is absent and agglutination becomes manifest in much higher dilutions than with living cultures, where this phenomenon has been obscured by the lysis. The titer of the sera tested with killed antigens is on the whole somewhat lower than when the titer of lysis is determined with living ones.[3] The results with these antigens are less specific than with living organisms. The Formalin antigens can be kept for a limited time only, because clumping begins sooner or later, probably caused by formic acid originating from the Formalin under the influence of light.

---

[1] Lancet 1: 1290, 1936.

Complement fixation tests have also been used in serologic work, but they are less specific and have practically been abandoned. To determine the antigenic structure of a strain, monovalent rabbit sera are used, which should have a titer of not less than 10,000. They agglutinate and lyse strains of the same species to the same titer or sometimes less, the lowest being one-tenth of the titer.

Other species may show a strong co-reaction, but they never reach more than one-third of the titer.[4, 5]

Some species are serologically closely related (*L. canicola-L. icterohaemorrhagiae*); others are independent (*L. bataviae*). For an exact diagnosis, however, agglutinin absorption tests are necessary, especially in those cases where co-reactions are strong. The absorption test first described by Ruys and Schüffner[6] and improved by Schüffner and Bohlander[7] is made as follows:

Agglutinin Absorption Test

Use a well-grown culture in Vervoort's medium, killed with 0.5% Formalin. Centrifuge 100 c.c. of this culture for 20 minutes at 10,000 r.p.m.

Pipette off the supernatant fluid.

Mix the remaining 0.45 c.c. of concentrated cultures with 0.05 c.c. of the serum diluted to a titer of 1:3,000.

The antibodies are fixed within 4 hours, but the mixture can be left overnight at room temperature.

Centrifuge at 10,000 r.p.m. for 5 minutes, and use the supernatant fluid for agglutination tests. Van Riel[8] prefers to perform the absorption with living cultures.

It is difficult to absorb a serum with many strains because a leptospira culture cannot be entirely deposited at the bottom of a tube, and some fluid remains in the tube. The serum is diluted with the remaining culture fluid, and it might become too greatly diluted if more strains were used. We have no absolutely monovalent sera such as we use in our bacteriologic serologic work.

Strains of the same species remove antibodies from a serum, strains of a related one only those belonging to the strain itself. The clear-cut results obtained with this method allow of an exact identification. Several species are now recognized as serologic and biologic entities in which there is correlation with a distinct epidemiologic behavior.

However, strains considered to be of the same species may show minor serologic differences. Borg Petersen,[9] whose work was confirmed by Gispen and Schüffner,[10] demonstrated that the classical Weil strains fall into two groups, one complete with the antigens A and B, the other incomplete with only A. Both behave alike pathologically and epidemiologically, so that they may be considered as two biotypes of the same species. Probably the same relation exists between *rachmat*, incomplete, and *akiyami* A, complete biotype. Van Riel found the same relation between an Indonesian strain (Benjamin) and an African strain

TABLE 161.—IMPORTANT LEPTOSPIRA STRAINS*

SPECIES	GEOGRAPHY	HUMAN DISEASE	SEVERITY USUALLY	PRINCIPAL ANIMAL HOST	ADDITIONAL ANIMAL HOST(S)	NOTE
L. icterohaemorrhagiae	World-wide	Weil's disease	Severe	*R. norvegicus*	Other rats, mice, dog, fox, sheep, pig, horse	Biotypes AB A and *naami*
L. canicola	Widespread	Canicola fever	Mild	Dog	Horse, cow, pig	
L. pyrogenes	USA, S-E Asia	Febrile spirochetosis	Mild	*R. brevicaudatus*		*L. salinem*
L. australis B	S. Europe, Japan, Australia	Swamp fever, cane fever	Mild	*R. culmorum*	*R. conatus*	May be identical with *L. pyrogenes*
L. ballum	USA, C Europe	(Leptospirosis)	Mild	*M. musculus albus*	Other rodents, horse, cow, dog	
L. pomona	Widespread	Swineherd's disease	Mild	Pig	Cattle, horse	*L. suis*, *L. australis* C possible subtypes
L. hebdomadis	USA, Japan, S-E Asia	Seven-day fever	Mild	*Microtus montebelloi*	Cattle, dog	*L. wolffi* is subtype
L. sejro	USA, C-S Europe, S-E Asia	Sejrø fever	Mild	*M. spicilegus* *Apodemus sylvaticus*	Other rodents, horse, dog, cattle	
L. saxkoebing	C Europe	(Leptospirosis)	Mild	*A. flavicellis* *A. sylvaticus*	Cattle	
L. medanensis	S-E Asia, Australia	(Leptospirosis)	Mild	?		
L. grippotyphosa	Widespread	Swamp or mud fever Harvest fever Infectious jaundice	Mild	*Microtus arvalis*	Other rodents, cattle	*L. geffeni*, *L. bovis* and *L. andaman* B may be subtypes
L. autumnalis	USA, Japan, S-E Asia	Autumnalis fever Fort Bragg fever Pretibial fever	Mild	*R. brevicaudatus* *A. speciosus*	*M. montebelloi*	Serologic biotypes are AB (*akiyama* A), A (*rachmat* incomplete), Bangkiang
L. bataviae	Widespread	Rice-field fever Water fever Indonesian Weil's disease	Severe	*R. norvegicus* *M.m. soricinus*	Other rodents, pig, cat, dog	*L. oryzeti* identical *L. mitis* closely related
L. mitis	C-S Europe, S America	Swineherd's disease	Mild	Pig	Horse, cattle	*L. hyos* identical
L. australis A	Widespread	Swamp and cane fever	Mild	*R. culmorum*	Other rats, dog, horse, cattle	*L. baillico* identical
L. javanica	Widespread	(Leptospirosis)	Mild	*R. conocolor* *R. brevicaudatus*	Other rats, cat	*L. poi* identical

*Compiled after Ruys, Wolff, and Broom.

(Mukingilwa), neither of which has been fully tested with all other sera. According to van Riel, *L. canicola* also has the two types mentioned here. Table 161 is a list of strains examined with agglutinin absorption tests.

There are a number of other strains which have been more or less exhaustively examined: *L. bovis, L. vituloreum, L. icterohaemoglobinuriae, L. schüffneri, L. mukingliwa, L. andaman* A, the strains H and H.C., Veldrat, Semarang 173, Djasiman, and many others. Our knowledge of either the serology or the epidemiology of these organisms, however, is still too incomplete to include in Table 161.

Variability

So far as I (A. C. R.) know, no variation in serologic behavior has ever been observed. The old strains from the Amsterdam collection have all remained stable. No conclusive animal experiments have ever shown a transition of one type into another. The experiments of Uhlenhuth and Zuelzer[11] and of Baermann and Zuelzer,[12] who considered the various strains to be all variants of one classical species, are open to criticism.

Van Riel,[8] however, basing his conclusions on his experiments in Africa with a number of strains but not with all types now available, defends the thesis that intermediate types exist and that there are transitions from one type to another. He emphasizes that strains which belong serologically to *L. grippotyphosa* in Central Africa cause a disease with frequent jaundice and a high death rate. However, as long as no exhaustive study of the epidemiology has been made, the picture is not complete and conclusions are premature.

DEMONSTRATION AND ISOLATION OF LEPTOSPIRAS

In all leptospiral infections the microorganisms circulate in the blood during the first week of illness. After the first ten days, positive blood cultures are very rare. Bone marrow has been found positive even on the twentieth day.[13] In the latter phases of the disease the leptospiras may be excreted with the urine.

Sometimes the spinal fluid contains leptospiras in incipient stages. At autopsy, both the liver and the kidneys may contain leptospiras.

Leptospiras in the Blood

Blood films stained with Giemsa stain rarely show leptospiras. Ordinary dark-field examination of blood also rarely gives a positive result, and many so-called positive findings have been caused by pseudoleptospiras mistaken for actual leptospiras. With the centrifugal method, however, leptospiras may be demonstrated in the blood in some cases during the first days of the illness.[14]

Mix 1 part of 1% sodium oxalate solution in phosphate buffer pH 8.1 with 9 parts of blood.

Centrifuge 15 minutes at 1,500 r.p.m.

Examine the clear plasma under the dark-field microscope with low magnification. If no leptospiras are found, centrifuge the remainder of the plasma for 20 minutes at 10,000 r.p.m. The sediment might show the leptospiras.

Blood collected in Liquoid Roche can be used for dark-field examination after the first centrifugation, and sediment can be obtained from the plasma.[15]

Liquoid Roche: 15 to 20 c.c. blood in 4 c.c. of a 1% polyanethol sodium sulphonic acid solution in saline = Liquoid.

[14] Ruys: Nederl. tijdschr. v. geneesk. **77**: 3654, 1933.

[15] van Thiel: The Leptospirosis, Leiden, 1948, Universitaire Pers.

This rapid method, which permits an early diagnosis within half an hour after the sample has been taken, is not absolutely reliable. At times microscopically negative blood yields positive cultures or animal inoculations. All three methods should be used to demonstrate the leptospiras. The culture is the most reliable, but often positive results are obtained only after one and one-half to four weeks. If the material is contaminated, the addition of 400 mg. of sulfonamide to the medium may give a pure culture of leptospiras.[16]

To demonstrate the leptospiras by means of test animals, young guinea pigs, 150 to 200 gm., should be used, preferably also young hamsters, because these animals are sensitive to leptospiras (*L. canicola*) which are only slightly pathogenic for guinea pigs.[17]

The inoculation should be made into the peritoneal cavity, with 0.5 c.c. of blood. Daily examinations from the third day on may show leptospiras even in those cases in which the strain does not cause the animal to become sick. If the animal develops fever, the blood is usually positive, and pure cultures may be obtained by inoculation of the blood, obtained by puncture of the heart, into suitable media. Guinea pigs dying of leptospirosis show hemorrhages and mostly a severe jaundice. At autopsy the liver and kidneys sometimes contain leptospiras in abundance; in other cases very few or none are found. The adrenals are always positive.

White mice are also used; they are susceptible to many strains of leptospiras, but one must bear in mind that white mice may also be spontaneously infected, as first described by Bessemans and Thiry[18] and later by Schüffner (not published). Ruys and associates[19] found two colonies of white mice to be heavily infected with *L. ballum* which were excreted in large quantities. One must be sure that the colony of mice in use is free from spontaneous infection. Bessemans and co-workers[20] demonstrated that some strains of *L. icterohaemorrhagiae* kill the mice quickly and that others cause practically no symptoms except a constant urinary excretion of leptospiras virulent for guinea pigs.

Leptospiras in Urine

Leptospiras may appear in the urine from the beginning of the second week of the illness on. Direct examination in the dark field sometimes shows the leptospiras in great numbers. If the urine is acid, most of them will be dead and will show the typical rigid appearance. Passage through a susceptible animal (guinea pig, hamster) is necessary to isolate them from the urine.

The patient should be given an alkalinizing diet a few days before the specimen is to be collected, to prevent the damage of acid urine. The simplest way to obtain a positive result is to take the second portion of urine of the day and to inoculate the animals intraperitoneally with 1 c.c. of the freshly excreted urine at the bedside of the patient. Urine sent to the laboratory seldom contains living leptospiras.

Leptospiras in Cerebrospinal Fluid

As early as 1916, Costa and Troisier[21] described a case of Weil's disease in which the principal symptom was meningitis. Since that time the involvement of the meninges as a constant and sometimes predominant symptom of leptospiral infection has become well known. There is, however, no correlation between the seriousness of the clinical symptoms and the pathologic changes or the presence of leptospiras in the spinal fluid.

[19] Proc. 4th Internat. Cong. on Trop. Med. & Mal., 1948.
[20] Acta brev. Neeland. 8: 1, 1933.
[21] Bull. et Mém. Soc. Méd. de Hôp., 1916.

In all cases of Weil's disease or canicola fever in Amsterdam, Minkenhof could demonstrate a serous meningitis in the second week, while in only a few cases was the number of cells high. Gsell and Rimpau[22] stress that, in the various leptospiral forms of meningitis, during the first days of the illness no inflammatory changes can be observed, despite distinct meningeal symptoms. They always appear in the second and third weeks, however. Only rarely can the leptospiras be isolated from the spinal fluid. Schüffner and Walch-Sorgdrager[23] found them only in one out of twenty-five cases of Weil's disease with meningeal symptoms. Cultures and animal inoculations are indicated when it is necessary to examine spinal fluid.

Leptospiras in Post-Mortem Material

The demonstration of leptospiras at autopsy may be possible by darkfield examination of smears from the liver, kidneys, or adrenals. In tissues, the silver impregnation by the Krajian method will show the leptospiras in these organs. Cultures will be possible only immediately after death. In all other cases, animal passage is necessary. In chronic animal carriers (rats, dogs, mice, but not rabbits or man), the process in the kidneys is sharply localized to limited parts of the cortical substance; leptospiras will be found in layers on the epithelium of the convoluted tubules. Several parts must be examined before a diagnosis of leptospiral infection can be excluded.[24]

Leptospiras in Surface Water

Surface water is often the source of infection with leptospiras (Weil's disease, mud fever), but it is very difficult to demonstrate these microorganisms in the water. Microscopically, they cannot be distinguished from the nonpathogenic *L. biflexa* which is often found in water.

The only reliable method to date is that of van Thiel and co-workers who bring the warmed water (37° C.) into immediate contact with the tissues of susceptible animals either by bathing guinea pigs with an abraded skin in the suspected water or by letting this flow through the subcutaneous tissue of the animal. By this method even very small numbers of pathogenic leptospiras can be isolated from the water.

SEROLOGIC DIAGNOSIS

If no leptospiras have been isolated from the patient, the diagnosis can be made serologically in a number of cases. The antibodies do not usually appear before the seventh to tenth day of the illness. They then increase rapidly and reach the highest titer in the third or fourth week. The reliability of this method depends to a great extent, however, on the number of strains with which the serum is tested.

If there are no co-reactions and the titer has risen to 1:1,000 or more during the course of the illness, the probable cause of the disease may be established in this way.

Strong co-reactions are, however, often observed, and in these cases absorption tests are indicated (see also Ruys, Minkenhof, and Wolff[19]). Sera of patients infected with the incomplete biotype of *L. icterohaemorrhagiae* may show titers against *L. canicola* which are as high as and at certain moments even higher than against the causative strain. This nonspecific titer rises more quickly and disappears sooner than the specific one, so that in convalescence the titer against the causative strain is always the highest. Even a rising titer against a certain strain in itself, however, is no proof that this strain is the etiological one.

---

[22] Schweiz. med. Wchnschr. 74: 51, 1944.

[23] Nederl. tijdschr. v. geneesk. 80: 3000, 1936.

[24] Nederl. tijdschr. f. geneesk. 67: 2018, 1923.

The absorption test gives immediate and more reliable information.

A titer below 1:1,000 may indicate that the causative species was not included in the series of strains used for the tests; it may be only a co-reaction. In convalescence the titer drops but the serum may react positively for years after the illness, be it only in low dilutions (1:30 to 1:300).

In Sumatra, Wolff[25] found the reaction negative one year after the disease in most cases. Low titers always indicate further careful examination.

Patients who have been treated with immune serum at the beginning of the disease form antibodies only very slowly, and high titers are not reached at all.[26] The serologic diagnosis can be conclusive only if all sources of error have been considered and excluded.

Antibodies in Urine

In addition to the antibodies in the blood, the urine also may contain specific agglutinins and lysins.[27] Formalinized cultures should be used for nonsterile urines. The concentration of antibodies has no relation to the presence of albumin in the urine. The titer of the urine is lower than that of blood. In a few cases it was only 1:2, but it may rise to 1:256. Coreactions are much rarer with urine than with sera.

Antibodies in Spinal Fluid

In some cases of leptospira infections, the spinal fluid contains antibodies, but seldom in large quantities. Walch-Sorgdrager[4] found that undiluted spinal fluid was never positive in eleven patients with Weil's disease with and without meningeal symptoms. Gsell,[28] however, mentions positive results in low titers from the second week of the illness on, especially in cases with serous meningitis. The titer varies between 1:2 and 1:100 and sometimes it is even higher than 1:100. A titer of 1:10 is considered proof of the infection.

General Remarks

The various methods outlined above make an etiological diagnosis possible either by isolating the causative agent or by serologic examination. A refined serologic technic is often required. The question has often been raised whether it is necessary to go so far in serologic differentiation and whether the diagnosis of a leptospiral disease without further differentiation would not be enough.

A typical case of Weil's disease may be recognized as such by its sudden onset, high fever, conjunctival injection, muscular pains, jaundice, albuminuria, and meningeal symptoms. The death rate is high. However, the mistake of Noguchi's co-workers, who mistook cases of Weil's disease for yellow fever, is too well known.

Since more attention has been paid to the frequent occurrence of less typical cases, we know that practically all leptospiral infections produce in principle the same clinical picture.

In infections with some strains, jaundice is frequent (Weil's disease, *L. bovis*); with other ones it is rare (*L. canicola, L. grippotyphosa*); other groups are intermediate. Serous meningitis is a predominant feature in some (*L. canicola, L. pomona*); in others it is not often described. The renal and extrarenal disturbances which influence the production and composition of the urine[29] may be severe (*L. icterohaemorrhagiae, L. bovis, L. icterohaemoglobinuriae*) or practically absent (*L. canicola, L. grippotyphosa*). On the whole the differences are, in degree, never essential. The pathogenicity of the various types or species for experimental animals is not the same, but this quality is not essential either. Thus far the only reason, but a very important one, why differentiation seems indicated is the difference in epidemiology. The serologically different strains often show a quite distinct parasite-host relationship and hence a typical epidemiologic behavior.

---

[25] Geneesk, tijdschr. v. Nederl. Indië, p. 499, 1936.

[26] Schüffner: Nederl. tijdschr. v. geneesk. **86**: 163, 1942.

[27] van der Hoeden: Ann. inst. Pasteur **56**: 206, 1936.

[28] Bull. Acad. de méd., p. 688, 1946.

L. icterohaemorrhagiae lives in the kidneys of the rat (*Rattus norvegicus norvegicus, Rattus rattus alexandrinus*) where it may persist for the whole of the lifetime of the animal. *L. grippotyphosa* is found in the kidneys of the vole, but after a longer or shorter period the animal may be free of it.[30] *L. canicola* is found only in the dog as a carrier; *L. pomona* in Switzerland is found in infections of swine.[28] *L. hebdomadis* is confined to *Microtus montebelloi* in Japan and to dogs in Medan.

Sometimes it is difficult to decide whether finding a certain animal as a leptospira carrier is mere chance or whether it means that this is the real animal host and the reservoir which enables the parasite to persist. During the last years several diseases have been recognized as leptospiral infections; for example, swineherd's disease in Switzerland (*L. pomona*), jaundice in Palestine (*L. bovis*), a part of the cases with serous meningitis (*L. canicola, L. pomona, L. sejrø, L. grippotyphosa*), and many diseases in the Belgian Congo and Australia. Several animals have been found to be carriers. It will take some time and much work before we know how far minor differences in serology are accompanied by distinct epidemiologic behavior.

The complete and incomplete biotypes seem to behave practically alike in all respects and therefore all groups are considered to belong to the same species.

As long as the epidemiology of the various types or species has not been sufficiently clarified, we think it necessary to keep them separated, even though only provisionally for some.

COLLECTION AND EXAMINATION OF SPECIMENS

It is a mistake for laboratories to make a bacteriological examination for only one organism or for only one group of microorganisms. This procedure should be followed only when making special surveys; for example, when examining for carriers of meningococci or of diphtheria bacilli. It is contrary to the spirit of scientific bacteriology to examine a throat swab for streptococci only when the request or order for examination fails to specify anything else, and thus to overlook the possibility that the patient may be infected with *C. diphtheriae*. Many infections which could be discovered by more thorough examinations of the cerebrospinal fluids, stools, urine, pus, and wounds go unnoticed because the physician, burdened with his clinical and bedside tasks, may neglect to call the attention of the laboratory to the need for carrying out additional procedures.

---

[29] Klarenbeek and Schüffner: Nederl. tijdschr. v. geneesk. 77: 4271, 1933.

[30] Schüffner and Bohlander: Ztschr. f. Immunitätsforsch. u. exper. Therap. 104: 237, 1943.

For these reasons, routine methods are recommended in this chapter. These are suggested for every specimen, regardless of special requests. It is self-evident that special procedures must be carried out whenever ordered, in addition to certain routine methods. If this procedure is followed over some length of time, it will bring its reward for the loss of time and material spent in the examination of so-called "negative" specimens.

Whenever possible, specimens must be collected in a sterile manner. This is imperative for blood cultures, cultures of cerebrospinal fluid, pus, material from serous cavities, glands, and urine, not only to prevent contamination, but also, with the exception of urine, for the benefit of the patient. The material must often be collected by the physician. In such cases sufficient sterile collecting utensils must be put at his disposal and early delivery of the specimen to the laboratory must be assured.

BLOOD

Blood Cultures from Infections

Precautions.—

1. Too much blood will inhibit the growth of pathogenic organisms.
2. Too little blood will not contain enough bacteria to obtain a good growth.
3. The culture medium used must be highly buffered.
4. The container in which the medium is placed must have a broad base to insure a good growth.
5. There must be enough culture medium in the container to provide a growth.
6. Care must be taken to eliminate skin organisms from the culture.
7. Care must be taken to eliminate air organisms from the culture.

Method No. 1

Equipment Needed.—

1. Tourniquet.
2. Sterile sponges.
3. Tincture of iodine.
4. Alcohol.
5. Adhesive tape.
6. Alcohol burner.
7. Sterile tube or bottle containing 1 c.c. of 2.5% sodium citrate solution.
8. Bottle containing 100 c.c. sterile broth, M-4 or M-3.
9. One 10 c.c. Luer syringe with a 21 gauge, 1 inch needle, previously sterilized in the dry heat sterilizer at 170° C. for one and one-half hours.

Technic of Making the Culture.—

Place the tourniquet around the arm of the patient above the bend in the elbow.

Locate the vein by palpation.

Disinfect the skin with iodine, in a circular manner, covering a large area of the skin, but taking care not to touch the same area twice.

Prepare the syringe; take care not to touch the needle with the hands. This is accomplished by holding the needle in the paper in which it is wrapped, and placing it on the syringe without touching it.

Flame the tops of the bottles containing the sodium citrate solution and the broth.

Insert the needle into the patient's arm vein, and withdraw 10 c.c. blood.

Remove the tourniquet, then the needle (attached to the syringe) from the vein, holding a sponge saturated with 95% alcohol on the patient's vein.

Immediately eject, with sterile precautions, 5 c.c. of the blood into the broth, the other 5 c.c. into the sterile 2.5% sodium citrate solution. To keep air contaminants from entering the bottles, be sure to flame the tops and hold the bottles in a slanting position while ejecting the blood. Rotate both bottles gently to prevent coagulation of the blood.

Place adhesive tape over the puncture in the patient's arm.

Record the specimen on the laboratory chart.

Place the bottle containing the broth with blood in the incubator.

Melt two tubes of blood agar base M-27 and two of the same type tubes of dextrose agar (M-19). Keep the agar in a water-bath between 44 and 46° C. Agar at this temperature will remain liquid, but will not be hot enough to kill the bacteria which may be present in the patient's blood. If the agar is too hot, it will coagulate the blood which is added to it, giving a ''chocolate'' agar instead of undissolved or uncoagulated blood.

Using all sterile precautions, transfer 1 c.c. of the citrated blood to a tube of blood agar base (M-27), and the same quantity to a tube of dextrose agar (M-19), and rotate both immediately. To prevent contamination with air bacteria, flame the mouth of the tube, flame the pipette (not hot enough to coagulate the blood), hold the tube in a slanting position, and allow the blood to flow into the agar. Blood is mixed with agar in the manner described on pages 1430, 1431. Pour immediately into sterile Petri dishes and allow to harden.

Carry out the same procedure, using 2 c.c. quantities of blood in each tube of blood agar base and dextrose agar, and pour Petri dishes of the mixture. Incubate all four of the Petri dishes at 37° C.

Transfer 1 c.c. of blood also to Brewer's thioglycollate medium M-47 and incubate in the usual manner.

Examination of the Culture.—

Examine both the broth culture and the Petri dish cultures every day for evidence of growth of bacteria. It is not impossible, when the number of bacteria in the blood is low, to find a cloudy broth with no evidence of growth on the Petri dishes. Procedure for further investigation and reporting of apparently negative cultures is given below.

Make a hanging drop of the top fluid of the broth culture. At the same time, remove part of the material from the bottom of this culture with a long sterile capillary (page 1467). Make a Gram stain and observe the morphology and staining characteristics of the organisms.

If bacteria are present in the broth and not on the Petri dishes, transplant some of the broth culture to plates of blood agar (M-28 or M-29) and incubate at 37° C.

If smears or hanging drops show gram-positive cocci, transplant to blood agar plates. Use material both from the top of the broth culture and from the point of contact between the broth and the blood, which has settled to the bottom of the blood culture. Draw out a long capillary from sterile tubing (page 1394). Pick up a portion of the medium from the top of the bottle, from the interface between blood and broth, and from the blood at the bottom of the culture bottle.

Since some streptococci are anaerobic, it is well to transfer some of the culture to Brewer's thioglycollate medium M-49.

Place this material on the surface of a Petri dish of blood agar, and streak in such manner that individual, discrete colonies will develop. Or, add the material to a tube of melted dextrose agar at 45° C., add 1 c.c. of sterile rabbit blood to the agar, rotate quickly between the palms of the hands, and pour with sterile precautions into a sterile Petri dish. Be sure to autoclave the emptied tube, for it may contain virulent bacteria. Using this second method of transplantation, deep as well as surface colonies may be obtained. This enables one better to determine whether or not hemolysis occurs. As soon as the agar has solidified (if the second method is used), or as soon as the plate has been inoculated, incubate at 37° C.

If no subsequent growth occurs, repeat the transplantation. It may be necessary to use a richer culture medium for transplantation of the organisms. (See Method No. 2.)

If the original broth culture contained streptococci, keep it in the refrigerator (not the incubator) until the final examination is complete. This aids in preventing further contamination of the culture from too much handling.

Identify the streptococci if found. If the colonies on blood agar are surrounded by a zone of hemolysis, the organisms are *Streptococcus hemolyticus* group. If the colonies are surrounded by a zone of methemoglobin, showing a faint greenish cast, they are either *Streptococcus viridans* group or pneumococci. For further details on differentiation of types of streptococci, see pages 1487 ff.

Examination for bacteria other than streptococci is given in the alternate method immediately following this method.

Method No. 2

Alternate Method

1. Prepare for operation and draw blood as above.

2. Have on hand large test tubes containing (a) brain heart infusion with agar, p-amino benzoic acid and penicillinase M-4; (b) thioglycollate medium M-47; (c) trypticase soy broth M-3 *or* Huddleson's broth M-24. Chopped meat medium M-12 may be substituted for brain broth infusion.

3. Inoculate tubes with blood directly from the vein *or* collect blood in a sterile container containing 2 c.c. of 2.5% sodium citrate solution, and also inoculate tubes from the citrated blood.

4. Be sure that enough blood is withdrawn to inoculate: (a) *either* 2 tubes of each of the above media (containing 25 c.c. to 30 c.c. of medium per tube) with 2 to 3 c.c. of blood per tube; (b) *or* to inoculate one bottle of each of the above media (containing 100 c.c. of the medium per bottle) with 5 c.c. of blood per bottle.

Precautions.—The media in the tubes or bottles must reach a sufficient depth to allow microaerophilic or anaerobic conditions at the bottom of these containers. If the upper layer of the thioglycollate medium shows a bluish discoloration, heat it for a few minutes at 80° C. Do this, also, with brain heart infusion before adding penicillinase. Media must be cooled to between 20° and 38° C. before inoculating them.

It is not necessary to add p-amino benzoic acid to the thioglycollate broth. Trypticase soy broth and Huddleson's medium may be supplemented with both p-amino benzoic acid and penicillinase.

5. Incubate all tubes or flasks at 37° C. Trypticase soy broth or Huddleson's medium must be incubated in CO_2 atmosphere (pages 1472, 1575).

6. Observe all tubes for three weeks. Make readings and subcultures on the second, third, seventh, fourteenth, and twenty-first day of incubation.

7. Using a sterile capillary pipette, and observing sterile precautions, take material from the interface of blood and broth. If this cannot be done, shake the cultures and use a loopful of the material.

8. Make Gram stains. Proceed according to the findings:

(a) **If gram-positive cocci are seen,** plate on blood agar M-28, M-29, making streaked and poured plates.

(b) **If gram-negative cocci are present,** proceed as under (a) but also streak chocolate blood agar M-31, M-32, M-33, and incubate in CO_2 atmosphere and under normal conditions.

(c) **If gram-negative rods are present,** proceed as under (a) but also streak a MacConkey plate M-63 *or* an eosin-methylene blue plate (M-71 or M-72). Pour tryptose agar plates M-16 and incubate in CO_2 atmosphere. Streak azide or alcohol plates (M-21 to M-23).

(d) In tropical countries, **P. pestis may be present.** In such cases streak on 3% salt agar M-15.

If the blood culture is contaminated, repeat the test, obtaining a new blood culture from the patient immediately. Plate out the contaminated culture if permission is not granted to obtain another culture. If the pathogen can be fished from the contaminated culture, twenty-four hours can be saved in the examination.

Examination of Transplants

I. **If gram-positive cocci are present,** but do not grow under aerobic conditions, try anaerobic cultures on blood agar plates or yeast plate medium (M-14).

II. **If gram-positive aerobic cocci are present.**—

(a) **Staphylococci:** Test as described on page 1485. Be cautious if nonhemolytic, non-coagulase-forming staphylococci are found. They usually are contaminants. For rapid differentiation, hemolysis on blood agar M-28 or M-29, the coagulase test R-4, and fermentation of mannitol in broth M-5 or semisolid medium M-88 are satisfactory.

(b) **Streptococci**: Make preliminary differentiation according to growth and hemolysis on blood agar plates. Methods of differentiation are described on pages 1487 ff. For rapid differentiation, prepare β-hemolytic organisms for serologic classification; inoculate for hippurate reaction R-11 and for test of heat-resistance.

Alpha-hemolytic streptococci must be tested for bile solubility (R-10); fermentation of inulin M-5 or M-6; action on aesculin M-87; hippurate reaction R-11; dextran formation from 5% sucrose, page 1489.

(c) Bile soluble, inulin-negative organisms are suspected of being **Pneumococci.** Aesculin-positive organisms may be **Enterococci.** Inulin-positive, hippurate-negative, dextran-positive organisms are **Streptococcus endocarditicus.**

III. **If gram-negative cocci are present.**—

(a) They may be mutants or variants of gram-positive organisms. These grow well on blood agar plates and show typical reactions, if not changed too much.

(b) Meningococci grow well under aerobic conditions, while gonococci grow better in CO_2 atmosphere. Both give positive oxidase reactions R-18. For further differentiation serum broth with fermentable substances M-6, M-7 are used, together with serologic reactions, page 1502.

IV. **Gram-negative rods.**—

(a) **If gram-negative rods**, which grow well under aerobic conditions, are present, colonies from MacConkey or eosin-methylene blue plates are used. Test according to the schedule outlined under stool examination (pages 1632 ff.). If coliform organisms are present, test their IMViC reaction (page 1536).

(b) *Pasteurella tularensis* grows very slowly. It may be present in the blood during the first week of the disease.

(c) *Brucella abortus* grows only in CO_2 atmosphere, on tryptose agar, while other Brucellae grow well on this medium in a normal atmosphere. Differentiation is carried out by growing on liver infusion agar plates with the addition of dyes (M-26a) and by agglutination.

V. **If gram-positive bacilli are present,** aerobic sporeformers are usually indicative of contamination.

(a) Anthrax bacilli are differentiated according to the outline of Stein (page 1547). The most important reactions are pathogenicity for guinea pigs and lack of hemolysis.

(b) Anaerobic gram-positive organisms are classified as sporeformers (Clostridia) and "others." The latter are difficult to distinguish. Proceed according to pages 1554 ff.

VI. **For Leptospira,** see pages 1587 ff.

If a **blood clot** is received, pour it into a sterile 50 c.c. syringe; mount a small needle on the syringe; expel the air through the needle; discard the needle, and press the contents out into a flask containing culture medium.

The alternate method of bacteriologic examination of blood is recommended for routine procedures, if the patient has received sulfa drugs. Culture media containing p-amino benzoic acid are then used. If the patient has received penicillin, use media containing penicillinase (M-20). About 0.03 gm. cysteine hydrochloride or sodium thioglycollate will counteract streptomycin in 100 c.c. of medium.

ANIMAL INOCULATION WITH LAKED BLOOD

Collect 20 c.c. of venous blood and transfer immediately to a flask or bottle containing 90 c.c. of sterile distilled water.

Add a few drops of sterile 5% solution of tannic acid to form a precipitate.

Centrifuge at high speed.

Inject the entire sediment into a guinea pig.

Tag the pig. Record the number of the guinea pig, the date and number of the specimen, and the weight of the guinea pig. Proceed in the usual manner.

CEREBROSPINAL FLUID*

Whenever possible, collect the spinal fluid in three different sterile tubes. Discard the first tube if it contains blood. Use the second tube for cell count and chemical examination; use the third for bacteriologic tests.

Spinal Fluid in Meningococcus Meningitis†

Turbidity.—Meningitic spinal fluid is very turbid.

Globulin Test.—Make both the Nonne-Apelt and the Pandy tests for globulin.

Meningitic spinal fluid gives a strong positive globulin test.

Lange Colloidal Gold Test.—The curve in meningitis is typical. See Lange's colloidal gold reaction, pages 1253, 1255.

Cell Count.—The cell count in bacterial meningitis is unusually high. (See page 1243.)

Routine Procedure

The routine procedure in the bacteriologic examination of spinal fluids consists of two procedures: (1) examination of a Gram-stained slide of the sediment; and (2) proper culture methods.

Centrifuge the spinal fluid and examine the sediment after staining with the Gram stain.

At the same time, inoculate 1 to 2 c.c. portions of the cerebrospinal fluid into (a) one test tube containing brain infusion broth with p-amino benzoic acid and penicillinase M-4, and (b) one tube of thioglycollate medium M-47. Prepare the tubes as for blood cultures.

Certain information as to the proper procedure to follow can be gained from examining the Gram-stained slide.

1. **If gram-negative cocci or rods are found in the smears,** streak on (a) chocolate agar M-33; (b) blood agar prepared with human or rabbit blood, M-28, M-29.

Incubate duplicate plates, one set in CO_2 atmosphere, the other in normal atmosphere. Gonococci grow better in CO_2 atmosphere, and on chocolate agar.

Meningococci may be typed by serologic methods (page 1502) as soon as possible. Fermentation tests (page 1501) are helpful in differentiating them.

H. influenzae grows better on blood agar. Transfer the growth suspected of being *H. influenzae,* to a second plate. Streak over the second plate (cross-streaks) with a culture of *Staphylococcus aureus.* The *H. influenzae* grows better in the vicinity of Staphylococcus colonies (satellite phenomenon).

If large colonies are present on blood agar, transfer them to triple sugar iron agar M-80, and proceed as under "stool examination." Coliforms are differentiated by the aid of their IMViC reaction (page 1536).

One must keep in mind that Klebsiellae (page 1504) may also be found.

2. **If gram-positive organisms are found,** proceed as under "blood cultures."

3. Cultivation of cerebrospinal fluid on the chorio-allantoic membrane of the developing chick is an excellent method for detecting some infectious agents (viruses). See pages 1473 ff.

4. **If infections with yeasts or molds are suspected,** or if such organisms are seen in the stained smears, inoculate:

(a) Three blood agar plates M-28, M-29.

(b) Three plates of Sabouraud dextrose agar M-102.

Seal two of the blood agar plates and two of the Sabouraud plates with Plasticine or adhesive tape. Incubate one of the blood agar plates and one of the Sabouraud plates (sealed) at 37° C., the other plate (sealed) at room temperature.

Incubate the remaining blood agar plate and the Sabouraud plate (not sealed) under anaerobic conditions (pages 1469 ff.).

If only limited facilities are available, media in tubes may be used, provided the cerebrospinal fluid does not contain other microorganisms.

For further explanation, see under "Skin."

---

*See Chapter VII, Puncture Fluids, for other tests.

†See pp. 1260 ff. for other tests of meningitic spinal fluid.

5. **Rarely, P. tularensis may be present.** Grow such organisms on cystine agar M-30.

6. **In exceptional cases, Listeria monocytogenes will be found.** Culture the spinal fluid on blood agar M-28, M-29.

7. **Examination for tuberculosis.** Centrifuge the cerebrospinal fluid and streak the sediment directly on at least three media favorable for the growth of *Mycobacterium tuberculosis.* The author prefers Petrik medium (M-58). The medium of Dorset (M-59) or those of Petragnani (M-61) *or* Loewenstein (M-60) and Dubos (M-62) represent a good selection. More recent media are those of Tarshis (M-58^a) and Whalen (M-58^b).

Examine the sediment of the centrifuged specimen after staining with acid-fast staining methods.

If animal inoculation is desired, inject a guinea pig (page 1647).

8. **For Leptospiras,** see pages 1587 ff.

PUS FROM LOCALIZED ABSCESS

Assemble the following materials:

Sterile swab.
Sterile test tube.
Alcohol burner.
Iodine or Merthiolate tincture.
Alcohol.
Sterile sponges
Sterile scalpel.

Disinfect the skin over the abscess and allow to dry.

The attending physician makes the incision into the abscess.

Remove and discard the first pus from the abscess.

Without touching the skin, carefully remove a portion of the pus with the sterile swab. A platinum wire may be used instead of the swab. The wire must be heated and allowed to cool before using. Put the swab into the tube and rush it to the laboratory.

Inoculate (a) one tube of thioglycollate broth M-47; (b) one plate of blood agar M-28, M-29 or M-21 to M-23; (c) one tube of broth M-2.

Make smears and stain with Gram stain. If **staphylococci are present,** proceed with the coagulase test.

1. **If gram-negative rods are present,** streak on the surface of an eosin-methylene-blue plate M-71, M-72. This medium is selected because Protei do not spread on it if the surface is not wet. Proceed with the examination usually made for gram-negative rods as suggested under ''stool examinations.''

2. **If gram-positive bacilli are present,** proceed as for ''Anthrax'' and ''Clostridia'' outlined under *blood.* Nonsporeforming anaerobes are difficult to classify.

3. **If mycotic elements are seen,** inoculate 3 blood agar plates M-28, M-29, and 3 Sabouraud dextrose plates M-102, as outlined under ''spinal fluid.''

4. **If, as very rarely occurs, Past. pestis is present,** examine for this organism as described under *Past. pestis* on page 1568.

5. **If a tuberculous lesion is suspected,** the physician removes pus from the abscess by puncture, and submits it to the laboratory for examination. The pus is then treated as sputum.

A special method of examination of pus for tubercle bacilli is as follows:

In the examination of abscess pus for tubercle bacilli, it must be remembered that these organisms decolorize much more rapidly when present in pus than when found in other specimens or in cultures.

A smear is made and stained with the Ziehl-Neelsen stain and examined for tubercle bacilli. In tubercular pus, many mononuclear elements (monocytes) together with degenerated cell elements are present. There is also much granular material. However, the absolute differentiation of tubercular pus from other abscesses cannot be definitely made from the cellular content.

A portion of the pus may be injected into guinea pigs for evidence of tubercle bacilli.

MATERIAL FROM SEROUS CAVITIES

Material from serous cavities is examined like pus. Attention must be given, however, to its physical, chemical, and cytologic properties (see Chapter VII and pages 2156 and 2184 ff.).

A special method for detection of tubercle bacilli in pleural fluid is as follows:

Unless pleural fluid is centrifuged immediately after aspiration, a coagulum will form.

(1) Before coagulation takes place, add a small amount of calcium chloride to the pleural fluid, or defibrinate the fluid.

Add an equal volume of distilled water, or a small amount of 15% Antiformin.

Centrifuge at high speed.

Make smears. Fix in the flame. Stain with the Ziehl-Neelsen stain and examine for tubercle bacilli.

(2) If the pleural fluid has formed a coagulum, proceed in the following manner:

Separate the clot from the pleural fluid.

Add to the clot equal volumes of N/1 sodium hydroxide and 15% Antiformin solution.

Shake thoroughly.

Digest for thirty minutes.

Centrifuge at high speed for fifteen minutes.

Decant and discard the supernatant fluid.

To the sediment, add a few drops of N/1 hydrochloric acid.

To isolate *Streptobacillus moniliformis,* inoculate fluid medium M-118 with fluid from the joint.

After 2 or 3 days, streak the growth to the solid M-118 medium.

Either make smears, inoculate tubes of Loewenstein medium (M-60) or Petrik's medium (M-58^{a}) or Petragnani (M-61), Tarshis or Whalen (M-58^{a} and ^{b}), or inoculate guinea pigs.

WOUND SECRETIONS AND FISTULA*

Due to the variety of methods used in the treatment of wounds, the material available for examination may be a tissue specimen collected by biopsy, swabs, aspirated fluid, or fragments of skin.

1. Specimens, particularly tissues, should be shipped in the frozen state.

In all other cases it is recommended that the specimen be mailed in screw-capped tubes containing *either* chopped meat medium (M-12) *or* fluid thioglycollate medium (M-48). It is essential that the containers be large enough (e.g., 50 c.c.) and that at least 20 c.c. of the medium be in each of them.

For particular instructions, see Clostridia, page 1554.

2. Upon arrival in the laboratory, chopped meat medium (M-12) is inoculated with the frozen specimens.

All tubes, i.e., those inoculated at the bedside and those inoculated in the laboratory, are incubated for 24 hours at 37° C.

3. After incubation, 1 to 1.5 c.c. of the liquid are withdrawn with a sterile pipette and placed in thioglycollate broth (M-48) in 5 by ⅝ inch tubes, containing about 6 c.c. per tube.

The original liquid is kept at room temperature for reference, while the thioglycollate broth subculture is incubated for 24 hours at 37° C.

4. From tubes *3,* inoculate the following plates:

1 eosin-methylene blue plate (M-71 or M-72)
1 tellurite blood agar plate (M-41 or M-42)
2 yeast blood agar plates (M-14)
1 sodium azide-chloral hydrate plate (M-22)
1 modified Nagler plate (M-57)

---

*The method given here is that used in the 406 Medical General Laboratory of the U. S. Army, as described in its *Annual Historical Reports* for 1950, 1951, and 1952. We are indebted to Mr. Th. Wetzler, Research Bacteriologist, and Capt. J. Marshall for this outline.

5. Incubate the eosin-methylene blue, the tellurite, and one of the yeast blood plates aerobically for 24 hours at 37° C.

Incubate the other plates anaerobically for at least 40 hours, but not more than 60 hours, at 37° C., using anaerobic methods of incubation as recommended under Clostridia, page 1555.

6. Perform an acrolein test (R-19) in tube *3*.

7. Keep in mind that many aerobic organisms will grow well under anaerobic conditions. Thus, not all colonies grown on the plates contained in the anaerobic jars are Clostridia.

Gram-negative organisms will not grow on the tellurite and the azide-chloral hydrate plates. They will be picked up best from the eosin-methylene blue plate and examined as under *Stools*, pages 1631 ff.

The hemolytic reactions of cocci cannot be recorded from plates containing carbohydrates. Subcultures on plain blood agar plates (M-28 or M-29) must be examined for this purpose.

Gram-positive aerobic rods will not grow on eosin-methylene blue plates. Cocci, however, may form small colonies with a purple central dot on them.

8. Read the acrolein test (R-19) on the modified Nagler plate.

9. All gram-positive bacilli which show negative or negligible growth on aerobic yeast blood agar plates are tentatively classified as Clostridia and studied further according to the outline for that genus, pages 1548, 1557 ff.

SPUTUM

The examination of sputum consists of two procedures: macroscopic and microscopic examinations.

The macroscopic examination comprises the following examinations: (a) the total volume in twenty-four hours; (b) the color; (c) the odor; (d) the consistency; (e) the presence of nasal mucus, carbon, pus, blood, cheesy particles, food, or vomitus; (f) layer formation; (g) lung stones; (h) bronchial casts; (i) Dittrich's plugs.

A microscopic examination is made on the stained and the unstained specimen. The unstained specimen is examined for (a) elastic fibers; (b) Curschmann's spirals; (c) Charcot-Leyden crystals; (d) myelin globules; (e) pigmented cells; (f) ray-fungus (*Actinomyces bovis;* (g) pus cells; (h) epithelial cells; (i) blood. The stained specimen is examined for (a) pus cells; (b) epithelial cells; (c) tubercle bacilli, reported according to the Gaffky scale (see page 1609); (d) other pathogenic bacteria, such as pneumococci, Klebsiellae, staphylococci, streptococci, etc. Other bacteria which may contaminate the specimen are not usually reported, unless it is necessary to convey to the physician the fact that the specimen is badly contaminated either with air organisms, or with saliva. In such cases, report sarcinae, hay bacilli, yeast cells, molds, higher bacteria, spirochetes, fusiform bacilli. It is very important to examine the sputum for (e) pathogenic yeasts and molds, and (f) for eggs of animal parasites.

Collecting the Specimen

A one- or two-ounce sterile wide-mouthed bottle is used. This has been thoroughly washed, and sterilized in the dry heat sterilizer at 170° C. for two hours. The first specimen of the morning is collected. The patient is instructed to rinse his mouth well with water, then to cough up a specimen from his lungs, not to expectorate saliva from the mouth. Discard the first few specimens, thus avoiding food remnants.

Some laboratories prefer 24-hour specimens for *M. tuberculosis* examination.

Macroscopic Examination

1. **Total Volume in Twenty-Four Hours.**—Normally the quantity of sputum is negligible. It is very important in some cases, particularly in checking the progress of a tubercular patient, to measure the volume of the twenty-four-hour specimen of sputum.

2. **Color.**—Pour the specimen into a Petri dish on a black surface. The color may be gray, yellow, green, red, brown, or black. Pure mucoid expectoration is transparent and colorless. Leukocytes impart an opaque characteristic to the sputum, the specimen becoming green upon standing, if pus is present. In infections with *Pseudomonas aeruginosa (B. pyocyaneus)*, in jaundice, and in pneumonia during lysis and subacute pneumonia, the specimen may be green. A green sputum is also noted at times in pulmonary carcinoma, in bronchiectasis, and in pulmonary abscesses. A red color in the sputum may, and usually does, indicate the presence of blood. Bright red blood has recently been expressed, while the brown colors come from blood which has been retained in the lung. Bright red streaked sputums usually are seen in pulmonary tuberculosis, although this is not a diagnostic point. In pulmonary gangrene the sputum is a dirty brownish color, due to methemoglobin and hematin. In chronic passive congestion due to disease of the heart the sputum is also brown. The typical sputum of pneumonia is a rusty or chocolate color, often referred to as ''prune juice'' sputum. Vomited blood that has been swallowed is black and acid.

3. **Odor.**—Fresh sputum has no odor normally. In pulmonary gangrene and putrid bronchitis, a foul odor due to decomposition by anaerobic bacteria is noted. Old sputums undergo putrefaction rapidly.

4. **Consistency.**—Tenacious sputums usually contain mucus. Thick purulent masses that sink in water are found in sputum from cases of chronic tuberculosis. Sputums consisting of pure pus, which may be quite fluid, are found in cases of acute pulmonary gangrene, pulmonary abscesses, putrid bronchitis, and following perforations into the lung in empyema.

5. **Nasal Mucus, etc.**—Examine the sputum in the Petri dish. Cheesy masses may sink to the bottom, and may vary in size from a millet seed to the size of a pea. In far-advanced stages of pulmonary tuberculosis, and in acutely progressive tuberculosis, these particles are found. They usually contain numerous tubercle bacilli. Do not confuse them with food particles, or Dittrich's plugs (9, below).

6. **Layer Formation.**—Observe whether the sputum separates into three sharply defined layers when a large volume is standing in a tall vessel. This characteristic of sputum is seen in cases of bronchiectasis, gangrene, and abscess of the lung.

7. **Lung Stones.**—Pour the specimen through a fine wire gauze screen. Small calcified nodules of tuberculous tissue may be found. They are white or gray.

8. **Bronchial Casts.**—Transfer suspicious particles to water, float them, then mount on a slide with a cover glass, and examine with the low power

magnification. They are recognized by their imperfect branching structure. They are found in tuberculous hemoptyses, and are also demonstrated in croupous pneumonia immediately following resolution. They are white when caused by true fibrinous bronchitis, but not uncommonly are yellowish brown or reddish yellow. Most of the branches appear to be cylindrical, but some of them are flat.

9. **Dittrich's Plugs.**—They are yellowish or gray caseous masses usually about the size of a pinhead, but sometimes as large as a bean. They emit a foul odor when crushed. Do not confuse them with cheesy particles. They consist microscopically of granular débris, globules of fat, fatty acid crystals, and bacteria. They are seen sometimes normally, but more frequently in cases of putrid bronchitis and bronchiectasis.

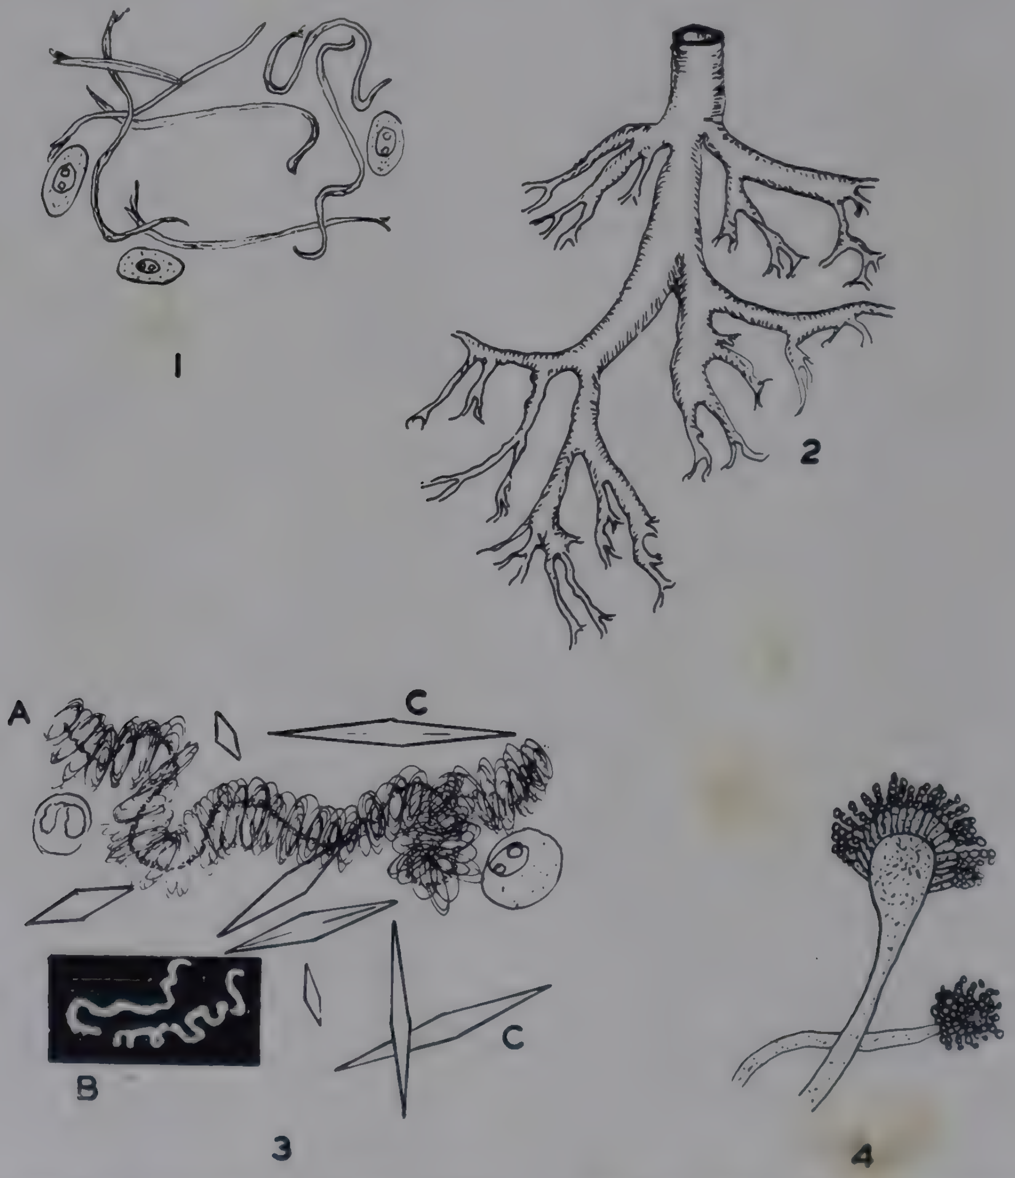

Fig. 389.—Unstained sputum: 1, elastic fibers; 2, bronchial cast; 3, A, Curschmann's spirals magnified and B, not magnified, C, Charcot-Leyden crystals; 4, aspergillus.

Microscopic Examination

(A) Unstained

A cover glass preparation is made by placing a drop of sputum on a glass slide and covering it with a thin cover glass. Examination is made with the low power magnification first, then with the high dry lens. Look for the following:

1. **Elastic Fibers.**—Bits of elastic tissue may be coughed up in the course of acute destruction of the lung parenchyma, as in cavity formation. Select small bits of necrotic

tissue, colored particles, or purulent masses. Place them on a glass slide, and tease with a drop of potassium hydroxide solution to dissolve the caseous matter. Press a cover glass over this preparation, and examine microscopically. The smears must be thin. They are coils of highly refractile, delicate, smooth, elastic fibers, with frayed ends. Do not confuse them with food particles and cotton fibers. Food particles are coarse, and have sharply cut angular or rounded ends, while elastic fibers are flat and twisted.

2. **Curschmann's Spirals** are found in true bronchial asthma. They consist of a twisted network of extremely delicate fibers containing epithelial cells and a number of leukocytes. Select a whitish, threadlike formation, place on a slide, cover with a cover glass, and examine with the 16 mm. objective. Typical spirals will be seen. They can sometimes be seen with the naked eye.

3. **Charcot-Leyden Crystals** often appear in the sputum after it has been coughed up and has stood for some time, even though they are absent immediately after collection of the specimen. They are pointed at the ends, and are colorless, often needle-like. On cross-section, they are hexagonal. They are present in bronchial asthma.

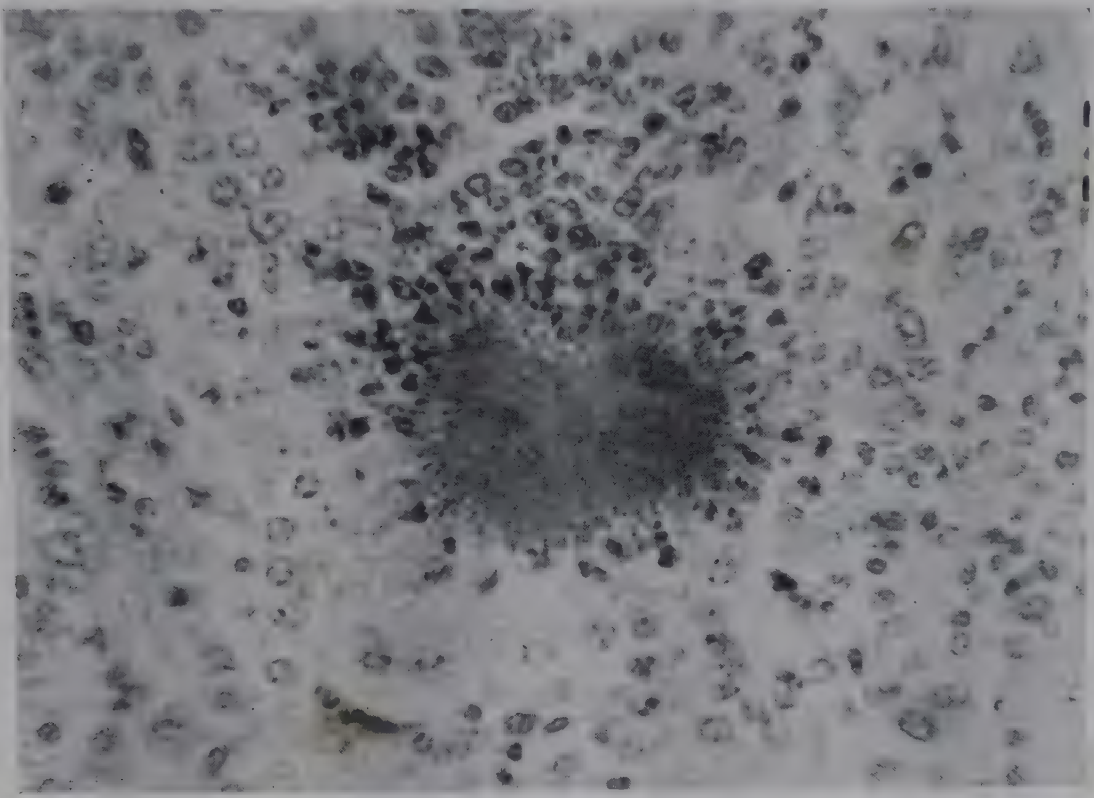

Fig. 390.—*Actinomyces bovis* (×1500). (Courtesy Dr. Oscar Felsenfeld.)

4. **Myelin Globules** are colorless, round, oval, or pear-shaped globules of various sizes, resembling fat droplets, often showing peculiar concentric or irregularly spiral markings. They have no clinical significance.

5. **Pigmented Cells.**—Heart-failure cells contain rounded clumps of brown-pigmented granules. The granules are present in large mononuclear cells.

6. **Ray-Fungus.**—Search the sputum carefully for small gray or yellowish "sulphur" granules. Crush one of these granules between a slide and a cover glass, and examine with the 16 mm. objective. The fungus is composed of a network of threads in a radial arrangement. Fig. 390. (See Actinomycosis, pages 1776 ff.)

7. **Pus Cells** and other leukocytes are characteristic.

8. **Epithelial Cells.**—The majority of epithelial cells in the sputum are the large squamous type. (See page 96.) They are easily recognizable. They are insignificant unless appearing in great numbers.

9. **Blood.**—Erythrocytes are characteristic when present. They are biconcave disks. They may be significant if the source of bleeding is within the lung. The macroscopic

examination of sputum for blood is more important than the microscopic. In tuberculosis, bloody expectoration is very important. Hemoptyses are frequent in bronchiectasis, lung abscess, cancer, silicosis, and heart disease.

Bleeding often arises from sources outside the lung. Streaks mingled with mucus and saliva may originate in the gums, pharynx, or tonsils. In severe bronchitis with tenacious exudate, the sputum is often streaked with blood.

(B) Stained

Pour the specimen into a Petri dish.

(a) Direct Smear

Search the specimen in the Petri dish for ''cheesy'' particles if examining for tubercle bacilli.

Spread the particles in an even layer over the surface of a glass slide.

Allow to dry in the air. Fix in the flame. Stain either with the cold Ziehl-Neelsen stain (24 hours), or with the hot Ziehl-Neelsen stain (3 minutes). (Page 1411.)

Stain other slides with Gram stain.

Examine with the oil immersion objective for the following:

1. **Pus Cells.**—Pus cells appear characteristically when stained. (See unstained examination above.) They stain blue.

2. **Epithelial Cells.**—Epithelial cells stain blue with the Ziehl-Neelsen stain, and are characteristic.

3. The relative **Number of Bacteria** is judged by the examiner. Number of bacteria is recorded as very occasional, occasional, few, moderate number, many or very many.

4. **Contaminants.**—Nonpathogenic yeasts and molds, hay bacilli, salivary organisms, diphtheroids, sarcinae, and other common contaminating organisms of sputum are not reported unless the sputum is so badly contaminated as to render an accurate examination impossible.

5. The **Lung Fluke** or *Paragonimus westermani* is sometimes found in sputum, since it inhabits the lung producing small cavities. The *Paragonimus westermani* (see Parasitology chapter) produces a moderate degree of hemorrhage at times. The eggs of this worm may be found in the sputum and also in the stool from swallowed sputum. The worms are seldom found except at autopsy in the course of the examination of the lungs. They are oval, red-brown, with a flat ventral surface and measure 8 to 10 by 4 mm. The eggs are very thin-walled, smaller than the Diphyllobothrium eggs and at one end have a small operculum.

6. If **Pneumococci** are present and typing is desired, proceed with the typing. When the number of organisms is small, inoculate a mouse and use the peritoneal exudate for typing (page 1494).

7. **Klebsiella pneumoniae** is cultured (a) on eosin-methylene blue agar M-71, M-72, on which it forms large, moist colonies; (b) or on blood agar plates.

8. Examination for **P. tularensis** and **Anthrax** is described in the section under blood cultures.

9. If examining for **Pasteurella pestis**, isolate on yeast agar M-14.

10. To examine for **molds** and **yeasts**, use the plating method, described under ''Fistula.'' Great care must be exerted when evaluating these cultures. For this type of examination, instruct the patient to rinse his mouth with a weak solution of alcohol in water before collecting the sputum specimen.

11. **Examination for Tubercle Bacilli.**—

The sputum is collected in the morning, in waxed paper cups. Some prefer sputum collected for a 24-hour period.

If the ''sputum'' delivered to the laboratory consists only of oral saliva, note this fact on the report.

Select a particle of the sputum and streak it over a slide which has never been used before, carefully rubbing it in the slide, so that a uniform smear results. Repeat this process with another particle collected from a different part of the sputum. Be careful not to scratch the slide with the loop. Carbol fuchsin often accumulates in these scratches and may resemble acid-fast organisms. New slides are used for the same reason.

Examine under the oil immersion objective and report the tubercle bacilli according to the Gaffky scale below. Count all the tubercle bacilli in 10 to 20 consecutive fields and take the average per field.

Gaffky Scale for Reporting Tubercle Bacilli in Sputum

Gaffky I —Only 1 to 4 bacilli in the whole preparation.
Gaffky II —Only 1 bacillus on the average in many fields.
Gaffky III —Only 1 bacillus on the average in each field.
Gaffky IV —2 to 3 bacilli on the average in each field.
Gaffky V —4 to 6 bacilli on the average in each field.
Gaffky VI —7 to 12 bacilli on the average in each field.
Gaffky VII —13 to 25 bacilli on the average in each field.
Gaffky VIII —About 50 bacilli on the average in each field.
Gaffky IX —About 100 bacilli on the average in each field.
Gaffky X —Innumerable bacilli on the average in each field.

Fluorescence microscopy (below) is also used to identify tubercle bacilli.

If the microscopic examination does not reveal tubercle bacilli, proceed with digestion and concentration of the specimen.

(b) Concentrated Smear

Concentrate the specimen (page 1613).

With the sediment make two smears. Stain with Ziehl-Neelsen stain.

Examine for tubercle bacilli.

This examination is carried out only when tubercle bacilli have not been found in the direct smear.

(c) Examination for Leukocytes

(a) **Eosinophiles.**
Eosinophiles may be detected in the smear by staining with the Giemsa, Wright, or Hansel stain. They are characteristic. (See pages 640 and 1353.)

(b) **Monocytes.**
Monocytes may be recognized by their typical form in the routine Ziehl-Neelsen stain, or they may be stained with either the Giemsa or other blood stain. The Giemsa stain is preferable, since it stains monocytes characteristically. (See page 641.)

Fluorescent Microscopic Demonstration of Tubercle Bacilli

Richards, Kline, and Leach[1] described a new and useful method of increasing the number of positive demonstrations of tubercle bacilli in sputum by means of fluorescent microscopy. Fluorescence is a property of certain substances whereby the absorption of invisible, ultraviolet radiation stimulates the emission of visible light. Exactly how this takes place is not clearly known, but it presumably involves electronic rearrangement. Since acid-fast organisms will absorb and retain certain fluorescent acid-fast materials in the same manner that they retain acid-fast dyes, the principle affords a new approach to the problem of demonstrating acid-fast organisms. In practice it seems to have advantages over other methods.

The spontaneous fluorescence of some substances was observed by Köhler in 1904 while experimenting with the ultraviolet dark-field microscope. Kaiserling demonstrated the whitish-blue fluorescence of a suspension of human tubercle bacilli in 1917. A bovine strain was greenish. A number of other reports have since been made, followed by Kline and Leach, the present writers, who reported in 1940 the fluorescence technic suitable for demonstrating tubercle bacilli, lepra bacilli, and nonpathogenic acid-fast organisms.

---

[1] Am. Rev. Tuberc., Sept., 1941.

Apparatus.—

For this demonstration a simple fluorescence apparatus for use with monocularmicroscopes has been designed by Richards. It consists essentially of light from a source rich in ultraviolet rays, passed through a blue ultraviolet transmitting filter, reflected through the microscope from an aluminum-surfaced mirror, and finally passed through a yellow contrast filter placed in the eyepiece. The high amperage, low voltage, concentrated filament bulb is satisfactory for this purpose. Filters are chosen so that the ultraviolet radiation and blue light transmitted by the lamp filter are absorbed by the yellow eyepiece filter and the field appears dark. Bacteria retaining auramine after staining appear as self-luminous, golden-yellow bodies with a distinctive morphology. They appear somewhat like dark-field preparations. The bacteria are easily recognized at comparatively low magnifications and can be found on a slide with a 16 mm. objective and the 20× compensating eyepiece. They can be seen in sufficient detail to be recognizable with the 8 mm. objective and the 20× compensating eyepiece or with a 4 mm. objective and a 10× eyepiece. The permanent glass filters are of American manufacture. The blue filter transmits ultraviolet, violet, and a small amount of blue rays. The yellow filter emitted by the auramine-stained tubercle bacilli is approximately of wave lengths 520 to 650 mμ. This method is not adapted to all types of fluorescence microscopy but serves for tubercle bacilli. The yellow filter used in the eyepiece prevents ultraviolet radiation from interfering with the visual picture and protects the observer's eyes from damage which might result from ultraviolet radiation.

Technic.—

Heat-fixed films are stained in the cold for three minutes with the following solution:

Auramine-O, made as follows: auramine-O, 1 gram; phenol absolute, 3 c.c.; and freshly distilled water, 97 c.c. This solution should be kept in the dark and made fresh every two weeks. It forms a slight precipitate without apparent loss of staining property.

Rinse the film in running water and decolorize for two minutes, and again for five minutes, with two applications of the following solution: concentrated hydrochloric acid, 4 c.c.; sodium chloride, 4 grams; 70 per cent alcohol, 1 liter. Decolorization may be continued much longer if desired, even for twenty-four hours. The slide is rinsed in running water, dried, and examined with the 4 mm. objective and a 10× ocular, or with an 8 mm. objective and a 20× ocular.

In films made from concentrates of sputum by sodium hydroxide digestion, practically no fluorescent material is seen, except the auramine-stained bacilli, so that the stain looks very much like a pure culture. Direct films from sputum or spinal fluid contain many fluorescent inflammatory cells which hinder the examination. In such cases, Hermann* suggests counterstaining for a few seconds with 0.1 per cent potassium permanganate solution followed by Loeffler's methylene blue, to make the cells so dark a blue that they become invisible.

Hughes Modification of Fluorescence Microscopy

An improved stain for fluorescence microscopy was suggested by Hughes.[1] He called renewed attention to the fact that the main factors preventing the wider use of this method has been the difficulty of adapting it to the use of the binocular microscope, as the illumination usually available is sufficient only for a monocular instrument. Since the proper style of lamp using a more powerful source of ultraviolet light is not as yet available, he tried to overcome this by improving the standard carbol-auramine stain. The "triple" stain finally developed has been found to give very satisfactory results, the brilliance of the fluorescing bacilli being increased and their contrast with the background emphasized because of a selective color effect.

---

*Hermann, W.: Deutsche med. Wchnschr. 12: 329, 1939.

[1] Hughes, G. C.: Tubercle 27: 91, 1946.

Reagents.—

Hughes Auramine Stain.—

Auramine O S	0.4	gm
Rhodamine B S	0.2	gm.
Acridine yellow, c.p.*	0.1	gm.
Liquid phenol (b.p.)	4	c.c.
Glycerine	30	c.c.
Distilled water	66	c.c.

Place the liquids in an Erlenmeyer flask, and add the dyes. Shake, heat to boiling point, and allow to cool.

Acid Alcohol.—

Add 0.5 c.c. of concentrated hydrochloric acid to 100 c.c. of 70 per cent ethyl alcohol.

Technic.—

Prepare very thin uniform smears, or the organisms will not stain evenly. No disinfectant should be present. Do not overheat in fixing.

Warm the stain to 70° C. by immersing the dropper bottle in a bath of hot water or by heating over a small flame.

Pour on the stain and leave for five minutes.

Wash off with tap water.

Decolorize with acid alcohol for five minutes.

Wash with tap water and allow to dry.

The tubercle bacilli are seen as brightly shining orange-red rods on the pale yellow-green background formed by the other constituents of the smear. Visibility is more marked, likewise the contrast, than with the orthodox auramine stain. No counterstains are necessary as they always cause dulling of the bright fluorescence of the organisms. This also makes examination of negative smears less tedious. Even a few bacilli are easily detected by this stain.

Where numbers of smears are to be examined in a laboratory, this method of examination is invaluable in saving time, eliminating eyestrain, and promoting accuracy. It is not recommended in a laboratory having only an occasional smear to examine.

Simplification of Fluorescence Microscopy

Graham[2] has very properly called attention to the fact that most of the literature on this subject makes it appear that this is a very difficult and complicated technic. He states that the insistence that a polished front-surface aluminum mirror must be used in place of the usual microscope mirror, in the belief that a silver surface absorbs the ultraviolet, is unfounded.

The simplified technic of Graham recommends a powerful, concentrated source of light, like a carbon arc or a 500-watt projection bulb, fitted with a condensing lens of about 7 cm. focal length with the blue filter in front of the condenser. This supplies an illumination bright enough to permit examination of films in a room darkened only by drawing the window shades. A satisfactory bulb for the purpose has been found in the 500-watt G.E. projection bulb operating on 110 to 115 volts. This is mounted in a ventilated sheet metal lamp box improvised in the laboratory. A condenser may be obtained from an old arc light, but a pair of ten-cent store reading lenses in tandem has proved equally useful. The proper relation of the lamp to the condensing lens is determined by trial and error, checking the effect of changes by the appearance of the field in the microscope. It has been found that the lamp should be set with the plane of the filament coils at an angle of about 30° to the optical axis so that the images of the coils will nearly overlap, as seen in the lighted field of the microscope. The housing should be large and provided with ample air inlet and outlet to dissipate the heat rapidly. It is better to place the filter in front of the condensing lens rather than behind it. The beam of light should practically cover the mirror of the microscope, and its location is best seen when the mirror is half covered with a card during adjustment.

---

*The acridine yellow (2:8 diamino-3:dimethyl acridine) used was prepared by Dr. Adrian Albert, Department of Organic Chemistry, University of Sydney. Commercial samples have not always proved satisfactory. The auramine and rhodamine B were ordinary commercial type dyes obtained from Imperial Chemical Industries, Ltd.

[2] J. Lab. & Clin. Med. 27: 1188, 1942.

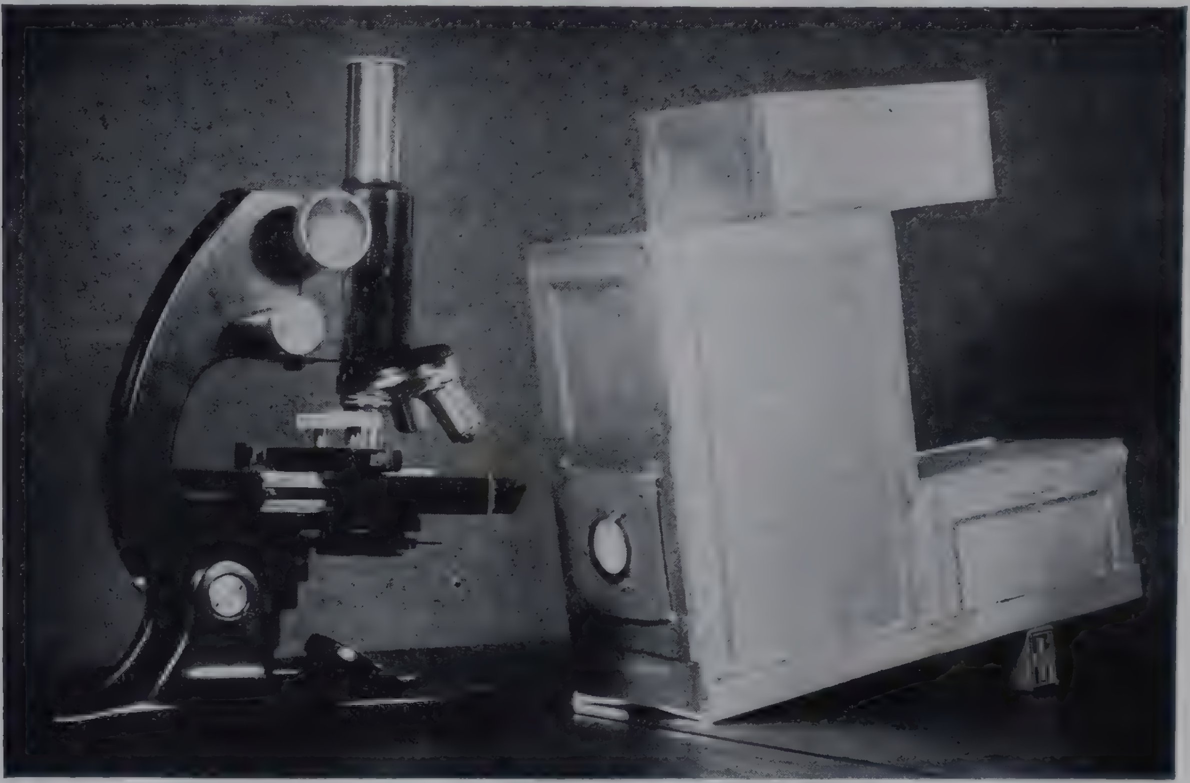

Fig. 391.—Graham's improvised light housing for fluorescent microscopy.[2]

In adjusting the illumination, it has been found convenient to pick up the light from the plane mirror with the low-power objective and center it properly before the high dry lens is swung into use. If organisms are abundant, they can usually be seen with the low power directly, and if the low- and high-power lenses are parfocal, the final adjustment is much simplified. The low-power field appears dark red, greenish, or almost black with any fluorescent particles showing as bright dots of light. The use of the immersion lens is unnecessary in routine examination of films, but it may be employed to check on the morphology of bacilli that appear atypical. Cedar oil, mineral oil, and sandalwood oil are not satisfactory as immersion media, since they all fluoresce and cast a haze over the field. Methyl salicylate (oil of wintergreen) is an excellent immersion oil with a high refractive index, and does not fluoresce. It can also be used as a mounting medium in the examination of tissue sections by the fluorescence method.

---

[2] Op. cit., p. 1611.

Note that an auramine-stained film will fade in the area exposed to the ultraviolet light if left in the field for about ten minutes. Stained films fade after the lapse of time, and the brightest preparations are those which have just been made. A Ziehl-Neelsen stain can be superimposed upon an auramine stain, but not vice versa.

A photograph of the improvised light housing is shown in Fig. 391. This photograph appeared in the article by Graham.

Richards and Miller believe that concentration and examination by fluorescence affords a more delicate test than has heretofore been available and it is recommended that at least for the present it be reserved for investigational work. It should not be substituted for the present accepted, less sensitive methods, in the clinical evaluation and classification of patients, until further information is obtained as to the clinical significance of such findings.

Concentration of Sputum

(1) Antiformin

The Antiformin method is the oldest method of concentrating sputum.

To 2 c.c. of the sputum add 6.5 c.c. distilled water.

Add 1.5 c.c. of Antiformin and mix well.

Let stand for 1 to 2 hours and centrifuge.

Wash sediment with distilled water and examine under the microscope after staining by the acid-fast method.

(2) Petroff's Method

The method of concentration of the specimen of sputum given here may be used for cultivating the tubercle bacillus, for making smears, or for guinea pig inoculation.

The specimen must be fresh.

Add to the sputum specimen an equal volume of 3% sodium hydroxide (3 grams sodium hydroxide sticks to 100 c.c. distilled water).

Place a piece of heavy paper over the cork, and shake vigorously until the specimen is of a homogeneous consistency.

Place in the incubator at 37° C. for one-half to three hours to destroy the contaminating bacteria.

Remove from the incubator, and add N/1 hydrochloric acid until the specimen is neutral to litmus paper. Add the hydrochloric acid slowly, and test the reaction frequently.

Add a few more drops of the N/1 hydrochloric acid until the specimen is slightly acid.

Transfer to test tubes, and centrifuge at high speed for thirty minutes.

Decant the supernatant fluid into a container which can be sterilized, and use the sediment either for smears, for guinea pig inoculation, or for cultivation.

For cultivation, select an egg medium M-58 to M-61.

Place three drops of the sediment over the surface of each of three slants of the medium. Rub the material into the medium by means of a platinum wire. Place the cork back into the test tube. Make a small opening in the cork by puncturing it with a sterile needle.

Replace the metal cap, and place into the incubator at 37° C. for six to eight weeks. If colonies appear overnight, they are not tubercle bacilli.

Take care not to agitate the test tubes on which the inoculation has been made, since the tubercle bacillus will not grow if disturbed to a great extent.

If tubes with cotton plugs are used, flame the cotton plug after inoculation, push it into the test tube about ¼ inch from the rim, then cover with paraffin. Allow the paraffin to harden. Puncture through paraffin and cotton to allow for exchange of gases.

If there is an abundance of water of condensation on the slants, it should be removed before inoculation.

Colonies are hard, dry, wrinkled, elevated, usually yellow or pink.

(3) MacNabb[1]

To the sputum in a sterile tube add an equal amount of 3% hydrochloric acid containing 0.002% brom thymol blue.

Shake vigorously.

Allow to stand at room temperature for 2 hours.

Neutralize with 3% sodium hydroxide.

Centrifuge for 30 minutes.

Use the sediment for inoculation of infusion agar slants M-15. If growth occurs in 24 hours, treat the specimen again for 1 hour with hydrochloric acid and again neutralize.

Plant about 0.25 c.c. of the sediment on each of 4 to 6 tubes of a combination of suitable media (see below).

(4) Hanks and Associates[2]

Digestion Fluid.—

Dissolve 4 gm. sodium hydroxide
0.2 gm. potassium alum
in 95 c.c. distilled water.
Add 5 c.c. 0.4% brom thymol blue

Mix 5 c.c. of the sputum with 5 c.c. of the digestion liquid in a sterile tube.

Incubate for 30 minutes at 37° C. in the water bath.

Neutralize with 25% hydrochloric acid.

Shake for 30 minutes.

If no flocculation occurs, add 0.2 c.c. of 1% ferric chloride solution.

Centrifuge for 5 minutes.

Examine sediment, or inoculate media, or inject guinea pigs.

(5) Clorox Method

Add to the sputum an equal volume of Clorox.

Mix well.

After 3 to 5 minutes, add an equal volume of 4% sodium thiosulphate in water.

Centrifuge for 30 minutes at 3,000 r.p.m.

Examine the sediment, inoculate media, or inject guinea pigs.

Evaluation of Media for Cultivation of Mycobacterium Tuberculosis

Bovine organisms grow better on media without glycerin (M-59) or with only a small amount of this substance.

Media without dyes may be used only for the culture of uncontaminated materials or materials which have been very carefully concentrated.

The author has had excellent results with Petrik's medium (M-58) and recommends it very highly. The reviewer of this chapter has excellent results with blood medium and with charcoal media and recommends them (M-58ª and M-58ᵇ).

Regarding the other media, those of Petragnani (M-61) and Loewenstein (M-60) are of about equal usefulness.

For routine use, the inoculation of two tubes without dye, and two tubes with dye is recommended. It is advisable to prepare only two types of media.

All tubes must be incubated for 8 to 10 weeks before final reading unless they are positive, at which time they may be reported.

For animal experiments, see under *Mycobacterium tuberculosis* (pages 1480 ff., 1647).

(A) (B)

Plate XLI.—Cultures of Tubercle Bacilli: (A) on Petroff's Egg Medium; (B) on Petroff's Gentian Violet Medium.

Neutral Red Virulence Test for Mycobacterium Tuberculosis

Dubos and Middlebrook[1] described the following test for the determination of virulence of tubercle bacilli:

Take 1 loopful of culture from a solid medium, or 1 c.c. from a liquid medium.
Suspend it in 5 c.c. of 50% methyl alcohol.
Mix well and centrifuge.
Suspend again in 5 c.c. of 50% methyl alcohol.
Mix well, centrifuge, and drain.
Suspend the sediment in 5 c.c. of Dubos buffer (M-62).
Add 0.2 c.c. of a 0.05% watery solution of neutral red.
Keep at room temperature for 1 hour (not longer).
Read with a hand lens.
Virulent cultures are pink to red.

Egg Inoculation for Diagnosis of Tuberculosis

Refer to page 1475

MATERIAL FROM EAR AND MASTOID

To cultivate organisms in furuncles of the external auditory canal, the skin should be cleansed with alcohol and pus picked up with a sterile swab, using blood agar and blood agar with sodium azide (M-21, M-22) or alcohol (M-23). In *otitis media,* the otologist collects the material after disinfecting the external auditory canal. The pus should be streaked to the plates, or inoculated in tubes of enriched broth M-4 or M-6. In *acute otitis,* cultures on Loeffler blood serum M-10 or blood agar M-28, M-29 are sufficient, but in *chronic otitis,* azide or alcohol plates should be added, since the infection is generally mixed, and rapidly growing organisms may readily overgrow streptococci and similar slowly multiplying organisms. The same procedures are recommended in *mastoid infections.*

Microorganisms most frequently found are gram-positive cocci, coliforms, Protei, Pseudomonades, and diphtheria bacilli.

For differentiation, proceed as under "Pus."

Examine for *C. diphtheriae* according to the methods used for nose and throat examination.

NASAL-SINUS-NASOPHARYNGEAL SPECIMENS

In taking material from the nose for bacteriologic work, sterile swabs should be used without touching the atrium. Cultures should not be made within an hour after the application of antiseptics.

Material from infected *sinuses* should be taken by the rhinologist, under direct illumination.

In connection with the study of nasal secretions, note the work of Jacobson and Dick,[2] who found that the normal nasal flora consists chiefly of *Staphylococcus albus* and diphtheroid bacilli, with *Staphylococcus aureus* and *N. catar-*

---

[1] Am. Rev. Tuberc. **58:** 698, 1948.
[2] J. A. M. A. **117:** 2222, 1941.

rhalis less frequently. They found that green-forming streptococci and pneumococci are occasional transients in the nasal cavity. The presence of streptococci, pneumococci, *Klebsiella pneumoniae,* Pfeiffer bacilli, and diphtheria bacilli indicates disease of the nasal mucosa or sinus disease or both. The work of other observers, Toerne,[2] Linton,[3] Lewis and Turner,[4] and Frankel,[5] who studied clinically normal sinuses at autopsy, proved that the sinuses are sterile in health. Frankel found that the pneumococcus was the predominant organism in sinuses which showed gross pathologic change. Oaks, Merrill, and Oaks[6] studied the bacteriology of antral washings and found one or both of the maxillary sinuses sterile in 234 of 475 patients who came to treatment because of what they presumed to be sinus infection. Jenssen[7] concluded that normal sinuses are sterile but that there are no bacteria characteristic of sinusitis. Jay[8] described a case of maxillary sinus infection in which fusiform bacilli and spirilla were isolated. Jacobson and Dick emphasize the point that the frequency with which green-forming streptococci, hemolytic streptococci, and pneumococci were isolated by culture of nasal secretion in cases of sinusitis, acute or chronic, shows the diagnostic value of this simple, inexpensive procedure.

I. Cultures From the Nasopharynx

When taking cultures from nasopharynx, use a curved wire swab that has been sterilized; avoid contamination with saliva.

Blood agar, M-28, M-29, is useful as a routine medium, also Loeffler serum M-10.

In *diphtheria,* use a sterile swab or a sterile platinum loop. Material should be immediately inoculated upon Loeffler's blood serum. The test should not be made unless some hours have elapsed after the application of an antiseptic. An attempt should be made to rub the swab deep for the reason that the diphtheria bacillus is often deeply located, while on the surface we find nothing but staphylococci. See page 1618 for the Brahdy rapid method.

To make a diagnosis of *Vincent's angina,* smears are required and the results are very definite. If interested in the diagnosis of *focal infection of the tonsil,* obtain material deep from the crypts. This material should be expressed from the crypts or secured with the aid of a special sterile glass tube attached to a suction pump. When dealing with *excised tonsils,* they should be placed in sterile gauze or saline solution immediately after removal, seared with a hot blade to sterilize the outside surface, and puncture made through the seared surface for deep inoculations.

For the examination of *meningococcus carriers,* material from the posterior wall of the nasopharynx, behind the uvula, is very useful. It is streaked to chocolate agar plates (M-31 to M-33).

II. Examination for Diphtheria

Examination for *C. diphtheriae* is carried out in the following manners:

Method No. 1

Cultures on Loeffler serum M-10 should be made from the throat, and from each side of the nose.

Incubate at 37° C. for twenty-four hours or less, preferably 12 to 18 hours.

Make smears from typical dew drop, gray colonies, and stain with Loeffler's methylene blue or other stain for granules. Look for organisms morphologically similar to the diphtheria bacillus. (Pages 1510 ff. and 1641.)

If these are found, plate out on blood agar, using the streak method of inoculation, and making the culture in such way as to give distinct colonies.

Incubate at 37° C. for twenty-four hours.

Examine the colonies microscopically to determine if they have the characteristics of the diphtheria bacillus. Margins are lacelike and irregular. Colonies are small, grayish, granular, and turn the blood brown.

Make a smear from part of one of these colonies to determine morphological similarity to diphtheria bacilli.

If the organism appears to be the diphtheria bacillus, transplant to tubes of Loeffler's blood serum medium. Make several transplants from different colonies.

Incubate at 37° C. for twenty-four hours, or until a good growth is obtained.

Make a smear and stain with Loeffler's methylene blue or other granule stain to determine whether the organism growing on the culture is the same one as that which was selected.

Add about 2 c.c. sterile physiologic saline (0.85% sodium chloride) to the slant of Loeffler's if a pure culture is obtained.

Loosen the growth from the slant by means of a platinum or nichrome loop so that the living organisms are suspended in the saline.

Inject 1 c.c. into the abdominal cavity of a guinea pig.

Tag the guinea pig. Record the number of the pig, and the laboratory identification of the culture on the record sheet.

If the organism isolated was the true diphtheria bacillus, the guinea pig will die within four days.

Diphtheria in a guinea pig is accompanied by an area of inflammation at the point of inoculation, necrosis of the tissue at the point of inoculation, and congestion in the adrenal glands so that they appear inflamed and enlarged.

If no true diphtheria bacilli are present, the guinea pig will not become ill.

For other toxicity tests, see under *C. diphtheriae*, page 1512.

Method No. 2

Collect swabs as above.

Streak to tellurite plates M-41 to M-43. The best tellurite plate for this purpose is that of Whitney and Damon (M-43). Some authors prefer other media.

Incubate for 48 hours and then pick suspicious-looking colonies.

Streak them on Loeffler slants M-10.

Inoculate guinea pigs as in Method 1 for toxicity test.

Use the growth from the Loeffler slant for biochemical tests.

Method No. 3

Brahdy Procedure

Brahdy, Brody, Lenarsky, Smith and Gaffney[1] reported their experience with the rapid culture method for the identification of diphtheria bacilli. Solé[2] stated that a description of the method had first been given by Folger at a medical meeting in Carinthia thirty-six years[2] ago but was not published. The technic is as follows:

---

[1] Proc. Soc. Exper. Biol. & Med. 32: 548, 1934.

[2] Wien. klin. Wchnschr. 47: 713, 1934.

> Impregnate cotton swabs with undiluted unheated horse serum to which no preservative has been added,[3] then squeeze lightly against the sides of the tube to remove excess serum. Heat gently over a flame to obtain surface coagulation and to destroy any antibodies in the serum. Do not overheat. Keep serum-impregnated swabs in sterile test tubes. Make nose and throat cultures with these swabs in the routine manner, replacing the swabs in their sterile test tubes. Put the test tubes containing the inoculated swabs in the incubator at 37° C. for two to four hours, making smears directly from the swabs at the end of this time. The physicians' vest pocket may be used to incubate the swabs.

This method was investigated for its reliability in cases of clinical diphtheria and was found to be effective.

Diphtheria Bacillus Carriers.—There is another aspect to this work that is important, namely, the investigation of diphtheria bacillus carriers. It is well known that in carriers the culture may be positive one day and negative the next, etc. The following technic was developed at the Willard Parker Hospital, New York City:

> Transplant the four-hour rapid culture to Loeffler's serum M-10 and incubate eighteen hours. Fish colonies and examine. If diphtheria bacilli are present, emulsify the growth and inject intracutaneously into guinea pigs for virulence tests.

III. Laboratory Diagnosis of Vincent's Angina

Vincent's angina is an inflammatory condition in the mouth, pharynx, or throat, often seen upon the tonsils. It frequently simulates diphtheria. Later, ulcers appear. This disease yields to local treatment.

Plaut[4] and Vincent[5] reported the bacteriologic findings in these cases. They showed in smears from the lesions a spindle-shaped or fusiform bacillus, often associated with the spirillum of relapsing fever. These fusiform bacilli described by Vincent and others are from 3 to 10 microns in length. They taper gradually toward the ends, ending in blunt or sharp points. They do not readily stain except with Loeffler's methylene blue, carbol fuchsin, or Giemsa stain. This organism has been listed as *Fusobacterium plauti-vincenti.* Weinberg, Nativelle and Prévot make a distinction between *Fusobacillus plauti* and *Fusiformis fusiformis* (Vincent), the former being actively motile and nonpathogenic and the latter nonmotile and pathogenic. The spirilla are longer than the fusiform bacilli, with shallow and irregular undulations. They do not stain well. There has been considerable discussion as to whether or not fusiform bacilli develop into spirochetes and spirochetes into fusiform bacilli. It seems from the weight of opinion that these fusiform bacilli do not develop into well-defined spirochetes. Evidently a spiral form by some of the fusiform bacilli produces loosely coiled spirochete-like organisms which are classified morphologically as a species of Borrelia.

---

[2] Op. cit., p. 1617.

[3] Horse serum saturated with chloroform as a preservative may be used.

[4] Deutsche med. Wchnschr. **20**: 920, 1894.

[5] Ann. de l'Inst. Pasteur **10**: 488, 1896.

Technic of Examination.—

Smears should be made from the ulcers or pus from the lesions on glass slides. Diagnosis is made from smears from the gums. Later the lesions spread over the entire mucosa of the mouth. Fix in the flame.

Stain one slide with dilute carbol fuchsin for about thirty to sixty seconds. Stain the other with Loeffler's methylene blue for 1½ to 3 minutes.

Wash with distilled water. Allow to dry in the air.

Examine for *Borrelia vincentii* and fusiform bacilli. The *Fusobacterium plauti-vincenti* is sharp-pointed at both ends. It stains gram-negative. Stain is irregular. It is a normal inhabitant of the mouth, and a secondary factor in the disease. Growth occurs on serum-containing media under strict anaerobic conditions.

The borrelia are found best in the dark-field.

If found in large numbers, report *Borrelia vincentii* and *Fusobacterium plauti-vincenti* found. This is a positive report.

A negative report may read: No evidence of Vincent's angina; or no borrelia or fusiform bacilli found.

IV. Beta-Hemolytic Streptococci

For beta-hemolytic Streptococci, streak a blood agar plate M-28, M-29. Incubate 24 hours and observe for typical colonies.

Recommended Procedure.—

Make direct smears and stain for Plaut-Vincent organisms.

Inoculate a Loeffler tube M-10 *or* a reliable tellurite plate M-41 to M-43.

Streak a blood agar plate M-28, M-29.

Proceed as above.

V. Pneumococci

In children, who swallow their sputum, the pharyngeal swab may help to isolate pneumococci.

Make streak inoculation from the swab on blood agar plate M-28, M-29, and select isolated colonies for further plating or mouse inoculation.

VI. Meningococci

The following procedure is highly recommended:

The original cultures are made either on a slant of Loeffler's blood serum medium M-10, or on plates with chocolate agar (M-31 to M-33).

Cultures should be made from the throat, and from each side of the nose. It is better in the case of the cultures from the nose to insert the swab into the nose from the back rather than to make a culture from the nasal secretions.

The plates, or the slants, should be incubated at 37° C. for twenty-four hours.

Select typical colonies, make smears, and stain with the Gram stain. If there are any typically shaped organisms, proceed with biochemical examination (page 1501).

The gram-negative diplococci which may be found in the nose and throat, with the exception of the *Neisseria catarrhalis*, all ferment levulose. The meningococcus ferments maltose, but the catarrhalis does not.

After biochemical identification, perform serologic tests as described on page 1502.

VII. Pertussis

Bradford and Slavin* devised a method for collecting suitable material from the nasopharynx by using a thin, flexible copper wire with a bit of cotton wrapped around the end. This is introduced into the nasopharynx through the nose.

Inoculate a plate of Bordet-Gengou (M-39) medium, preferably with penicillin (M-40), with the material.

---

*Proc. Soc. Exper. Biol. & Med. 43: 590, 1940.

VIII. Tuberculosis

A laryngeal swab on a long wire is passed into the larynx, under the control of a laryngoscope. The patient is instructed to cough.

The swab is withdrawn, taken off the wire with a pair of sterile forceps, and placed in some saline.

Use the material so collected for culture or animal inoculation.

IX. Leprosy

Swabs taken from the deep parts of the nasal passages are used to make smears for acid-fast staining.

COUGH PLATE

Hold the plate containing Bordet and Gengou medium (M-39 or M-41) a few inches in front of the patient's mouth and induce him to cough on the plate. Incubate the plate aerobically at 37° C. for four or five days. To prevent drying of the medium, keep the plates in a moist atmosphere. This may be accomplished by placing the plates on a piece of heavy wire mesh or perforated metal over a flat container of water, keeping the plates covered with an inverted glass vessel.

Colonies of *Hemophilus pertussis* usually appear in five days. They are small, gray-white, hemispherical, opaque, "mercury droplets." The quantity of blood in the medium is too great to make the reading of the zone of hemolysis distinct enough to be of diagnostic value.

Digestion of the hemoglobin will be noted.

Serologic Test:

Powell and Jamieson[1] reported their results with a simple test of agglutination for the diagnosis of pertussis. This test was suggested by the typhus bedside test of Castañeda, Silva, and Monnier.[2] The test can be carried out with a drop of blood from the patient's finger or ear, or with a drop of serum if the blood is drawn and sent to a central laboratory.

Antigen.—The antigen consists of a homogeneous suspension in sodium citrate solution of pertussis bacilli standardized against strongly positive, weakly positive, and negative agglutinating sera and usually adjusted to a turbidity of about 100 billion bacilli per c.c., colored to a desired intensity with methylene blue, and preserved with 1:10,000 Merthiolate. This antigen may be kept in capillary tubes similar to those used to dispense smallpox vaccine, or it may be dispensed in small dropper bottles. A capillary tube of antigen (approximately $\frac{1}{40}$ c.c.) is sufficient for one drop test, and multiple tests may be done, each with a single drop from a bulk dropper bottle. With proper care and cleanliness, the antigen in dropper bottles will not readily become contaminated in the presence of the merthiolate preservative.

Agglutinating Antibody.—This may be tested for in a single small drop of blood from the finger or ear as obtained with a Bard-Parker blade for blood count, or a similar drop of serum or citrated blood if the blood is sent to a central laboratory.

Technic.—

Place a small drop of the blue pertussis antigen comprising approximately $\frac{1}{40}$ c.c. on a piece of hard surface cardboard or stiff paper of the size of a microscope slide and not readily wetted through. With match stick, toothpick, or probe, quickly spread the drop of antigen to form a circle about one-half inch in diameter.

Add a similar drop of blood or serum to the drop of antigen, stir the mixture a few seconds, and then rock or tilt the cardboard or paper, holding the drops, back and forth for a minute.

The sodium citrate in the antigen-suspension prevents coagulation of the blood.

Reactions.—

A *positive* result is readily observed as granulation or clumping of the blue antigen. If blood is used, read against a reddish background; if serum is used, read against a white background. Too long agitation of the test-drop mixture giving a positive reaction may cause the clumped antigen to form a blue ring at the margin of the drop. A *negative* reaction shows a diffuse blue color modified with red if blood is used.

---

[1] J. Immunol. 43: 13, 1942.

[2] Rev. Med. Hosp. Gen. 2: 382.

Following agitation and observation of the antigen-blood mixture for about one minute, set aside the drop-mixture on cards or paper and allow to dry without disturbing. After partial drying has taken place, additional agitation may produce artefacts in the negative reactions.

The entire test may be conducted and read in two or three minutes, since only one minute's agitation suffices for the incubation period. The test card or paper holding the drop-mixture, after drying, comprises a permanent record which may be glued to the patient's record, or the original test may be done directly on a blank area of the record, if this is not quickly wetted through.

TEETH

(a) To make a bacteriologic examination of an extracted tooth, proceed as follows:

1. Wall off the operative field with sterile cotton rolls.
2. Dry off the area about the tooth with sterile gauze and apply 3 per cent tincture of iodine. Allow it to penetrate well into the gingival margin about the tooth.
3. Extract, and while holding the tooth in the extraction forceps, sever the apex with a pair of cutting forceps and drop it untouched into a sterile test tube or vial.
4. Cultivate this fragment in a rich broth medium like brain broth (M-4) or drop the fragment into a sterile screw-top vial containing a small amount of sterile sand and gelatin-Locke solution. Shake for ten minutes to macerate the tissue and transfer the material with a sterile pipette to tubes of glucose-brain broth and streak on blood agar plates.

(b) Cultures of the socket can be made by:

1. Walling off the tooth with particular care with sterile cotton rolls to prevent contamination with saliva or the tongue.
2. Sterilizing the gums with tincture of iodine.
3. Extracting with forceps with sterilized beaks.
4. Curetting with sterile curet or with a sterile cotton swab removing material for inoculation in glucose hormone broth or on blood agar plates.

(c) To culture the periapical region through the root canals with the tooth in position, proceed as follows:

1. Isolate the tooth with rubber dam.
2. Sterilize the coronal surface with a 3 per cent tincture of iodine.
3. Remove the filling with sterile instruments.
4. Remove filling in the root canal with sterile instruments.
5. Cleanse and dry the canal with sterile cotton and insert sterile paper points slightly moistened with sterile saline solution to absorb any moisture oozing into the canal; remove the points and drop them into a tube of glucose hormone broth.
6. If no moisture oozes in, pass a sterile, fine broach or pick through the canal and drop it into a tube of the medium.

Smears may be made from the gums. Allow to dry and stain for spirochetes and bacteria.

Lactobacilli are grown on L medium (M-114).

SKIN

1. The examination for *meningococci* and *Rickettsiae* is possible from material taken from petechiae.

2. To make smears for *Mycobacterium leprae,* make a cut into the thickened skin with a razor blade. Turn the blade 90 degrees and collect scrapings from the middle of the deepest point of the cut. Stain with acid-fast methods. Examine also for foam cells.

3. *Mycologic examination by culture.*—A good all-round method is to plate contaminated material on mycophil medium (M-106), blood agar (M-28, M-29), and Littman medium (M-105).

All mycotic material should be incubated at room temperature at 37° C., and under anaerobic conditions as 37° C. At least two plates should be used for each incubation. Plates which are not incubated anaerobically must be sealed with Plasticine, adhesive tape, or other material, to prevent evaporation.

The plates must be incubated for at least 3 weeks.

When colonies of molds or yeasts appear, they must be obtained in pure culture by transferring them to fresh plates. Wort agar M-101 and malt extract agar M-100 are frequently used as differentiating media. Fermentation reactions and growth in broth must also be observed.

For details, see the section on mycology, Chapter XI.

EYE EXAMINATION

Generally speaking, the bacteriologic causes of *ocular* diseases are best found during the stage of the disease when the disease is developing and not in the stage of retrogression. In *conjunctivitis,* avoid taking material which has been in contact with the angles or margins of the lids. It is best to evert the lids and take the inoculation with a sterile platinum loop from inside. In dealing with infections of the cornea, the greatest care must be exercised to avoid injury to the tissue. Anesthetize the cornea and use the point of a sterile Graefe knife or needle if the organism is likely to be deeply located.

When looking for bacteria in the anterior chamber, the specimen is obtained by an ophthalmologist himself with a small syringe and needle. In iridectomies, a piece of the iris should be placed in chopped meat medium M-12, with a pH 7.4 to 7.6, suitable for the cultivation of streptococci and pneumococci.

In general, do not make smears or cultures within three or four hours after the use of an antiseptic solution. In attempting to make bacteriologic studies from enucleated eyes, the outside of the eye should be seared with a hot iron and openings made through this sterilized point.

Laboratory Diagnosis of Eye Affections*

Unlike other mucous membranes of the body, the conjunctiva has a limited normal bacterial flora, the only two constant inhabitants being *Corynebacterium xerose* and *Staphylococcus epidermidis,* both of which are saprophytes. The mechanical cleansing action of the tears as well as their lysozyme content act to eliminate accidental contaminants, usually air bacteria, as well as to inhibit the normal conjunctival flora. In the presence of an acute or subacute conjunctivitis the saprophytes are often crowded out by the invading microorganisms to such an extent that in secretion films or epithelial scrapings the exciting agent is found in pure or almost pure culture. It is this feature which renders the film diagnosis of conjunctivitis a practical and often simple procedure.

The Importance of an Etiological Diagnosis

The determination of etiology, when possible, is a fundamental principle of scientific medicine. The importance of knowing the active microbic agent in conjunctivitis is obvious for epidemiologic, diagnostic, and prognostic purposes, and proper management is often possible only when the etiology is known. In the stress of private and clinic practice, however, a bacteriologic diagnosis is often neglected. A technic adequate for diagnostic purposes but simple enough to require a minimum amount of time and effort follows. The film technic is designed particularly for the ophthalmologist in private practice while the combined film and culture technic is designed for the clinic.

Film Technic

Material Required.—Two stains are necessary. The Gram stain (see page 1409) gives all information needed in conjunctivitis of bacterial origin. Giemsa stain gives the information required in trachoma and in inclusion conjunctivitis (inclusion blennorrhea and swimming-pool conjunctivitis), and also enables the eosinophilia of vernal catarrh to be determined.

Giemsa Stain.—Fix scrapings (on a glass slide) in methyl alcohol for ten minutes. Stain overnight in the incubator at 37° C. with Giemsa stain diluted 1 drop to each c.c. of neutral distilled water. Decolorize in 95% alcohol twice for a total decolorizing time of five seconds. Dry in the air and examine.

If rapid diagnosis is required, the following technic may be used: Fix one minute with Wright stain. Dilute the fixative with an equal number of drops of neutral distilled water and allow the solution to remain for four minutes. Transfer to dilute Giemsa and stain for fifteen minutes or longer. Decolorize in alcohol. Dry in the air.

Method.—Make four preparations from each case, two epithelial scrapings, two secretion films. Place one epithelial scraping and one secretion smear in absolute methyl alcohol. Stain secretion film with Gram stain. If it gives satisfactory information, discard the other slides.

Culture Technic

Media.—Use blood agar plates M-28, M-29 routinely. Loeffler serum (M-10) and chocolate agar (M-31 to M-33) should be available.

Method.—Cultures are taken most satisfactorily from the lower cul-de-sac, with care to avoid the lashes and lid margin. In chronic blepharo-conjunctivitis, take cultures also from the lid margins and the inner canthus. Incubate at 37° C.

---

*We are indebted to Dr. Phillips Thygeson, of the Department of Ophthalmology, Columbia University College of Physicians and Surgeons, New York, for much of the information on this subject.

The Conjunctival Bacteria

The morphologic and biologic characteristics the determination of which is essential for the diagnosis of the conjunctival bacteria are outlined in Tables 162 and 163. Other characteristics are enumerated below.

Saprophytes.—

Corynebacterium xerose (xerosis bacillus). Often found in large numbers on degenerated epithelial cells. Colonies on blood agar are characteristically small, grayish white, dry, granular, and slow-growing. Barred and granular forms of the bacterium usually occur in specimens from culture but are often absent in direct smears.

TABLE 162.—DIFFERENTIAL DIAGNOSIS BY CULTURE OF THE COMMON CONJUNCTIVAL BACTERIA

- COCCI
  - GRAM-POSITIVE
    - CLUSTERS—STAPHYLOCOCCUS—
      - Golden pigment. Beta-hemolysis. Coagulase positive. Pathogenic. *STAPHYLOCOCCUS AUREUS*
      - Same except no pigment. *STAPHYLOCOCCUS ALBUS*
      - No pigment. No hemolysis. Coagulase negative. Pathogenic. *STAPHYLOCOCCUS EPIDERMIDIS*
    - CHAINS
      - Blisterlike colony with central depression. Alpha hemolysis. Bile soluble. Ferments Inulin. *D. PNEUMONIAE*
      - Minute colony with opaque heaped-up center. Insoluble in bile. Does not ferment inulin.
        - Beta (clear hemolysis) *STREPT. HEMOLYTICUS*
        - Alpha Hemolysis. *STREPT. VIRIDANS*
        - No Hemolysis *STREPT. NONHEMOLYTICUS*
    - PACKETS *SARCINA*
  - GRAM-NEGATIVE
    - Scanty or no growth on ordinary media. Good growth on chocolate agar. Ferments dextrose, not maltose. Grayish opalescent colony. Oxidase positive *N. GONORRHOEAE*
    - Good growth on glucose blood agar, chocolate agar. Ferments dextrose and maltose. *N. (MENINGITIDIS) INTRACELLULARIS*
    - Good growth on plain agar. Does not ferment dextrose nor maltose. *N. CATARRHALIS*

Corynebacterium pseudodiphtheriticum (Hoffman's bacillus). Typically shorter and fatter than the xerosis bacillus. Not barred nor granular. Colonies on blood agar are large, opaque, and granular.

Staphylococcus epidermidis (Staphylococcus albus). Large, china-white colonies. No hemolysis.

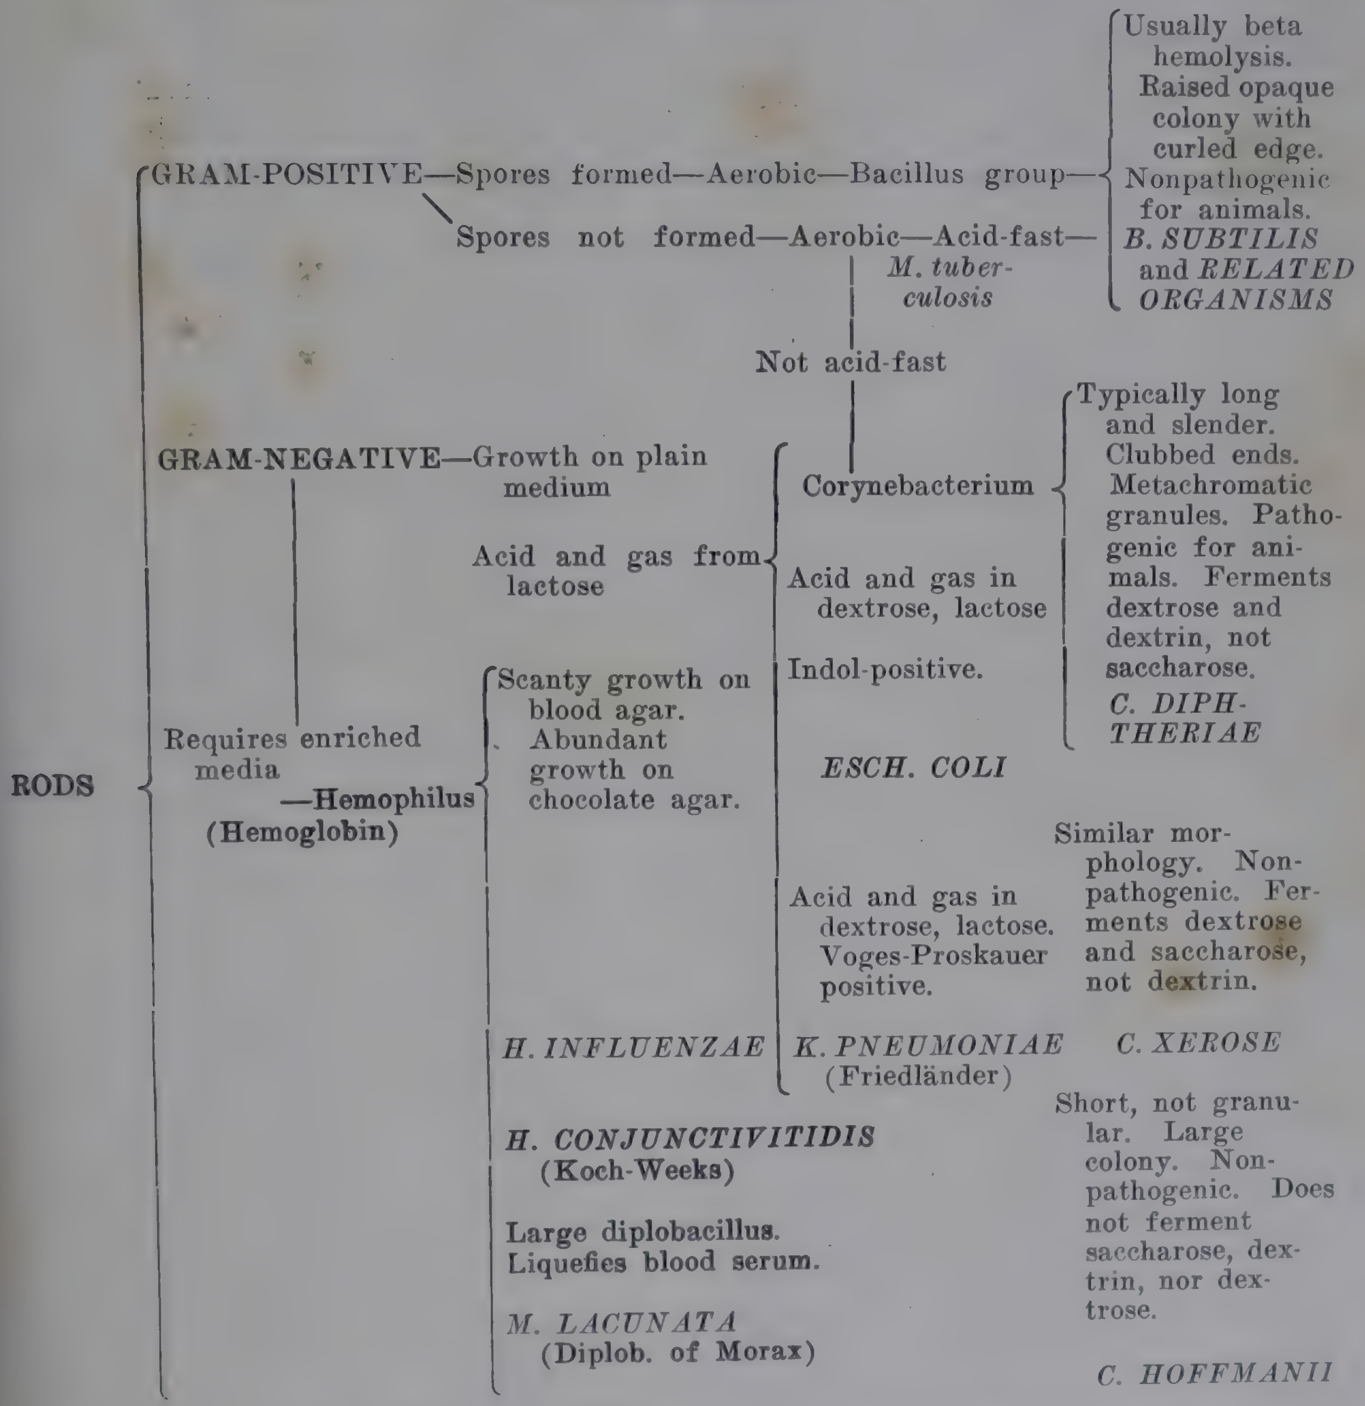
Sarcinae. Air bacteria. Colonies large, granular, and usually pigmented.

Pathogens.—

Neisseria gonorrhoeae (gonococcus). See pages 1497, 1640, for culture methods.

Hemophilus conjunctivitidis (Koch-Weeks bacillus). Produces typically an acute conjunctivitis with marked bulbar injection. Epithelial scrapings usually show turflike arrangement of the bacteria on the cells. The essential morphologic characteristics are minute size and slender bacillary shape.

TABLE 162—CONT'D



- RODS
  - GRAM-POSITIVE
    - Spores formed—Aerobic—Bacillus group—
      - Usually beta hemolysis. Raised opaque colony with curled edge. Nonpathogenic for animals. *B. SUBTILIS* and *RELATED ORGANISMS*
    - Spores not formed—Aerobic—Acid-fast—
      - *M. tuberculosis*
      - Not acid-fast
        - Corynebacterium
          - Typically long and slender. Clubbed ends. Metachromatic granules. Pathogenic for animals. Ferments dextrose and dextrin, not saccharose. *C. DIPHTHERIAE*
          - Similar morphology. Nonpathogenic. Ferments dextrose and saccharose, not dextrin. *C. XEROSE*
          - Short, not granular. Large colony. Nonpathogenic. Does not ferment saccharose, dextrin, nor dextrose. *C. HOFFMANII*
  - GRAM-NEGATIVE—Growth on plain medium
    - Acid and gas from lactose
      - Acid and gas in dextrose, lactose. Indol-positive. *ESCH. COLI*
      - Acid and gas in dextrose, lactose. Voges-Proskauer positive. *K. PNEUMONIAE* (Friedländer)
    - Requires enriched media —**Hemophilus** **(Hemoglobin)**
      - Scanty growth on blood agar. Abundant growth on chocolate agar.
        - *H. INFLUENZAE*
        - ***H. CONJUNCTIVITIDIS*** **(Koch-Weeks)**
      - **Large diplobacillus. Liquefies blood serum.** *M. LACUNATA* **(Diplob. of Morax)**

Hemophilus influenzae (influenza bacillus). Produces typically a subacute conjunctivitis with bulbar injection. Secretion films show minute cocco-bacilli, often paired, occasionally in short chains. Some individuals, except for their reaction to the Gram stain, could be confused with small pneumococci. The cultural characteristics are identical with those of Koch-Weeks bacillus and the morphology in direct smears is the only means of distinguishing between the two microorganisms.

Many bacteriologists[2] believe that *H. conjunctivitidis* and *H. influenzae* are identical. The morphologic differences between them, however, though lost in culture, are striking in direct secretion preparations. On the basis of this differentiation, *H. conjunctivitidis* produces typically an acute conjunctivitis while *H. influenzae* is almost invariably associated with a subacute disease. In support of this conclusion, and indicating that the geographical distribution of the two bacteria is not the same, Thygeson observed in Iowa City that mild conjunctivitides are associated with influenzal infections of the nose and throat, while the severe infections are almost invariably pneumococcic. Koch-Weeks conjunctivitis, according to his diagnosis, is almost never seen.

Diplococcus pneumoniae (pneumococcus). Capsules are usually not demonstrable in pneumococci from the conjunctiva. Saprophytic forms are usually not bile soluble, but this property can be readily restored by mouse passage.

Table 163.—Differential Diagnosis by Morphology of the Common Conjunctival Bacteria

COCCI	GRAM-POSITIVE	Clumps or Pairs. Pleomorphic. Never in live epithelial cells—*STAPHYLOCOCCUS.* Pairs or short chains—*STREPTOCOCCUS.* Lancet-shaped diplococci—*D. PNEUMONIAE.*
	GRAM-NEGATIVE	Kidney-shaped diplococci—*N. GONORRHOEAE.* Parasitic in live epithelial cells.
RODS	GRAM-POSITIVE	Pleomorphic-clubbed ends—Growth on live epithelial cells—*C. DIPHTHERIAE.* Similar morphology—Not parasitic on live epithelial cells—*C. XEROSE.*
	GRAM-NEGATIVE	Encapsulated—*KLEBSIELLA PNEUMONIAE (FRIEDLAENDER).* Large diplobacillus—*M. LACUNATA* (Diplobacillus of Morax). Minute coccobacillus—*H. INFLUENZAE.* Minute slender rod—*H. CONJUNCTIVITIDIS* (KOCH-WEEKS).

Streptococcus pyogenes. Rarely produces a catarrhal conjunctivitis and exhibits no affinity for the conjunctival epithelium. It is probably the cause of the majority of the cases of chronic pseudomembranous conjunctivitis which are not diphtheritic. The streptococcic type is really a subconjunctivitis and the bacteria are usually demonstrable only when the epithelium is broken.[10]

Corynebacterium diphtheriae (diphtheria bacillus) produces typically a pseudomembranous conjunctivitis. Scrapings for direct microscopic examination and for culture should be taken after removal of a portion of the membrane. The finding of pleomorphic gram-positive rods on living epithelial cells is diagnostic. Diagnosis by culture on Loeffler serum is obtainable in from twelve to eighteen hours.

Staphylococcus aureus: a common cause of subacute conjunctivitis in the newborn and chronic conjunctivitis in the adult. Pathogenic strains generally show wide areas of beta hemolysis on blood agar. Strains vary widely in amount of pigment produced.

[2] Durand, P., and Lumbroso, U.: Arch. l'Inst. Pasteur Tunis 15: 71, 1926.

Moraxella lacunata (Diplobacillus of Morax) produces typically a chronic blepharo-conjunctivitis. A gram-negative, large diplobacillus which does not grow on plain medium, but which actively liquefies Loeffler serum, may be considered to be the *Diplobacillus of Morax.*

Special Considerations

Lacrimal Conjunctivitis.—This type of conjunctivitis is secondary to infection of the lacrimal sac and does not respond to treatment of the conjunctiva. The prognosis is most favorable in the newborn in whom the lacrimal stenosis usually heals spontaneously. In adults the condition usually requires either removal of the sac or one of the more physiologic operations which restore drainage into the nose. The chronic conjunctivitis which follows dacryocystectomy is usually nonbacterial and probably results from the disturbance in lacrimal function.

The commonest agents in lacrimal conjunctivitis are, in order of frequency: *D. pneumoniae, H. influenzae,* and *Str. pyogenes.*

Vernal Catarrh.—The constant finding of eosinophilic cells in the conjunctival secretion is of diagnostic importance. The eosinophiles are typically fragmented and the eosinophilic granules widely scattered. The finding of scattered eosinophilic granules, even though but few cells are present, is extremely suggestive of vernal catarrh and is particularly useful in doubtful cases in which the clinical signs of the disease are not fully developed. A number of subclinical cases which have the subjective but not the objective signs of the disease yield positive microscopic findings. Scrapings from the upper tarsal conjunctiva are the most instructive.

Trachoma Bodies and Other Inclusion Bodies

See pages 1736 ff.

GASTRIC CONTENTS

The most important bacteriologic examination of gastric contents is that for tubercle bacilli.

The examination of the gastric contents for tubercle bacilli frequently gives positive evidence that the minimal infiltration of lungs is pathologically active and in need of treatment. This procedure is of great value in helping to determine, especially in the asymptomatic cases, how long active treatment should be continued. According to Stiehm,[1] this examination revealed positive evidence of tuberculosis in 71 per cent of the cases recorded by him. He considers that one of the criteria of a healed lesion is the repeated absence of tubercle bacilli in the gastric contents as indicated by guinea pig inoculation. Strict adherence to this principle should result in fewer recurrences in the patients with apparent but not real cures.

Armand-Delille and Vibert reported on this procedure in 1927 and in the course of the following nine years Armand-Delille and Kérambrun investigated 1,298 cases of respiratory disease in children by this method. Of these, 712 were exposed to tuberculosis in their homes and manifested signs of pulmonary or lymph node tuberculosis and positive cutaneous reactions. The gastric contents were examined by direct microscopy and in some instances by inoculation into guinea pigs or by the culture method of Loewenstein or of Petragnani. Bacilli were recovered in more than 50 per cent of 668 tuberculous children. The method demonstrated the possibility of discovering bacillus carriers in children presenting no more than tracheobronchial adenopathy.

---

[1] Am. J. M. Sc. **194**: 340, 1937.

Poulsen and his co-workers[2] in Denmark examined 622 tuberculous children and found 199 positive for tubercle bacilli by guinea pig inoculation of gastric contents. Nils Levin[3] of Sweden examined 283 children with active primary tuberculosis and found that 68 per cent had tubercle bacilli in their gastric contents. Only a few were positive on direct smear. Gourley[4] reported the results of studying a series of 210 tuberculous children by means of gastric lavage and guinea pig inoculation. Tubercle bacilli were demonstrated in 40 per cent. Stadnichenko and Cohen[5] reported their results of using the method on 600 adult patients admitted to the Chicago Municipal Tuberculosis Sanitarium. Examination of the patients with clinical tuberculosis who had never shown a positive sputum revealed the presence of tubercle bacilli in 46 per cent when gastric sediment was injected in guinea pigs; 39 per cent of these were positive in smears.

It is generally believed that inoculation into guinea pigs of centrifuged fasting gastric contents is undoubtedly the most sensitive method for the diagnosis of pulmonary tuberculosis.

Technic.—

The method of examination, as advised by Stiehm,[6] is as follows:

Centrifuge the specimen for one hour at 2,000 r.p.m. Pour off the supernatant fluid and make smears directly from the sediment; stain for acid-fast bacilli. Mix the remainder of the sediment thoroughly with an equal quantity of 10% (by weight) sulphuric acid and allow to stand for 45 minutes with occasional shaking. Neutralize with 8% potassium hydroxide using brom thymol blue as the indicator. After neutralization again centrifuge the specimen, pour away the supernatant fluid, and divide the sediment into two equal parts. One part is used for cultures and the other for guinea pig inoculation. The cultures are made by inoculating each of two tubes of egg medium M-59 with 0.5 c.c. of the sediment. Stopper the culture tubes with corks and incubate at 37° C. for 3 to 4 weeks. Inject the remaining half of the sediment intraperitoneally into a guinea pig; watch for a period of six weeks. At the end of this time, kill the guinea pig and examine for gross evidence of tuberculosis. If gross lesions are found, confirm the diagnosis of tuberculosis by the presence of acid-fast bacilli in stained smears made either from an enlarged lymph node or the spleen.

To prevent the possibility of outside contamination, sterilize the Rehfuss tube, syringe, and bottle used in obtaining the specimen by boiling. Prepare the reagent solutions with sterile distilled water, and use sterile pipettes.

Another technic which is used at Mount St. Rose Sanatorium in St. Louis, Missouri, is that advised by Henske,[7] as follows:

To the specimen of sputum or stomach washing from a fasting stomach, add an equal portion of 10% Antiformin solution. Allow to stand 24 hours.

Centrifuge at 2,000 r.p.m. for 30 minutes. Pour off supernatant fluid and make smear from residue.

---

[2] Am. J. Dis. Child. 47: 307, 1934.

[3] Acta paediat. 17: (Supp. 1) 160, 1935.

[4] Nat. Tuberc. Assoc., 33rd annual meeting, 1937, p. 131.

[5] Nat. Tuberc. Assoc., 33rd annual meeting, 1937, p. 125.

[6] Loc. cit. (Stiehm).

[7] Henske, A. C.: Personal communication.

Stain with Ziehl-Neelsen stain. Examine 24-hour sputum specimens for ten consecutive days or three days of stomach washing.

If smears fail to reveal the presence of acid-fast organisms, then inoculate guinea pig. The percentage of positive findings with this technic is far greater than with the ordinary sputum examinations and is employed at Mount St. Rose Sanatorium as a final procedure before discharging a patient as an arrested case.

Most laboratories use the media of Loewenstein (M-60) and Petragnani (M-61) for the culture of concentrated gastric washings.

Gastric contents may be examined for lactic bacilli. The so-called Boas-Oppler organism belongs to this group.

Streak with the centrifuged gastric contents 1 or 2 L agar plates (M-114). Incubate and observe for typical colonies.

BILE

The bile should be sent to the laboratory in a sterile container.

Plate out the bile on blood agar, M-28, 29.

At the same time, make inoculations to an eosin-methylene blue plate (M-71, M-72).

Incubate for twenty-four to forty-eight hours, or until a growth is obtained.

Proceed in the usual manner for differentiation of the bacteria present.

If a search for typhoid bacilli is to be made, proceed in the manner described under Salmonella.

Report the organism isolated.

STOOL EXAMINATION

I. Collection of Material

Stool examinations are not complete if they do not include both bacteriologic and parasitologic studies.

Only fresh or properly preserved material may be used. Many pathogenic organisms, such as, Endamoebae, Shigellae, etc., can be recovered from specimens only if the specimens have been cultured or fixed within a few minutes after the stool has been passed.

Both stool and fecal material collected from the intestines may be examined.

(a) Fresh Stool Specimens.—

In hospitals the nurses usually collect fresh stool specimens and deliver them immediately to the laboratory. In clinical laboratories the technician is often responsible for the collection of the stools. The patient is asked to come to the laboratory in the morning, and instructed to collect the stool on a cardboard tray fitted into the toilet.

Or, the patient may be given a sputum collecting waxed-paper box and wooden spatulas and instructed to collect the specimen in this container. Some laboratories supply the patients with one-half pint ice cream cardboard cartons or wide-necked glass bottles, and ask the patients to obtain the specimens directly in these.

(b) Post-Cathartic Stool Specimens.—

Instruct the patient to take one to three teaspoonfuls of sodium sulphate in water before breakfast. Collect material from the second or third bowel movement. Do not give oil as a cathartic. If permanent hematoxylin stained slides are to be made for examination for protozoa, glycerin suppositories are admissible, principally for children.

The laws in many states require use of post-cathartic stools for examination for carriers of Salmonellae.

(c) Fecal Specimens.—

Material for fecal specimens is collected by the proctologist.

A method of obtaining a swab of material for bacteriologic examinations, which is very practical and useful, is that advocated by Hardy, Watt, and DeCapito.[1] Their method is to introduce a small lubricated rubber tube into the anus. Before introducing it, a dry swab is placed within the lumen of the lubricated tube. The necessary materials are inexpensive and readily available. Gum rubber tubing (0.5 cm. inside and 0.8 cm. outside diameter) is purchased in bulk and cut into 12 cm. lengths. One end is beveled for about 1 cm. Cotton swabs are prepared on the usual wooden applicators, but the cotton must be wound tightly, the end covered completely, and it must pass readily into the lumen of the tube. For use, the swab is placed in the rubber tube with its tip slightly short of the beginning of the beveled opening. The external surface of this end of the tube is lubricated. The jelly should not reach the swab nor cover the opening. With patient in convenient position the unit is very easily inserted past the sphincter and up about one-half the length of the tube. The swab is exposed by withdrawing the tube 2 to 3 cm. The specimen is collected by rotating the applicator while sweeping it in a circular motion. The swab is then drawn back into the tube and in this position removed from the patient. The rubber tube and swab are separated and the latter is immediately used for plating. Later the tubes are boiled, washed, sterilized, and stored for future use. One precaution must be observed in collecting specimens from individuals with a watery diarrhea; the rubber tube must be compressed between the fingers to prevent an undesired discharge of fecal material.

This method is especially advised for hospitalized cases and for use in the studies of men in military barracks. Nurses may be permitted to collect specimens in this way from individuals ill at home.

II. Preserving Fluids

(a) For Bacteriologic Examinations.—

Prepare preserving fluids in 30 c.c. screw-capped bottles. Put about 10 c.c. of the preserving fluid in each bottle. Put the inoculum, consisting of 1 to 2 gm. of the fecal material, or of the end of the swab on which the rectal material was collected, into the bottle.

Mix the stools thoroughly with the preserving fluid and send to the laboratory.

The best general preservative is buffered glycerol-saline formula M-96. As yet no reliable medium is known for Shigellae.

If the specimen is to be carried only a short distance, from the proctologist's office to the laboratory, both in the same building, put the swab in peptone broth formula M-1 or M-2.

Fecal material must never be permitted to dry before plating.

(b) For Parasitologic Examination.—

Use the proctologic swab or the Hardy swab directly to make smears for permanent hematoxylin stained preparations. *Under no conditions must the material dry on the swab or on the slide.* Drying precludes the finding of amebae. If such material is to be preserved, fill a Koplin jar with Schaudinn's fluid, and ask the proctologist to prepare smears on slides, place them in the Schaudinn fluid, and send the jars back to the laboratory for staining and examination.

---

[1] Pub. Health Rep. 57: 521, 1942.

When larger amounts of stools are to be transported (in examination for eggs of parasites, etc.) mix about 1 to 2 gm. of the feces with 10 c.c. of 10% Formalin in a 30 c.c. screw-capped bottle and mail to the laboratory.

Details on the parasitologic examination of feces are given in Chapter XII.

III. Plating

Little can be learned from examining a Gram-stained slide made from the stools. Gram-negative organisms and sporeformers are always present. No importance is attributed to the so-called "milk reaction." For this reaction sterile milk is inoculated with the stool and incubated. If "stormy" fermentation is present, *Cl. perfringens* (*welchii*) is reported. At least twenty organisms in addition to *Cl. perfringens* cause stormy fermentation of milk, and may be found in the intestines. Scientific basis for this test is, therefore, lacking. *Cl. perfringens* does not seem to be pathogenic in the normal bowel, except type F.

It is not possible to determine from the clinical picture whether Shigellae alone or Salmonellae should be looked for. The methods presented here are therefore directed to finding members of both genera.

Both enrichment fluids and plates are used. The enrichment fluids serve primarily to facilitate isolation of Salmonellae, including the typhoid bacillus. Of the plating media, those with bismuth sulphite, formulas M-69 and M-70, and brilliant green-phenol red agar M-73, while highly selective for Salmonellae, do not permit isolation of Shigellae. Shigellae require nonselective media, such as desoxycholate agar M-64, eosin-methylene blue agar M-71, M-72, etc. Of the media of average selectivity, SS agar M-67 is most popular.

In the methods presented here, various suggestions are offered for laboratories of different equipment and size. Small establishments require simpler methods; fewer plates are used. There is, however, no possibility of using fewer plates than indicated if good results are to be obtained.

Suggestions are offered, also, for laboratories which prepare their own media and for establishments using desiccated products.

In tropical countries the number of nonselective plates must be increased, because of the greater probability of encountering organisms which require such media *(Sh. dysenteriae, S. paratyphi A, S. sendai,* etc.*)*.

(a) Small Laboratories Using Desiccated Media.—

Inoculate one tube of selenite-F (M-78) *or* tetrathionate broth (M-76). Incubate.

Streak two SS plates (M-67) and one eosin-methylene blue plate (M-71 or M-72). Incubate.

The second day, streak from the selenite-F *or* tetrathionate tube one SS plate (M-67). Incubate this plate for 24 hours.

(b) Small Laboratories Making Their Own Media.—

Inoculate one tube of tetrathionate broth (M-76). Incubate.

Streak two D.E.C. plates (M-68) and one eosin-methylene blue plate (M-71 or M-72). Incubate.

The second day, streak from the tetrathionate broth one D.E.C. plate (M-68). Incubate this plate for 24 hours.

(c) Large Laboratories Using Desiccated Media.—

Inoculate one tube of selenite-F broth (M-76) and one tube of Kauffmann's medium (M-77). Incubate.

Streak one MacConkey plate (M-63) *or* one desoxycholate plate (M-64) and one eosin-methylene blue plate (M-71 or M-72). Incubate.

Streak *either* two SS plates (M-67) *or* one DC (M-65) and one DCLS (M-66) plate. Incubate.

The second day, streak from the selenite-F medium and from Kauffmann's fluid, each, one bismuth sulphite (M-70) and one brilliant green (M-73) plate.

Incubate for 48 hours.

(d) Large Laboratories Making Their Own Media.—

Inoculate one tube of tetrathionate broth (M-76) and one tube of Kauffmann's fluid (M-77). Incubate.

Streak one MacConkey plate (M-63) and one eosin-methylene blue plate (M-71 or M-72). Incubate.

Streak two D.E.C. plates (M-68). Incubate.

The second day, streak from the tetrathionate broth and from the Kauffmann tube to one Hajna-Perry plate (M-69) and one D.E.C. plate (M-68) each.

Incubate the Hajna-Perry plates for 48 hours, the other for 24 hours.

IV. Special Methods

Special methods may be used for the control of carriers or for special surveys. These methods are applicable in closed communities such as military establishments, mental hospitals, etc., and during outbreaks of diseases caused by certain organisms. After the organism has been identified the special methods serve as specialized examinations of contacts and carriers.

(a) Typhoid Bacilli.—

Examine post-cathartic stools in cases without diarrhea. Use stools of patients with diarrhea.

(1) Inoculate one tube of selenite-F M-78 and one tube of tetrathionate broth M-76 with the stool. Incubate for 24 hours at 37° C.

(2) Make an emulsion of the stool in saline.

Place one drop of the emulsion in a sterile Petri dish.

Place 0.5 c.c. of the emulsion in a second sterile Petri dish.

Have ready Hajna-Perry medium M-69 *or* bismuth sulphite agar M-70 melted and cooled to 45° C.

Pour the agar into both Petri dishes and mix well.

Allow to harden and incubate for 48 hours.

(3) Streak from the selenite-F one SS plate M-67 *or* a D.C. plate M-65; from the tetrathionate fluid streak a Hajna-Perry M-69 *or* bismuth sulphite plate M-70 after the enrichment fluids have been incubated. Incubate the plates.

(4) Let enrichment fluids stand at room temperature for 24 hours more and then repeat the streaking (3) and incubating.

(b) Salmonella.—

Examine those cultures from cases and carriers of Salmonellae which form hydrogen sulphide using the same technic as for typhoid bacilli. The Kristensen plate M-73 may be used for streaking from selenite-F or Kauffmann.

Organisms from cases and carriers of Salmonellae which do not form hydrogen sulphide must be examined as follows:

Inoculate one tube of selenite-F M-78 and one tube of tetrathionate M-76 and incubate.

Streak three MacConkey M-63 *or* D.E.C. M-68 plates *or* desoxycholate medium M-64 *or* D.C.L.S. medium M-66. Incubate.

The second and third day, plate from the selenite-F tube and tetrathionate to one plate each of D.E.C. M-68 medium *or* desoxycholate agar M-64. Incubate.

(c) Shigella.—

Collect specimens by means of a Hardy swab and also collect the post-cathartic stools.

Using the Hardy swab, streak either SS agar M-67 *or* D.E.C. plate M-68. Streak sectors on the surface of the medium. Incubate.

Using the stools, streak two plates each of (a) either MacConkey agar M-63 *or* desoxycholate medium M-64; and (b) eosin-methylene blue M-71; (c) D.E.C. medium M-68 *or* SS agar M-67 *or* desoxycholate-citrate plate M-65, and incubate.

If the organisms do not grow on SS agar or on the desoxycholate medium, use the other two plates in triplicate.

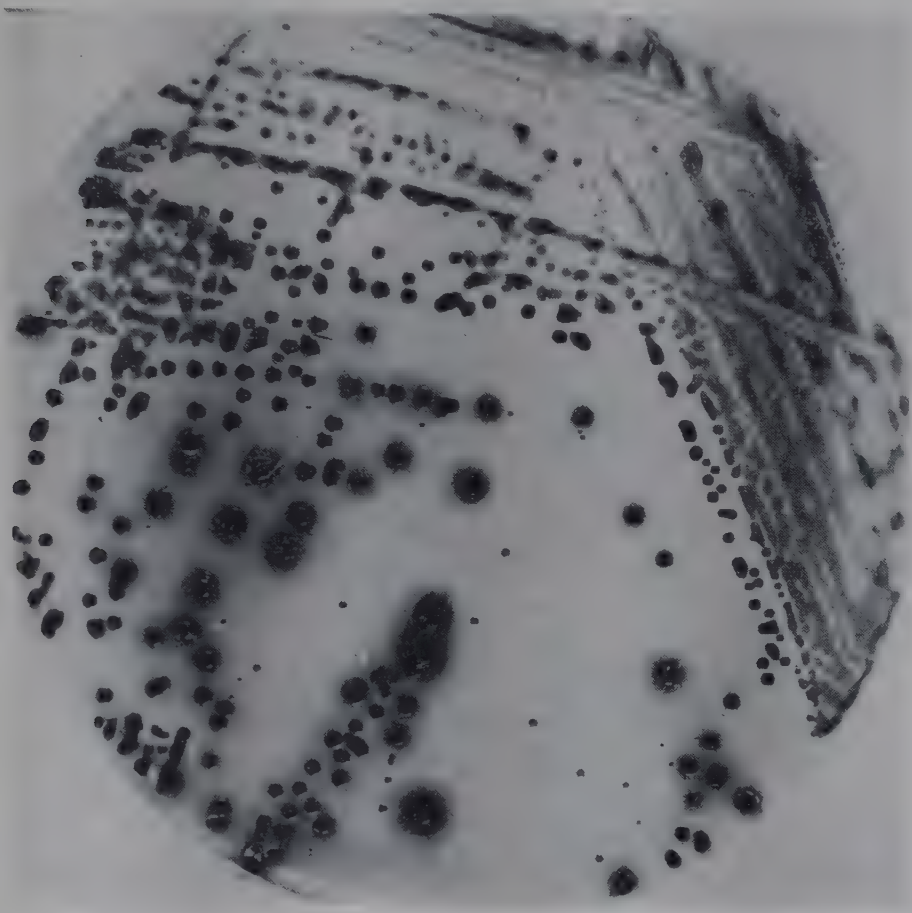

Fig. 392.—Hajna and Perry plate with Salmonellae. (Courtesy Dr. Oscar Felsenfeld.)

V. Technical Suggestions

Use about 1 to 2 grams of inoculum for 10 c.c. of enrichment fluid. Mix the stools well with the fluid. Before plating from the enrichment fluids, shake the liquid.

The above outlines are tentative and substitutions can be made. If substitutions are made, keep in mind the efficacy and selectivity of the different plates and fluids.

Selenite-F, M-78, is preferred by many laboratories to the tetrathionate broth M-76. These enrichments are used only for the propagation of Salmonellae.

The Endo plate and that of Drigalski belong to the past.

Eosin-methylene blue agar M-71, 72 is nonselective and excellent for most fastidious enteric pathogens.

Of the media which inhibit gram-positive organisms by addition of bile, MacConkey's plate M-63 is the least selective, but it gives very large colonies which can be used for direct agglutination tests. Somewhat less effective but much easier to prepare and to streak is the desoxycholate plate M-64 which may be used instead of the MacConkey plate.

The D.E.C. plate of Panja and Ghosh M-68 is the best medium for general use. Unfortunately, some workers consider its preparation a laborious procedure.

SS agar formula M-67 is average in its selective qualities; it is excellent. The desoxycholate-citrate medium M-65 is more selective and more inhibitory for fastidious organisms.

Media which utilize bismuth sulphite are very selective and can be used only for detection of hydrogen sulphide-forming Salmonellae, including the typhoid bacilli. The only disadvantage is the long incubation period (48 hours). The latest modification of Hajna and Perry M-69, and the Difco desiccated product M-70 are widely used.

Kauffmann broth M-77, and Kristensen medium M-73 were devised only for Salmonellae other than *S. typhosa.*

To use nonselective media, inoculate with a small amount of the specimen; selective media require large inocula. Only experience can teach the proper amount of stools to be used for the various plates.

Some media contain sucrose, which permits of the exclusion of a number of Protei and paracolon organisms (D.C.L.S. agar M-66). These plates must be used only when the physician is interested in no organisms other than Salmonellae and Shigellae.

VI. Differentiation of Microorganisms

Those colonies on plates showing reactions of pathogens, black, shiny with metallic halo on bismuth plate; colorless, yellowish, or brownish on others, are transplanted to Kligler agar M-79 or T.S.I. medium M-80. Mickle and Hajna have developed a combination medium which contains three sugars, dextrose, lactose, sucrose, and an iron indicator for the detection of hydrogen sulphide formation. These tubes are inoculated by stabbing deep in the tube, to the bottom, and then streaking the rest of the material on the needle over the slant of the medium. After 24 to 36 hours' incubation, the reactions are read and media for further differentiation are inoculated, according to the organism which is suspected.

Another important characteristic is motility. Motility is determined by inoculating semisolid media M-82, 84, or 88. These media may contain additional carbohydrates, so that fermentation reactions can be obtained along with motility of the organism. Use stab cultures and inoculate by thrusting the wire through the medium. Growth only along the line of stab characterizes nonmotile organisms, like Shigellae, while motile organisms grow into the medium.

All Salmonellae and Shigellae fail to give a positive Voges-Proskauer test R-14. It is advisable, therefore, to determine this reaction.

Mannitol fermentation is used to differentiate subgroups of Shigellae. Protei, with the exception of *Pr. rettgeri,* do not ferment mannitol. The use of this carbohydrate is, therefore, imperative. Use a medium such as M-88. Protei produce urease. They may be excluded, therefore, by testing for urease formation R-15. To do this test, it is necessary to sterilize the urease medium M-90 by filtration.

Many paracolon organisms must be differentiated from Salmonellae by their slow action upon lactose, sucrose, and salicin. Media like M-86, M-87 are recommended. The reaction in medium M-86 is considered positive only when a pink or red color is developed.

Salmonellae do not form indol R-12. This reaction aids in differentiating them from coliforms. This test should, therefore, be made routinely.

Suggestion of Methods for Differentiation of Salmonellae, Shigellae, and Related Organisms

Method 1.—

Discard all Kligler or triple sugar iron agar tubes showing acid slant.

Classify those showing only surface growth and dark discolorization of the slant as *Pseudomonas aeruginosa.*

I. Inoculate from tubes showing alkaline slant, acid and gas in the butt, with or without hydrogen sulphide formation:

(a) one tube of tryptone or trypticase broth M-1
(b) one tube semisolid mannitol M-88
(c) *either* one tube of semisolid sucrose-lactose-salicin M-86 *or* use formula M-87 (optional)

After 24 hours' incubation, make indol test (R-12) in tube (a); read motility and action on mannitol in tube (b).

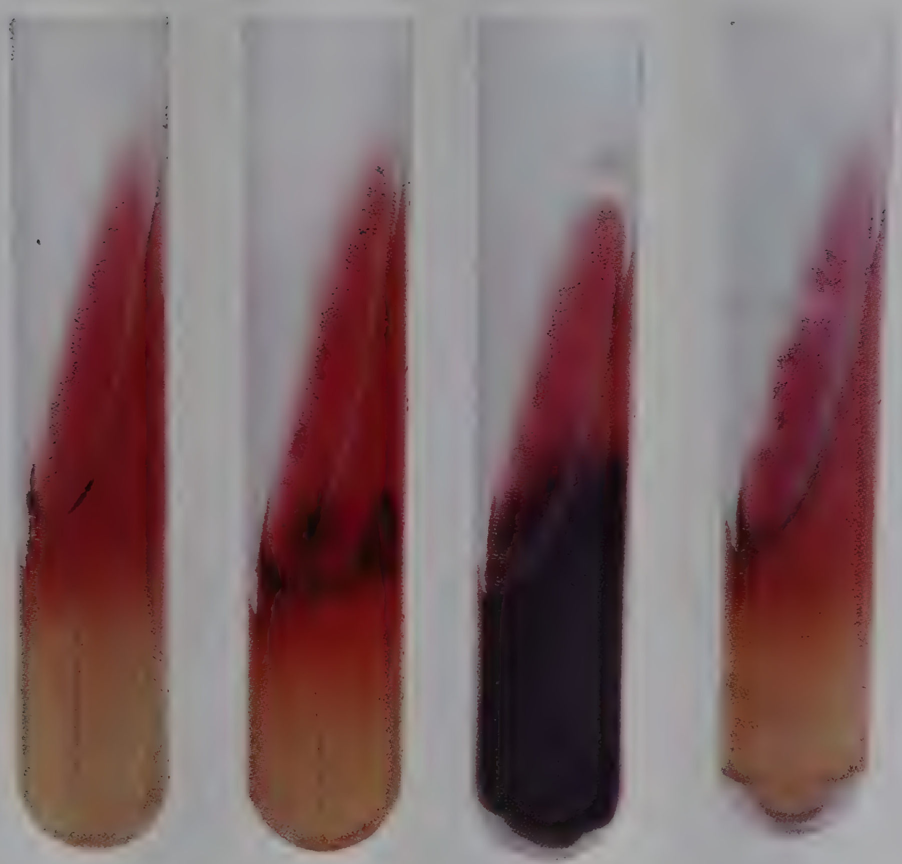

Plate XLII.—Hajna's Triple Sugar Iron Medium. Reaction of Shigella, Salmonella Typhosa, Hydrogen-Sulphide-Forming Salmonella, and Hydrogen-Sulphide-Not-Forming Salmonella.

If indol is negative and acid and gas are formed in mannitol (bubbles of gas in the medium) and no change is noted in medium (c):

Inoculate agar slants for mailing the culture to a Salmonella typing center; or inoculate broth tubes M-1 and agar slants M-16, M-17 for typing.

Reincubate tubes (c) and (d).

Test growth on Kligler or triple sugar iron medium with polyvalent Salmonella sera.

The next day make Voges-Proskauer tests R-14.

If the medium in tube (c) does not show changes, type growth in broth tubes M-1, or mail to a Salmonella center.

II. Inoculate from tubes showing alkaline slant, acid but no gas in butt, and a little hydrogen sulphide formation:

(a) one tube of tryptone or medo-peptone broth M-1
(b) one tube of semisolid mannitol M-88
(c) one tube of semisolid lactose-sucrose-salicin M-86, *or* one tube of semisolid sucrose M-85.

Test the growth on the slant of triple sugar iron agar with (1) polyvalent Salmonella serum (p. 1523); (2) group Salmonella serum D; (3) Salmonella Vi serum; (4) Salmonella "d" serum.

If the serologic reactions are positive, report *typhoid bacillus,* but examine the media for confirmation.

After 24 hours' incubation, make indol test on tube (a). Observe for motility and reaction in tube (b). Keep tube (c) for later reading if agglutination tests are negative.

III. If the growth in Kligler or in triple sugar iron agar shows an alkaline slant, acid butt, and no hydrogen sulphide formation, inoculate:

(a) one tube of tryptone or trypticase broth M-1
(b) one tube of semisolid mannitol M-88
(c) one tube of each: rhamnose broth M-5 and dulcitol broth M-5.
(d) one tube of citrate medium M-93.

Test the growth on the surface of the triple sugar iron agar with (1) polyvalent Salmonella serum, to exclude anaerogenic strains; (2) Salmonella Vi serum, to exclude typhoid bacillus forming little hydrogen sulphide; (3) Shigella sera in the U. S. A. in the order: *Sh. sonnei,* smooth and rough, *Sh. paradysenteriae* Flexner, polyvalent, *Sh. alkalescens-dispar, Sh. boydii.*

If the serologic reactions are positive, test with type sera.

If the serologic reactions are negative, it is better to wait for further testing until the reactions in carbohydrates are read and the growth transferred to at least two agar slants, M-16 or M-17, so as to have sufficient material for further testing.

The second day, make an indol test R-12 on tube (a). Read motility in tube (b). Record the reaction on mannitol and sucrose. Read changes in the carbohydrates in tubes (c). Observe growth on (d).

Make agglutination tests with live and heat-killed growth from the transplants on agar M-16 and M-17.

Keep tubes (c) and (d) until final readings are made.

Table 152 shows the biochemical reactions of the most common Enterobacteriaceae isolated from stools.

The serologic classifications are given in the section describing the various microorganisms.

Method 2.—

Pick suspicious colonies and transfer to a tube of tryptone or trypticase-lactose broth M-5 or M-85. Incubate.

After 4 to 6 hours, if the indicator has not changed color, inoculate from this broth:

(a) one tube of semisolid mannitol M-88
(b) one tube of T.S.I., M-80.

Incubate for 24 hours. Make a Gram stain. Perform indol test in lactose broth (R-12). If gram-negative, and no acidity in lactose broth:

(1) *Organisms nonmotile, acid formed but no gas in (a) and (b):* type with Shigella sera and with Salmonella group IX sera using the growth from the surface of the slant (b). Inoculate carbohydrates for confirmation, as in Method 1.

(2) *Organisms motile, (b) shows acid slant:* discard—coliform.

(3) *Organisms motile, (a) unchanged, (b) alkaline slant, gas in butt:* discard—Proteus.

(4) *Organisms motile, (a) shows only acid but no gas, (b) alkaline slant, acid butt, some H_2S:* test growth on agar slant with Salmonella group D, Vi, and "d" sera.

(5) *Organisms motile, (a) shows acid and gas, (b) alkaline slant, gas in butt, indol test* (R-12) *negative:* keep tube (a) and mail tube (b) to typing center or transfer to further media as in Method 1.

(6) *Only surface growth:* discard—Pseudomonas, Alkaligenes.

Method 3. Alternate Method, Sanders and Okabe.*—

Inoculate lactose broth containing brom cresol purple (M-85).
Four to six hours later, if negative, inoculate from it:
- one tube citrate agar (M-93)
- one tube of semisolid motility agar (M-82)
- one tube of Kligler medium (M-79).

The next morning perform indol test in the lactose broth (R-12).
Set up and perform rapid urease test (R-15B).

This method is especially helpful in regions where Shigellae are frequent, since these organisms do not grow on citrate agar.

Use method 2 only when the technic of isolating and fishing colonies has been well mastered and if sufficient sera are at hand. The Lederle Laboratories, Pearl River, N. Y., produce reliable Shigella species-specific sera, Salmonella group sera, and a few Salmonella single factor sera. These sera must be used in strict adherence to the instructions of the manufacturers, if good results are to be achieved.

Method 4. Broh-Kahn procedure† for routine stool cultures is as follows:

All specimens, either anal swabs or actual stools, should be streaked to plates of SS agar M-67 and brilliant green agar M-72, and, in addition, inoculated into tubes of tetrathionate enrichment broth M-76, from which a second brilliant green plate M-73 is streaked the next day. Typical colonies should be studied both by inoculation into tubes of Kligler's agar M-79 and by agglutination with polyvalent sera. Owing to the selectivity of Kauffmann brilliant green agar, cultures which show typical reactions in either the polyvalent sera or the double sugar agar may safely be reported as possible Salmonella and should then be forwarded to a Salmonella Center for confirmation and species identification.

The SS agar plates should be examined for growth of dysentery strains and the presence of the latter demonstrated by conventional methods.

Method 5. Braun's Two-Tube Method.‡—

Melt tubes of Braun's medium *B* (M-81) and keep them at 45° C. in a water bath.

Pick a colony and transfer part of it to one Braun tube *A* (M-81), inoculating slant and stabbing it, and part to one tube of melted medium *B* (M-81), preparing a shake culture in the latter.

Insert indol reaction paper R-12d between plug and neck of tube *A*.

Insert hydrogen sulphide indicator paper R-9 between plug and neck of tube *B*.

Incubate for 24 hours at 37° C. and read results.

All Salmonellae and Shigellae produce a blue slant and a green butt in tube *A*.

---

*U.S. Armed Forces M. J. 4: 1053, 1953.

†Mil. Surg. 99: 770, 1946.

‡Istanbul Seririyati 21: 3, 1939.

Mannitol fermentation is indicated by a yellow color in tube *B*, which will show gas formation, too.

Alcaligenes faecalis does not grow in the depth of medium *B*.

Method 6. Micromethods.—

For rapid identification of Shigellae and Salmonellae, medium M-95 may be used, in conjunction with a preliminary identification medium such as M-85, M-87, M-90, or M-91. Such preliminary or primary medium will produce enough growth after 4 to 6 hours' incubation that further media, especially M-89, can be inoculated from it.

The initial growth in M-85 can be used for rapid agglutination tests.

Attention must be called to the fact that there are many pitfalls in using rapid methods. They should not be used except by those whose technic is flawless, and in emergencies, such as in outbreaks, where a rapid diagnosis is most essential.

An infinite number of combinations and variations of the media and methods can be set up. The two most useful are:

(a) *Pick each suspicious colony and transfer simultaneously to:

One tube of lactose broth with indicator M-85.

One tube of semisolid mannitol with yeast extract M-89.

Incubate for 4 to 6 hours and observe reactions. If the indicator in the lactose broth has changed, discard.

If the indicator in the lactose broth has not changed, transfer part of the lactose broth to an empty, sterile, small test tube.

Observe the mannitol tube, preferably with the aid of a dissecting microscope.

If mannitol negative, no motility, no hydrogen sulphide:

Test growth in broth which was transferred to the empty tubes with Shigella group A, B, C, and D, and Salmonella polyvalent sera. (Some typhoid bacilli will give this reaction, too.)

If mannitol tube shows acid production around the stab but no gas, no hydrogen sulphide production, no motility:

Test with Shigella group B, C, and D, and Salmonella polyvalent sera. (Some typhoid bacilli will give this reaction.)

If mannitol tube shows acid, no gas, no hydrogen sulphide or some hydrogen sulphide production, some motility:

Test with Salmonella sera, especially for *S. typhosa.*

If mannitol tube shows acid and gas production, hydrogen sulphide (most frequently) produced, motility present:

Test with Salmonella polyvalent serum.

There is seldom enough growth in the lactose broth to complete the typing. It is essential to inoculate only small amounts of broth with the colony, otherwise after four hours there will not be a dense enough suspension available.

The usual method of agglutination is that with sera diluted 1:5, using the slide test. It is possible to perform tube agglutinations, using 0.2 c.c. of the growth in lactose broth and 0.2 c.c. of the proper serum dilution. This is, however, difficult to read.

The mannitol tube serves as a source for further inocula. An indol test may be made the next day with the lactose broth.

(b) Pick colonies and transfer to urea broth M-90 or M-91.

Incubate for 4 to 6 hours; then, if negative, inoculate M.R.-V.P. medium M-92 for rapid Voges-Proskauer test (R-14d), and broth for rapid indol test (R-12).

Prepare sterile Petri dishes and, after properly marking sectors, put into them drops of agar M-95 containing:

lactose
sucrose
mannitol
motility medium with hydrogen sulphide indicator.

Inoculate the drops by stabbing.

---

*Goldner, H.: Am. J. Digest. Dis. 21: 198, 1954.

The preferred technic is to use drops with one carbohydrate in the same plate.

Incubate the Petri dishes for 2, 4, and 6 hours.

Observe under low power, or with a lens, for motility and fermentation along the stabs.

Re-read the urea medium.

Read the Voges-Proskauer and indol tests.

Cocci

Not many conclusions can be drawn from the presence or absence of certain cocci in the feces. This question is often raised when staphylococcus food poisoning outbreaks are investigated. This type of food poisoning is caused by the toxin of the organisms formed during their growth in food; thus the presence or absence of hemolytic staphylococci in the stools has little significance.

If enterococci are to be isolated, streak the stools on two sodium azide blood plates M-21 and test the cocci as follows:

Inoculate a tube of trypticase soy broth M-3.

After incubating 24 hours, heat the tube for 30 minutes in a water bath at 60° C. The enterococci survive.

Inoculate from the heated broth

(a) one tube of Chilton and Fulton medium M-87. Observe for blackening.

(b) Add 0.5 c.c. of the broth in which the cocci were grown to 0.5 c.c. of a 5% suspension of washed sheep red blood cells. Incubate for 2 hours in a water bath at 37° C.

This divides the enterococci into two groups, hemolytic and nonhemolytic.

Attempt typing with Lancefield D serum, if hemolytic.

Cholera

Tests for the presence of cholera vibrios are made only in regions where cholera is present or when suspicion arises as to a possible diagnosis of cholera.

Mix 1 to 2 gm. of the stools in tubes containing alkaline sea-salt medium M-90 and alkaline peptone water M-1. The former is a good preservative and may serve as a preservative for mailing stools or water.

Streak the stools directly on two D.E.C. plates M-68 and two Aronson plates M-74.

Incubate for 24 hours. Pick colonies from the plates.

Streak out colonies from the sea-salt medium to a Wilson and Reilly plate M-75.

Incubate, then pick colonies as above.

Transfer suspicious colonies to alkaline tryptone broth M-1.

Incubate for 6 to 8 hours and inoculate from the tryptone water:

(a) one tube of agar slant M-16 or M-17
(b) one tube of sucrose broth M-5;
    one tube of arabinose broth M-5
(c) one tube of nitrate broth M-8
(d) one tube of Voges-Proskauer medium M-92.

If possible, test the colonies with polyvalent cholera serum directly, using the spot agglutination method.

The second day, make indol test (R-12) in tube of tryptone broth M-1.

Observe if sucrose was fermented and arabinose remained unchanged.

Make the cholera red test (R-16) in tube (c).

Carry out agglutination tests with the growth on agar slants (a).

Observe tubes (b) for 5 more days.

Make the Voges-Proskauer reaction on the third day with the growth in tube (d) (R-14).

Test for hemolysis, using 5% suspension of washed goat cells.

Tuberculosis

(Petroff's Method)

Collecting the Specimen.

The morning stool is collected in a wide-mouth sterile fruit jar. See collection of specimen in Chapter VIII.

Concentration of the Specimen.

Add to the stool 2 volumes of distilled water.

Stir thoroughly and filter through gauze to remove the coarse particles.

Add enough sodium chloride crystals to make a saturated solution.

Mix thoroughly and allow to stand at room temperature for several hours. The bacteria float on the surface, and may be collected in the scum.

Collect the scum by means of a sterile spoon and place in a sterile wide-mouth bottle.

Add 2 volumes of N/1 sodium hydroxide. Shake thoroughly.

Place in the incubator at 37° C. for one to two hours.

Centrifuge at high speed.

Decant and discard the supernatant fluid.

Add to the sediment 3 or 4 drops of N/1 hydrochloric acid.

Divide the sediment into three portions.

Make 2 smears with one portion. Stain with Ziehl-Neelsen.

Examine for tubercle bacilli.

Spread one-third of the sediment on media M-58, M-58a, M-58b, or M-59, M-60, and incubate, making allowance for exchange of gases by punching a hole through the corks. Incubate egg media six to eight weeks. Growth occurs more rapidly on Petrik medium.

The other third should be injected into a guinea pig (page 1647), since the finding of acid-fast bacilli in the feces does not necessarily mean the presence of tubercle bacilli. If the guinea pig dies of tuberculosis, or shows lesions of tuberculosis, report: Tubercle bacilli present in specimen.

Animal inoculation is the method of choice.

Brucellosis

Examination for brucellosis by examining the feces is usually a futile attempt.

Streak the stool on tryptose agar plates M-16 or liver infusion agar M-26 and incubate in a carbon-dioxide atmosphere.

Fish suspicious colonies and transplant to liver infusion agar with dyes M-26^a for differentiation.

Gonococci

Cleanse anal opening.

Introduce anoscope.

Cleanse lesions with saline.

Take material as from the urethra and proceed according to instructions for urethral, prostatic, and cervical material.

URETHRAL, PROSTATIC, AND CERVICAL MATERIAL

Smears of urethral pus are very important for bacteriologic diagnosis of the diseases of the genitourinary tract, but they should be backed with proper bacteriologic culture methods.

In the male, the smears of urethral pus must be taken in the following manner: the glans penis is cleaned with alcohol, especially around the meatus. A platinum loop is then very carefully inserted into the urethra and a drop of pus is picked up and inoculated upon medium in a Petri dish. In cases where it is necessary to examine material from the deep urethra, the use of a long sterile probe through an endoscope with electric illumination is necessary. For the examination of prostatic and seminal vesicle material for gonococci, the glans should be disinfected with alcohol and, with the patient bent over, the prostate and vesicles are massaged, allowing the material expressed from these organs to run into a sterile Petri dish. From this dish, inoculation is then made on the gonococcus medium.

An alternative method is to press on the urethra, massage the prostate, and then release the pressure on the urethra. The outflowing material is collected into a tube or Petri dish.

In the female, inoculations are made from the urethra and from the vagina. In children, a female glass catheter is introduced into the vagina and rotated. When sufficient material is collected, the vagina may be washed with a few c.c. of tepid saline.

Cervical material is collected through a speculum. The cervical plug, if present, is cleaned out and the material is collected from the introit.

Make cultures on Gradwohl plate M-37 or on chocolate agar M-31, M-32, M-33, M-36. Incubate the plates in a carbon-dioxide atmosphere and examine after 48 hours with the aid of the oxidase reaction. The colonies on Gradwohl plate have the following characteristics:

1. **Gonococcus (Neisseria Gonorrhoeae).**—Twenty-four-hour colonies are distinct, flat, gray, larger than streptococcus colonies, but usually smaller than staphylococcus colonies, although they vary greatly in size. Granules, while fine, are very dense. Occasionally twenty-four-hour colonies show one or two radial striations, or a concentric ring. If held up to the light, so that the light shines through them, they exhibit a pearly opalescence.

They are almost transparent. The iris diaphragm of the microscope must be nearly closed to obtain a clear picture of the structure.

Margins of the twenty-four-hour colony are fairly regular. There is no central structure.

Colonies show changes in forty-eight hours. As they become older, autolysis of the organisms takes place, thus changing the size and structures of the colonies. The edges become undulated, the center flatter than the edges, and radial striations become marked, although they are visible only when the light is cut down. Occasionally there will appear in the center of the colony a crumblike structure. This structure does not add opacity to the colony, which remains almost transparent throughout the course of its growth. Smears from forty-eight-hour colonies almost invariably show marked autolysis.

Seventy-two-hour and ninety-six-hour colonies show changes in size; that is, the colony enlarges. The edges tend to become lobate, the striations marked, and many of the crumblike structures may appear. Smears from old colonies will show that the majority of the organisms have undergone autolysis. The medium remains purple. (See Figs. 393*A*, 393*B*, and 394.)

2. **Neisseria Catarrhalis.**—The 24-hour colony of the *Neisseria catarrhalis* is almost identical with that of the gonococcus, although there are never any striations, and the granules seem less dense. The older colonies of the catarrhalis do not show much change, although they assume a shriveled appearance microscopically. The colonies may have concentric rings. Like the gonococcus, the colonies are gray. They do not react with the sugar; therefore, they do not turn the medium yellow. No autolysis is noted.

3. **Gram-Negative Streptococci.**—Colonies, macroscopically, are distinct, elevated, shiny, pinpoint. They are surrounded by a yellow zone of fermentation. This color is sometimes not visible within twenty-four hours, although, if the plates are held up to the light, the evidence of fermentation may usually be noted. They have a deep center, and a lacelike periphery, the edge being slightly undulating.

Smears from the colonies show typical chain cocci which stain gram-negative.

They should never be confused with gonococcus colonies, since they are uniform in size, shiny, and have a yellow zone around them.

4. **Colon Bacillus (Escherichia Coli).**—The identification of this organism is not important in the diagnosis of gonorrhea, although its differentiation from the gonococcus is important.

Colonies are about the size of a staphylococcus colony. They are flat and dull to shiny, and usually ferment the levulose of the medium, giving a yellow zone around them. If this fermentation is delayed, they can be distinguished from the gonococcus colonies by the fact that they are moist, whereas the gonococcus colonies are fairly dry.

Microscopically, they are evenly granular, semitranslucent, with a rather uneven margin. Smears show typical gram-negative bacilli of the morphology of the colon bacillus.

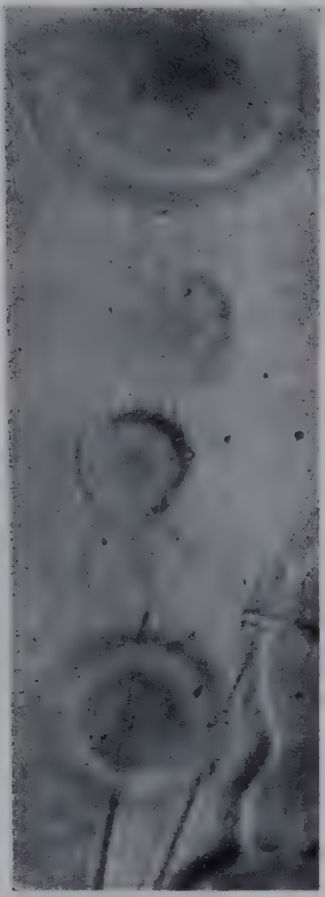

Fig. 393*A*.

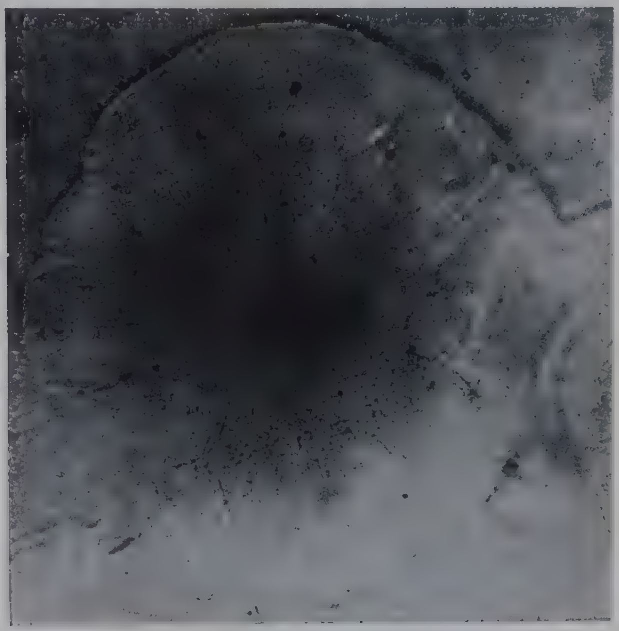

Fig. 393*B*.

Fig. 393*A*.—Twenty-four-hour colonies of *Neisseria gonorrhoeae* on Gradwohl gonococcus medium growing along the streak made by the platinum wire. Note the concentric rings.

Fig. 393*B*.—Forty-eight-hour colonies of *Neisseria gonorrhoeae* on Gradwohl agar. Note the radial striations of the large colony and the concentric rings of the small colony.

5. **Friedländer Bacillus (Klebsiella Pneumoniae).**—These colonies may be differentiated from the gonococcus colonies by the fact that they usually show a white pigment. They are slimy, and semitransparent. Smears show typical gram-negative bacilli.

6, 7, 8. **Diphtheroids.**

Three types of diphtheroids have been noted.

6. **Pinpoint colonies,** distinct, and possessing a deep center; they are never confused with gonococcus colonies. They show this deep center macroscopically as well as microscopically. Edges are even. Emulsification of the colony is quite difficult, since the organisms tend to stick together. Smears show typical diphtheroids, usually stained gram-variable.

7. **White pigmented colonies,** slimy, small, sometimes fermenting the levulose, sometimes not reacting with the sugar. Morphologically, they are club-shaped diphtheroids with granules or bars of metachromatic substance.

8. Colonies are **flat, transparent, distinct, small,** and do not ferment the levulose. They, therefore, do not show a yellow zone around them. A beginner may mistake them for gonococcus colonies, if the macroscopic appearance alone is studied. Microscopically, they show fine, regular granules at the periphery; the central portion is composed of rather coarse, large, round granules that give the appearance of a collection of crude projections from the surface. There is no distinct central structure, and no radial striation. They are less densely granulated than colonies of gonococci, and more translucent. Smears show typical diphtheroids.

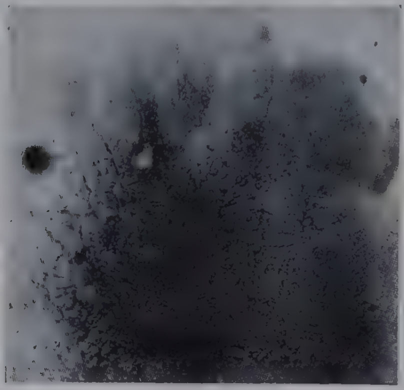

Fig. 394.

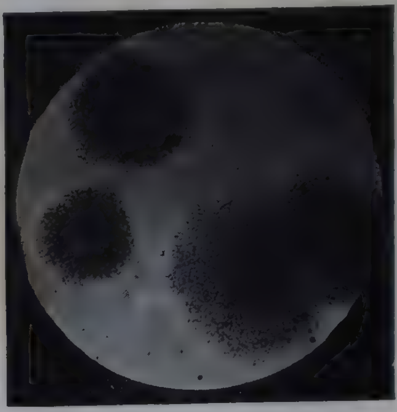

Fig. 395.

Fig. 394.—Ninety-six-hour colony of *Neisseria gonorrhoeae* on Gradwohl agar showing deep lobulation, radial striations, and coarse "crumbs." Only a portion of the entire colony is shown.

Fig. 395.—Colony of *Streptococcus mitis* on Gradwohl agar.

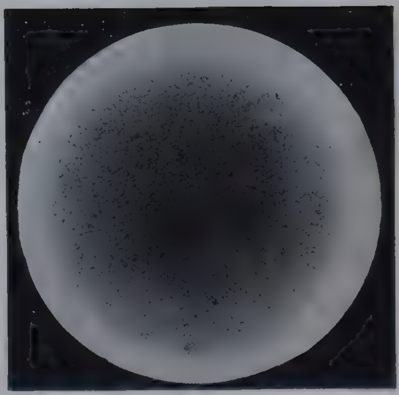

Fig. 396.

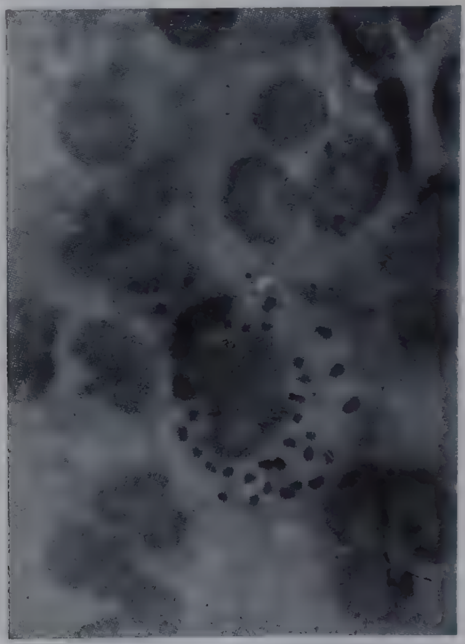

Fig. 397.

Fig. 396.—Colony of a diphtheroid on Gradwohl agar.

Fig. 397.—Gonococci in a pus cell (×1,000).

9. **Staphylococci.**—Colonies are characteristic; that is, they are circular, shiny, opaque, with unbroken margin, and produce pigments. They ferment the levulose, showing a yellow zone around the colony. Stained preparations show typical staphylococcus formation; that is, spherical organisms in grape-like formation, taking a design-like appearance. If fermentation of the levulose is complete, they may stain gram-negative instead of gram-positive.

10. **Sarcinae.**—These colonies resemble the colonies of staphylococci. Smears show spherical organisms in bundle formation. They may stain either gram-positive or gram-negative.

11. **Air Contaminants.**—Air contaminants can always be recognized by their size and the location on the plate. They usually are not on the streak made by the platinum wire.

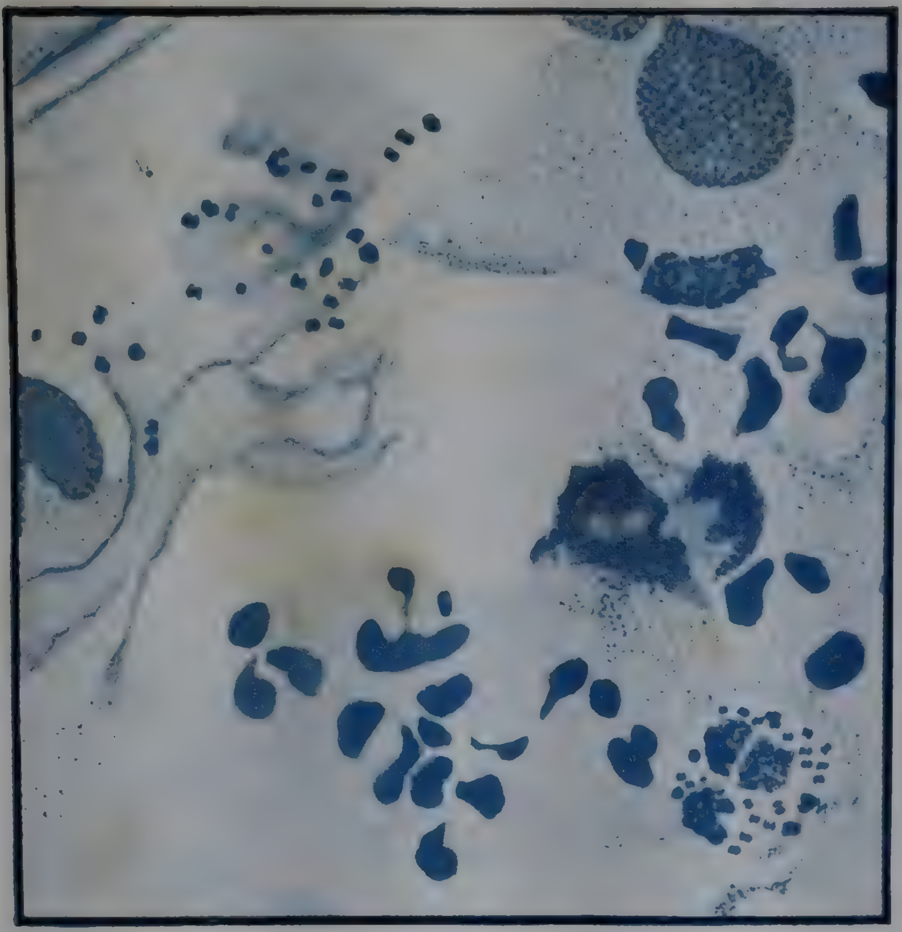

Plate XLIII.—Gonococci in Pus, Methylene Blue Stain.

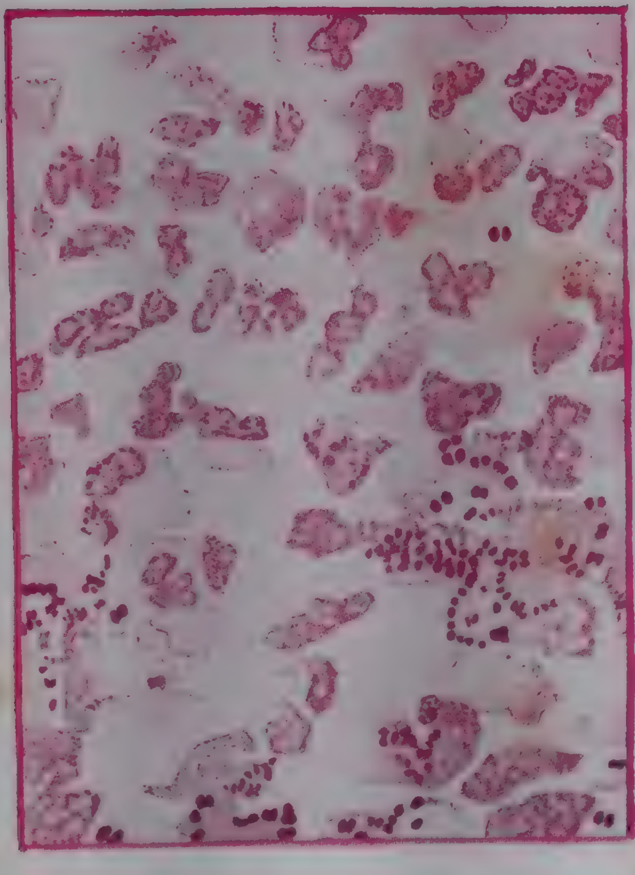

Plate XLIV.—Gonococci in Pus from Urine Sediment, Gram Stain.

If it is impossible to culture the material immediately, it should be kept in a cold place, to prevent overgrowth of contaminating organisms.

Public health laboratories have sought a method of keeping cultures or inocula of gonococci alive in transit: most of the cultures submitted by physicians to such laboratories are necessarily sent by mail. It is well known that in most cases, unless the material inoculated with the suspected gonococci reaches a laboratory very quickly, no growth will be obtained and the whole purpose of gonococcus culture is without results. An ideal medium for such purpose would be one that would maintain the viability of the gonococcus and inhibit the growth of other bacteria at the temperatures to which the medium might be exposed en route.

Alternative media for preservation and mailing were suggested by Hirschberg (M-34) and Sanders (M-35).[1]

Place 3 c.c. of the media with sterile precautions in a suitable vial (approximately 120 by 22 mm.)[2] containing a plastic screw cap (phenol Formalin-free) with a well which holds the cotton swab applicator. The applicator should be long enough to reach the bottom of the vial. In this way the swab is practically imbedded in the medium. Add carbon-dioxide gas with sterile precautions after the agar has solidified. Securely tighten the caps. Test the vials for sterility, and store at room temperature until used, preferably within 1 week. The vials should be kept upright at the time of use in order to avoid excessive loss of CO_2.

These media prevent the growth of many contaminants which ordinarily would overgrow and prevent the isolation of the gonococcus.

Smears of Pus or Urine for Gonococci

(From Discharge Pus, etc., or Urinary Sediment.)

If the pus is obtained from urine, the urine must be centrifuged at high speed for about fifteen minutes, and the sediment smeared on glass slides.

Fix the slides in the flame.

Stain with Gram stain.

When decolorizing, keep the slide in the alcohol until the pus is colorless.

Examine for bean-shaped diplococci, intracellular or extracellular.

Report.—Gram-negative diplococci **resembling** gonococci. Report pus cells, epithelial cells, and other bacteria. No definite identification of the organisms can be made by the smear method. Culture methods are the only means of absolute identification of gonococci. If negative, report no gonococci found.

Dried Pus for Gonococci

Place the material to be examined in a Petri dish.

Soak off the dried pus in a small amount of sterile physiologic saline.

Plate out on several plates of special media M-31, 32, 33, 36, or 37, and incubate, lid on top, for twenty-four to forty-eight hours.

Identify the colonies microscopically, and confirm their presence by stained smears from the colonies.

Report: Gonococci found, or no gonococci found.

For other organisms causing inflammation and pus formation, proceed as for the examination of fistulas.

Special methods are used for the investigation of infections with *H. ducreyi.*

[2] Glassco No. 7350.

Diagnosis of Hemophilus Ducreyi by Smears

Kornblith* in a series of 175 cases reported that the smear was the best single criterion of diagnosis, positive identification being possible in 88.57 per cent of their cases. Greenwald** uses the Gram stain. In his hands the smear was positive in 65 per cent of his cases.

Some workers prefer Wright stain or methyl green pyronin.

Cultivation of the Hemophilus Ducreyi (Bacillus of Soft Chancre)

Method of Sanderson and Greenblatt

Sanderson and Greenblatt advocate the following method for the cultivation of *Hemophilus ducreyi*[1, 2, 3]: Soft beef infusion agar (with only 0.5% agar) M-15 is put up in aluminum screw cap vials of 10 c.c. capacity, in 5 c.c. amounts and sterilized. When ready for use, 1 c.c. of human or rabbit defibrinated blood is added per vial. Bubo pus is aspirated under strictly aseptic conditions to prevent admixture of skin contaminants, and not more than 0.2 c.c. inoculum to a vial. The culture is incubated at 37° C. Growth in filaments or long chains of gram-negative bacill usually occurs in 48 hours, although cultures should not be discarded as negative within a week. Sometimes in initial cultures the bacilli are to be found in masses of tangled clumps, and it may take careful search to locate them. Once grown, the cultures must be transferred every few days to retain viability, until the organisms have become adjusted to the new environment. They may be then subcultured at weekly to ten-day intervals.

Little success is had in obtaining pure cultures from ulcers or buboes that have become infected with secondary invaders owing to the more rapid proliferation of these organisms. As a general rule, *H. ducreyi* grows poorly or not at all on the surface of culture media. Hence, the usual plating methods are of little value in the isolation of this bacillus. Unruptured buboes offer the best source for obtaining pure cultures.

For the detection of *Treponema pallidum,* dark-field examination or tissue biopsy may be necessary.

Dark-field Examination for Treponema Pallidum (Spirocheta Pallida)

The organism which causes syphilis is the *Treponema pallidum,* which was described by Schaudinn and Hoffmann in 1905. They can be identified readily by their movement in spirals with dark-field examination. For details in preparing specimen see Chapter I, page 11. This organism is a delicate, thin spirocheta ranging from 6 to 15 microns long and from 0.25 to 0.3 microns wide. The spiral amplitude is 1.0 micron, regular. The spiral depth is 0.5 to 1.0 micron and very constant. Waves, one or more, slight, undulating curves may be present. Progress is due to the rotary motions with undulations with some expansion and contraction of the coils. There is an absence of the chambered structure. If a membrane is present, it must be flexible. Flagella are absent. A highly motile end portion is absent.

In the preparation of the specimen for the diagnosis of syphilis with the dark-field examination, one must be careful to avoid confusion with other spirochetes. For instance, preparations from the mouth for dark-field exami-

---

*J. A. M. A. **117**: 2150, 1941.

J. A. M. A. **121: 9, 1943.

[1] South. M. J. **30**: 147, 1937.

[2] Am. J. Clin. Path. **7**: 193, 1937.

[3] Arch. Dermat. & Syph. **36**: 486, 1937.

nations for *Treponema pallidum* must be made very carefully and one must bear in mind the possibility of differentiation of the species from the *Treponema microdentium,* which resembles the *Treponema pallidum* very closely. In general, spirochetes other than the syphilitic organism have slower motion, greater width, and longer spirals. This is particularly true of the *Borrelia refringens,* which is found upon the genitals. There should be no difficulty in making a diagnosis of *Treponema pallidum* by dark-field methods from preparations from extragenital chancres on the lip, face, hands, and from genital chancres, but in respect to lesions within the mouth, one must be very careful in not confusing the *Tr. pallidum* with the *Tr. microdentium.*

Diagnosis of Congenital Syphilis by Dark-Field Methods.—The diagnosis of congenital syphilis is very important. Demonstration of spirochetes by dark-field examination of fresh preparations from the wall of the umbilical vein has been recommended by Norman R. Ingraham, Jr.[1]

He presents results of dark-field examination from scrapings from the umbilical vein in diagnosis of congenital syphilis. Spirochetes have been found in the blood stream, in the nasal secretion, in conjunctival secretion, syphilitic cutaneous lesions, the urine, and in the meconium of syphilitic infants. Spirochetes have been described as present in the umbilical cord by a number of European workers. Huebschmann and Simmonds in 1906 found spirochetes in sections of umbilical cord stained by the Levaditi method. This was confirmed by others. Emmons found spirochetes in silver stained sections of the umbilical vein in only one of fifteen syphilitic infants. Manouélian found spirochetes in congenital syphilis in cases of periphlebitis of the umbilical vein.

Demonstration of spirochetes by dark-field examination of fresh preparations made from scrapings from the wall of the umbilical vein was mentioned by Gräfenberg as early as 1908. It was rediscovered by Vulovic in 1923 and has been employed by others.

The **method of Vulovic** used by Ingraham was as follows:

> Immediately after delivery, a portion of the umbilical cord, about 3 inches long, is cut from the distal end, that is, the end nearer the child, and placed in a sterile moist bottle without preservative. Examination must be made as soon as possible. Examination is made by dividing the specimen in half and looking for the two arteries and the single vein. Pass through the vein a small blunt instrument, like a probe, and cut longitudinally to expose the lumen. Blood adhering to the intima of the vessel is scraped away with a knife. Fresh scrapings are made from the wall of the vessel, placed in physiologic solution of sodium chloride, macerated, placed on a slide and examined in the dark-field microscope.

Ingraham found this method useful in nineteen of eighty-seven cases, or 21.8 per cent.

Diagnosis of Syphilis by Examination of Biopsy Tissue.—(See Method of Krajian, page 2138.)

URINE

1. Urine for bacteriologic examination should always be collected by catheterization under very proper sterile and aseptic technic, into a sterile container.
2. The examination of urine for Spirochaetales, helminthic eggs, and Trichomonas is described in Chapter XII.

---

[1] J. A. M. A. **105**: 560, 1935

3. See pages 1521 ff. and 1632 ff. for examination for typhoid and other Salmonellae.

Transfer urine, with all sterile precautions, to two sterile corked test tubes.

Centrifuge at high speed for one-half hour.

Remove the supernatant fluid with a sterile dropper with rubber bulb. Always place the supernatant fluid from any material which may contain bacteria into a container which can be placed in a sterilizer and destroyed.

The sediment is used for inoculation.

If no definite information is given as to the probable type of organism which may be found, a complete bacteriologic examination must be made for

1. Streptococci
2. Staphylococci
3. Pneumococci
4. Gonococci
5. Coliform organism and Salmonellae
6. *Pseudomonas aeruginosa*
7. Tubercle bacilli, etc.

4. With the sediment inoculate
   - (a) one blood agar plate M-28, M-29
   - (b) one eosin-methylene blue plate M-71, M-72.

If gram-positive cocci and gram-negative rods are seen in the smears, inoculate as well
   - (a) one sodium azide blood plate M-21, 22, or alcohol plate M-23.
   - (b) proceed with the examination of colonies as described under "Pus."

Inoculate also one gonococcus plate (M-35 to M-37) and incubate in carbon-dioxide atmosphere. Proceed as for gonococcus examination of urethral material.

For the isolation of Salmonellae, inoculate one tube of selenite-F M-78 with the urine. Use about 2 c.c. of the urine for each tube.

Incubate for 24 and 48 hours. Streak the growth from the tubes on SS plate M-67 *or* desoxycholate-citrate M-65 plates and on bismuth sulphite M-70 plates. Proper modifications or media made by the laboratory (not from desiccated products) may be substituted.

Proceed according to the directions under "Stool."

Examination of Urine for Tubercle Bacilli

The finding of an acid-fast bacillus in the urine is not necessarily evidence of tuberculosis. Because of the possibility of the presence of the smegma bacillus (*Mycobacterium lacticola)* in the genitourinary tract, it is necessary either to cultivate the organism, or better, to inoculate a guinea pig.

Collecting the Specimen.[1]—

Prepare 1 or 2 liter bottles by washing well in alkali, followed by washing in potassium dichromate-sulphuric acid cleaning solution. Rinse thoroughly in tap water, then in distilled water, cork well, and sterilize in the dry heat sterilizer at 170° C. for two hours. Wrap a glass funnel in a towel, and sterilize in the same manner.

Instruct the patient to collect the morning specimen, and the remainder of the specimen for the twenty-four hours until the following morning. The patient should also be instructed not to touch the inside of the bottle with the fingers, and to avoid as far as possible contaminating the specimen in any manner whatsoever.

No preservative should be used, although a small crystal of thymol or camphor may be added if the specimen is to be sent some distance.

(a) Direct Examination:

Allow the sediment to collect. Select especially the shreds of fibrin and pus. A smear is made, and stained with the Ziehl-Neelsen stain after fixation. It is well to make the smears in a loopful of serum or egg albumen to avoid the possibility of washing the smears off the slide in the process of staining.

Tubercle bacilli are characteristic, although no definite diagnosis may be made by this method.

---

[1] Baldwin, Petroff, and Gardner: Tuberculosis; Bacteriology, Pathology, and Laboratory Diagnosis, Lea & Febiger, 1927.

Report: Acid-fast bacilli resembling tubercle bacilli.

(b) **Sedimentation Method** (Petroff):

Use the twenty-four-hour specimen collected in the manner described above.

If not acid, acidify by adding a few drops of 30% acetic acid.

To every 1000 c.c. of the acidified urine add 2 c.c. of 5% solution of tannic acid. Shake thoroughly.

Place in the ice box for twenty-four hours. A heavy precipitate will collect at the bottom of the bottle.

Decant and discard the supernatant fluid.

Centrifuge the sediment at high speed for ten minutes.

Decant and discard the supernatant fluid.

To the sediment add 1 c.c. N/1 sodium hydroxide to dissolve it.

Warm in a water-bath at 37° C. for thirty minutes.

Dilute with 3 volumes of sterilized water.

Mix thoroughly and centrifuge at high speed.

Decant and discard the supernatant fluid.

Spread the sediment on slides, making the smear in either serum or egg white. Fix in the flame, and stain with the Ziehl-Neelsen stain.

Tubercle bacilli are characteristic, but cannot be definitely identified by the smear when found in urine.

Report: Acid-fast bacilli resembling tubercle bacilli.

(c) **Animal Inoculation** (Petroff):

This is the method of choice for the identification of tubercle bacilli in urine.

Prepare the sediment from a twenty-four-hour specimen in the manner described above (Petroff).

Inject the entire sediment subcutaneously into the skin fold of the right inguinal region of 2 guinea pigs.

Tag the pigs, and record on the laboratory chart, giving the date of inoculation, the number and weight of the pigs, and the identification of the specimen.

If pigs die within a few days, contaminating organisms have probably caused the death.

Five weeks, or longer, after the injection, a tuberculin skin test is made on the animals.

If the animals do not react, they should be kept a few weeks longer before an autopsy is performed.

If, after two months, the skin test is still negative, one of the pigs is sacrificed with chloroform, and autopsied.

The other pig is retained for several months.

If there were any tubercle bacilli in the specimen, the pigs will show lesions of tuberculosis on the spleen, the kidneys, the liver, or other abdominal organs.

(d) **Isolation and Cultivation of Tubercle Bacilli from Urine** (Petroff):

Prepare a sediment from a twenty-four-hour specimen in the manner described above (Sedimentation Method, Petroff).

To the sediment, add 5 volumes of N/1 sodium hydroxide.

Shake thoroughly.

Incubate in a water-bath at 37° C. for thirty minutes.

Centrifuge for five minutes at 2000 revolutions per minute.

Decant and discard the supernatant fluid.

To the sediment, add 2 drops of N/1 hydrochloric acid.

Distribute the entire sediment by means of a capillary pipette over the surface of 4 or 5 tubes of egg media or Petrik's medium (M-58, M-58a, M-58b). Smear the surface with a platinum wire.

Replace the cork. Bore a hole in the cork, and cover with the metal cap.

Incubate two weeks or longer to obtain a growth.

(e) **Isolation and Cultivation of Tubercle Bacilli From Urine** (*Peppler and Hill*): Collect urine in 1 liter bottles containing 1.5 c.c. of a 1% solution of acriflavin and 40 c.c. of phosphate buffer pH 4.0.

Add to each bottle 5 c.c. of a 20% solution of tannic acid.

Let stand overnight in the refrigerator.

Remove the sediment with a pipette and centrifuge it at 3000 r.p.m.

Decant supernatant fluid and add an equal amount of 3% sodium hydroxide to the sediment and let it stand at 37° C. for 30 minutes.

Add 2 to 3 volumes of saline and centrifuge again.

Use the sediment for culture on Loewenstein M-60 *or* Petragnani media M-61 or for guinea pig inoculation.

BACTERIOLOGIC EXAMINATION OF AUTOPSY SPECIMENS

It is imperative that the body should not be embalmed if cultures are to be made. In order to make proper bacteriologic examinations of organs and cadavers, the outside of the organs should be seared with a hot iron and then opened with a sterile knife into the deeper parts. From this, material is removed with a sterile platinum loop.

Bacteriologic Examination of Tissue for Tubercle Bacilli*
(Mycobacterium Tuberculosis)

Grind up the granulations from curetted surfaces in either Antiformin or sodium hydroxide (normal solution) in a sterile glass mortar.

Dilute slightly.

Centrifuge at high speed for fifteen to thirty minutes.

Either make smears and stain with Ziehl-Neelsen stain, or inoculate guinea pigs. If guinea pigs are inoculated, large needles may be used, or a small skin puncture made with a sterile scalpel, and loopfuls of the sediment thrust under the skin. Seal the cut with collodion, after disinfecting with iodine.

Proceed with the examination of the guinea pig as discussed on page 1647.

ANTIBIOTIC AGENTS AND THEIR ASSAY

Antibiotic agents are defined as antimicrobial agents produced by living cells. In a Harvey Lecture,[1] Selman A. Waksman made the following observations in summarizing the chemical and biologic properties which distinguish antibiotic agents from the common antiseptics and disinfectants:

1. They are produced by living organisms, often designated as antagonists because of their ability to inhibit the growth of or to destroy bacteria and other microorganisms. Certain purely synthetic compounds have antibacterial and antifungal properties similar to those of typical antibiotic agents.

2. Their action is primarily bacteriostatic in nature, bringing about inhibition of growth; their bactericidal properties may also, however, be very pronounced.

3. They are selective in their action upon bacteria, some affecting largely gram-positive and only to a limited extent gram-negative forms, whereas others act upon certain specific bacteria within each of these groups, and only to a limited extent or not at all against other bacteria. These differences are

---

*For cutting and staining tissue for tubercle bacilli, see Chapter XIV.

[1] Waksman, Selman A.: Harvey Lectures, Series XL, 1944-1945.

qualitative as well as quantitative; hence one may speak of a ''bacteriostatic'' or ''antibiotic spectrum,'' namely the selective antibacterial or antimicrobial action of an antibiotic substance.

4. The effect of the substrate upon the antibacterial activities of different antibiotic substances varies greatly. Some substrates have no effect at all upon a specific substance; others reduce the activity of the substance, due to the neutralizing effect of some constituent, such as peptone, glucose, or serum; some, like blood, may adsorb the substance, thus completely inactivating it; some substances require for their activity the presence in the medium of specific constituents, such as glucose, in order to become effective.

5. Antibiotic substances vary greatly in their chemical nature. A large number of compounds have already been isolated, although only comparatively few have so far been crystallized.

6. Antibiotic substances vary greatly in their toxicity to animals, some being highly toxic, others having virtually no toxicity at all, and most others falling between these two extremes. They also vary in their in vivo activity.

7. The mechanism of antimicrobial action of various antibiotic substances is different. Some interfere with the growth of bacteria and their cell division, others with some phase of bacterial respiration, and still others with the utilization of essential metabolites by the bacteria.

8. Many antagonistic organisms produce more than one antibiotic substance. *Pseudomonas aeruginosa* has long ago been known to produce two agents, pyocyanase and pyocyanin, distinct from one another both chemically and in their antibacterial action. *Bacillus brevis* produces gramicidin and tyrocidine; *Penicillium notatum* forms penicillin and notatin; *Aspergillus flavus* produces aspergillic acid and flavicin; *A. fumigatus* is capable of forming four substances; namely, spinulosin, fumigatin, fumigacin, and gliotoxin. The culture filtrate of an organism producing an antibiotic substance often differs, therefore, in its antimicrobial activities from that of the isolated substance.

9. Some substances are produced by different types of organisms. Penicillin and penicillin-like compounds are formed by many different strains of *P. notatum, P. chrysogenum, A. flavus, A. giganteus, A. parasiticus,* and other fungi. Gliotoxin is produced by species of Trichoderma, Gliocladium, and *A. fumigatus.* Clavacin (claviformin, patulin, and clavatin) is formed by a large number of fungi, including *A. clavatus, P. claviforme, P. patulum,* and Gymnoascus. Considerable confusion may thus result from the duplication of names for the same substance.

10. The same type of substance, when produced by different organisms or even by the same organism grown on different media or under different conditions, may show variation, both in its chemical nature and in its antibiotic spectrum, from those of the established type.

The earliest observation on antibiotics was that made by Pasteur and Joubert in 1877, followed by Cantani in 1885, by Emmerich and Low in 1899, by Vaudremer in 1913, by Much in 1924, by Fleming in 1929, and finally by Dubos in 1939. Thus, an observation on this remarkable property of certain organisms toward certain bacteria was practically overlooked for some fifty years.

Penicillin

It was Fleming who, in 1929,[2, 3] first quite accidentally observed a growth of staphylococci in a blood agar plate which had been contaminated with a mold. He saw a widely inhibited zone of bacterial growth around this mold and also noted that colonies of staphylococci within the zone became transparent as the result of varying degrees of lysis. Fleming called this substance "penicillin" and thought it might be valuable in the isolation of *Hemophilus influenzae* by preventing the overgrowth of plates by staphylococci and other penicillin-sensitive microorganisms since the penicillin had no inhibitory action on the growth of the influenza bacillus. He also suggested that it might be an efficient antiseptic to be used on areas infected with penicillin-sensitive bacteria. The classification of this mold by Fleming was not quite correct. It was Thom in this country who classified it as belonging to the *Penicillium chrysogenum notatum* series, now known as *Penicillium notatum* Westling. Florey became interested in penicillin in 1938, and in cooperation with Chain studied it carefully. They confirmed Fleming's observations, first isolated penicillin in impure form, and showed its high activity against staphylococci, streptococci, pneumococci, diphtheria bacilli, *Cl. perfringens, Cl. septicum,* and *Cl. novyi* in vitro. It was in this country that Florey found a warm welcome in 1941, and through the aid of the Department of Agriculture developed methods for increasing the production of this substance. Production on a large scale was begun by a group of American biological manufacturers.

Since the epoch-making introduction of penicillin, many other antibiotics have been added. The laboratory is often called upon to perform two tasks: (1) to determine the antibiotic concentration in the blood of the patient (antibiotic level); and (2) to determine the sensitivity of an organism, isolated from a patient, to antibiotics.

(1) Bacteriologic Control of Antibiotic Therapy

Method No. 1. Oxford Cup Method

Use *Staphylococcus aureus* PCI 209 for penicillin, *Bacillus subtilis* ATTC 6633 for streptomycin, *Sarcina lutea* PCI 1001 for Chloromycetin, Aureomycin, and Terramycin, and *Streptococcus* ATTC 8668 for Ilotycin and Magnamycin.

Enumeration of Test Organisms.—

1. Pour 21 c.c. sterile base agar M-119 into standard 100 mm. by 20 mm. Petri dishes and let it solidify. Keep for 24 hours in a refrigerator before overlaying.

2. Inoculate assay broth M-120 with the test organism and incubate for 18 to 20 hours.

3. Transfer 0.1 c.c. of this culture to 100 c.c. of melted and cooled (45° C.) seed agar M-121 or yeast beef agar H-122.

4. Pour 4 c.c. amounts of the inoculated seed agar into the Petri dishes over the base agar. Keep in a refrigerator until use.

5. Sterilize glass cylinders, 12 mm. by 8 mm., in a dry heat oven. Before use, pass them through a flame. Put 6 of these lightly, equally distanced, on the surface of each plate (No. 4). Put the plates back into the refrigerator.

6. Just before the test is carried out, prepare dilutions of the antibiotic in M/50 phosphate buffer pH 7.0 containing 0.01, 0.05, 0.1, 0.5, 1.0, and 2.0 units or micrograms, respectively, per 0.1 c.c. of the buffer.

---

[2] Fleming, A.: Brit. J. Exper. Path. **10**: 226, 1929.

[3] Fleming, A., and McLeon, I. H.: Brit. J. Exper. Path. **11**: 127, 1930.

7. Put 0.1 c.c. amounts of the dilutions prepared under No. 6 into the cups of plate No. 5. Prepare 6 such plates identically. This is the **standard series of the day.**

8. Pipette off 0.1 c.c. amounts of the plasma or serum to be tested and the same plasma or serum diluted 1:9 with M/50 phosphate buffer, and place into cups of Petri dishes prepared as under No. 5. It is advisable to use two cups on three different plates for each plasma or serum sample. On a set of three plates, three samples may be run, each of them occupying two cups of each plate. This is the **test series.**

9. Incubate standard series and test series for 18 to 20 hours.

10. Measure the zones of inhibition on the standard plates, and plot the average curve.

11. Calculate the average zone of inhibition from the test plates and find the exact value from the curve.

12. Multiply the results by 10 to obtain the number of units or micrograms per c.c. of blood or plasma.

NOTE: This is the most precise method of antibiotic level determination. The standard curve must be set up every day. When *Sarcina lutea* PCI 1001 is used for penicillin level determinations, the plates are incubated at room temperature.

Method No. 2. Serial Tube Dilution Method

Use Staphylococcus PCI 209 or *Sarcina lutea* 1001 for penicillin and Chloromycetin; *B. circulans* for streptomycin; Staphylococcus PCI 209 for Aureomycin and Terramycin; Streptococcus ATCC 8668 for Ilotycin (erythromycin) and Magnamycin level determinations.

1. Prepare culture of test organisms by growing it for 18 to 20 hours in assay broth M-120.

2. Set up four series of sterile tubes, each containing 1 c.c. of double strength assay broth M-120. Two identical series will serve as controls, two others for the test proper. If several tests are carried out with the same antibiotic, one series of controls suffices for the day's run.

3. Make up dilutions of the antibiotic containing 5.0, 2.5, 1.25, 0.625, 0.312, 0.156, 0.078, 0.039, 0.0195, and 0.0 or no units or micrograms of antibiotic per c.c. of M/50 phosphate buffer pH 7.0.

4. Add 1 c.c. amounts of these dilutions to the tubes in the control series.

5. Make up dilutions of the plasma or serum to be tested in M/50 phosphate buffer containing 1.0, 0.5, 0.25, 0.125, 0.0625, 0.03125, and 0.015, and 0.0 or no c.c. of the plasma or serum per c.c. of buffer.

6. Add 1 c.c. amounts of these dilutions (5) to two series of test tubes prepared as in (2).

Note that there are 10 tubes in each control series but only 8 tubes in each test series. The last two places in the rack may be used for sterility controls: 1 c.c. of plasma or serum alone; 1 c.c. of buffer alone; 1 c.c. of broth alone; 1 c.c. of antibiotic alone.

7. Add to each tube 0.5 c.c. of the culture described under No. 1, diluted 1:100 with assay broth M-120.

8. Incubate for 18 to 20 hours.

9. Observe the tubes with the aid of a slit lamp. Find the tube containing the smallest amount of antibiotic which inhibits the growth of the test organism, in the control series.

10. Find the tube containing the smallest amount of plasma or serum which completely inhibits the growth of the test organism.

11. The two tubes described in (9) and (10) contain the same amount of antibiotic.

Calculation.—All tubes contain 2.5 c.c. Thus the amount of antibiotic added to the tube must be divided by 2.5 to obtain its concentration per c.c. The amount of serum actually contained in each c.c. of the fluid also can be obtained by dividing the amount added by 2.5. Thus the concentration of antibiotic per c.c. plasma or serum can be calculated by dividing the amount of antibiotic added to the last tube which still inhibits the growth of the organism by the amount of plasma or serum present in the last tube which shows inhibition of the test organism:

$$\text{Concentration of Antibiotic per c.c. Serum or Plasma} = \frac{\text{Amount of Antibiotic in Last Tube}}{\text{Amount of Serum or Plasma in Last Tube}}$$

Example.—

The last tube, in the control series, which completely inhibited the growth of Staphylococcus PCI 209 contained 1.25 units of penicillin. The last tube containing serum of the patient which completely inhibited the growth of this organism contained 0.25 c.c. of serum.

The penicillin level in this example is $\frac{1.25}{0.25} = 5$ units of penicillin per c.c. serum.

NOTE: Difficulties arise when two antibiotics are given to the patient. Penicillin can be inactivated by using penicillinase, about 10 units per c.c. of serum or plasma. Streptomycin will be counteracted by 0.05 gm. cysteine hydrochloride per 100 c.c. of serum or plasma. Sulfa drugs will be inhibited by 0.05 mg. p-aminobenzoic acid per 100 c.c. of serum or plasma. Such determinations, however, seldom give reliable results.

(2) Determination of Microbial Sensitivity to Antibiotics

Method 1. Tube Dilution Test

1. Grow the organism to be tested in assay broth M-119 for 18 to 20 hours.
2. Prepare a series of sterile tubes, each containing 1 c.c. of double-strength assay broth M-119.
3. Prepare dilutions of the antibiotic to be tested in M/50 phosphate buffer pH 7.0: 50, 25, 12.5, 6.25, 3.125, 1.526, 0.781, 0.39, 0.185, 0.092, 0.046, and 0.0 or no units or micrograms per c.c. of buffer.
4. Add 1 c.c. amounts of these dilutions to the tubes prepared in (2).
5. Dilute growth in (1) with assay broth M-119 1:100, and add 0.5 c.c. of this dilution to each test tube prepared in (4).
6. Prepare a control tube containing 1 c.c. of one of the antibiotic dilutions and 1 c.c. of broth.
7. Incubate for 18 to 20 hours.
8. Observe which tube contains the smallest amount of the antibiotic that still inhibits the growth of the organism.
9. Divide the total amount of antibiotic added to that tube by 2.5 to obtain the number of units or micrograms per c.c. necessary to inhibit the growth of the organism.

NOTE: Blood levels achieved by treatment with different antibiotics vary considerably. The results obtained by this method and similar methods are indicative only of the susceptibility of the organism; there is no possibility of predicting, without actual experimentation, if the necessary blood level may be obtained in a certain patient by the administration of a certain antibiotic.

Method 2. Disk Method, Difco*

Use Bacto-sensitivity disks. These disks are sterile. They must be removed from their vials with aseptic technic. The antibiotics are differentiated by the color of the disk. Concentrations are identified by the markings on each disk. Keep the vials stoppered when not in use, and store in a refrigerator.

The sensitivity test may be performed on plates of medium inoculated either with the isolated organism or with pathologic material containing the organisms.

Prepare plates of Bacto-heart infusion agar M-15, with or without added blood.

Inoculate either by smearing or streaking with a heavy suspension of the test organism or with the specimen containing the causative organisms, to obtain confluent or solid growth. Avoid excessive moisture.

Immediately place the Bacto-sensitivity disks on the surface, spacing them about 3 to 4 cm. apart. Use flamed forceps to remove the disks from the vial so as not to contaminate the remaining disks.

Incubate the plates at 35° to 37° C. for 12 hours, or until growth develops.

Examine for zones of inhibition of growth.

It is recommended that the etiological agent always be isolated, since mixed cultures might not always give dependable sensitivities.

---

*Baltimore Biological Laboratories now have available BBL Sensi-Discs for determining microbial sensitivity to antibiotics.

With heavy inoculation of plates, definite zones of inhibition often occur within 5 to 6 hours after inoculation. Generally 5 or 6 sensitivity disks can be placed on a 95 mm. Petri plate. Larger plates may be used, to permit testing of the sensitivity of an organism to a larger number of antibiotics or therapeutics. Avoid crowding of disks.

A base and "seed layer" technic may be employed.

Pour 15 to 20 c.c. of sterile Bacto-heart infusion agar M-15 in sterile 95 mm. plates and allow to solidify. Use 60 c.c. for 140 mm. plates.

Incorporate the inoculum in sterile melted Bacto-heart infusion agar M-15 with or without blood, at 45° C.

Pour this inoculated seed agar on the base layer, and distribute evenly over the surface by tilting the plate to give a thin "seed layer" inoculation.

Place the disks on the surface of this layer after it has solidified.

A moderate zone of inhibition around the lowest concentration of one or more antibiotics classifies the organism as being sensitive to any or all of these antibiotics, even though there might be a difference in zone size. Resistant organisms are not inhibited in the maximum concentration of the antibiotic, while very sensitive strains show marked zones of inhibition even in the lowest concentrations. With sensitive strains, zones of inhibition are often obtained around the disk containing the lowest concentration, which are nearly as large as those obtained around the higher concentrations, due to the diffusion characteristics of the test.

Presence of zones of inhibition of growth around the disks indicates that the organism is sensitive to the antibiotic. The diameter of the zone depends not only upon the sensitivity of the organisms, but also upon the diffusability of the antibiotic and other factors which might limit the availability of the antibiotic to the organisms in the medium.

If blood agar is used for the test, one must consider hemolytic properties of microorganisms. Growth of such organisms is characterized by a lysed, cleared, or discolored background, with the presence of colonies, while zones of inhibition leave the medium unchanged, that is, with no hemolysis. Upon longer incubation, the hemolysin produced by the organism may diffuse toward the disk, giving a cleared zone, without growth, around the periphery of the zone of inhibition. The true zone of inhibition on blood agar includes both the unchanged nonhemolytic as well as the hemolytic areas showing no bacterial growth.

Frequently, isolated colonies will be observed growing within the zone of inhibition. These represent variants of the strain or culture under test. Appearance of several such resistant colonies in the zone of inhibition does not indicate the true resistance of the culture which is demonstrated by the zone of inhibition of growth.

Method 3. Rapid Method for Determining Microbial Sensitivity to Antibiotics*

Principle.—

In this method, the hemoglobin acts as a color indicator system. The characteristic bright red color of blood depends on the presence of oxyhemoglobin. When hemoglobin is reduced, the color changes from bright red to purplish red. On a Petri dish containing blood agar in a base layer and overlaid with an inoculated nutrient agar medium, the metabolism of the microorganisms results in a color change of the blood from bright red to purplish red. Where the antibiotic activity inhibits microbial metabolism, no color change of the blood occurs.

Tehnic.—

The inocula consist of clinical specimens or bacterial cultures.

Prepare Petri dishes with a thin solidified layer (5 c.c.) of heart infusion agar M-15 containing 20% citrated whole human blood. This is the base layer-hemoglobin indicator.

---

*Department of Microbiology, Air University, USAF School of Aviation Medicine, Randolph Field, Texas, March, 1955. Demonstration at A. M. A. Meeting, Atlantic City, N. J., June 1, 1955.

Have at hand antibiotic-impregnated disks, which are commercially available, and tubes of melted brain heart infusion agar M-15 containing 0.8% dextrose or other appropriate nutrient media (seed layer).

Incubate the Petri dishes containing the base layer at 37° C. to pre-warm them.

Thoroughly agitate the inoculum in a tube of brain heart infusion agar, or appropriate nutrient media, which has been kept liquid in a 45° C. water bath. This produces a heavy seeding of organisms.

Pour this inoculated liquid agar as a seeded layer over the pre-warmed base layer; the latter contains the 20% whole blood.

Press color-coded filter paper disks, each impregnated with a known antibiotic, firmly on the surface of the inoculated seed layer.

Incubate the plate at 37° C. and check at 30-minute intervals for the occurrence of zones of inhibition of hemoglobin reduction surrounding the antibiotic disks.

Results.—

Prior to the appearance of visible growth, the metabolic activities of most strains of bacteria produce relatively intense reducing conditions within the medium. These conditions are reflected by a so-called ''reduction'' of oxyhemoglobin and a characteristic color change of the blood from a bright red to a purplish red. In this rapid method, readings can be made in 2 hours. The organisms reduce the oxyhemoglobin in the base layer and the bright red color of the blood turns to a purplish red except in zones around disks where the antibiotic has inhibited microbial metabolism and growth. These zones retain the bright red color of blood. Often a hemolytic organism will lyse the blood in the base layer and this plate will clear, but the zones remain easily discernible. The zones of inhibition of hemoglobin reduction are similar in size to those measured from inhibition of visible growth produced after further incubation of the inoculated plate or on control plates inoculated by the conventional surface-streaking procedure.

The incubation period for sufficient hemoglobin reduction varies with the nature of the test organism and the size of the inoculum.

This method provides the same information as the standard agar diffusion technic, but in much less time; the tests have approximately the same value in predicting the clinical outcome.

SANITARY BACTERIOLOGY

BACTERIOLOGIC EXAMINATION OF GLASSWARE OR CHINA FOR SANITARY QUALITY

Both the public and the public health officer are vitally interested in improving the unsanitary conditions prevailing in connection with dispensing of beverages. The use of single service paper cups solves the problem in some places, but we know that glasses are frequently used and are only superficially washed or disinfected between patrons. It is very probable, as has been pointed out by many observers, that beer glasses are sometimes not washed at all. Certainly, as pointed out by Calver,[1] there is a real opportunity for better control of respiratory diseases by means of improved sanitation of glasses and other eating utensils. Fellers, Levine and Harvey[2] suggest a standard method for these bacteriologic examinations. They found 18 different methods already described to be largely difficult to use and unsatisfactory. They proposed the following standard method of sampling.

---

[1] Calver, H. N.: Techniques for the Bacteriological Examination of Glasses. Mimeograph. The Public Health Committee of the Cup and Container Institute, 30 Rockefeller Plaza, New York, 1935.

[2] Am. J. Pub. Health 26: No. 12, 1936.

Use medium-sized cotton swabs. Immerse in 3 c.c. of 0.85% saline in 25 c.c. culture tubes, leaving the applicator sticks protruding slightly above the plugs. Sterilize in the autoclave at 10 pounds pressure for 20 minutes, and store at low temperatures.

To secure sample, remove plug, press out excess saline from swab with a rotary movement, thoroughly swab inside and outside lips and rims of glasses. Replace applicator in culture tube and insert cotton plug. Obtain similar specimens from a number of glasses in each establishment. Label tubes. Plate on culture media within a few hours, preferably not more than two hours, as follows.

Plating.—Agitate tubes by striking against hand about 25 times. Remove plugs, squeeze out excess saline against sides of tubes, transfer entire liquid contents to Petri dish. Inoculate Loeffler's blood serum M-10 with the swab. Pour 7 c.c. agar M-113 into the Petri dish and mix thoroughly. Incubate at 37° C. for 48 hours. Record counts for individual glasses, not as averages. This method, slightly modified, may be used in the examination of dishes and silverware.

Although occasional plates may show vast numbers of colonies too numerous to count, it is better to use the entire sample for plating. This will at least give a good idea as to the sanitary quality of the glassware examined. This method is applicable to the study of bacteriologic effectiveness of mechanical dish washers and cleaning and sterilizing compounds.

"Seeing Is Believing" Method for Sanitary Examination of Restaurants

Method of Jamieson and Chen*

This ingenious method of controlling the sanitary state of eating and drinking utensils permits one at the same time to educate the personnel of restaurants in cleanliness. Swabs are taken and media are inoculated and incubated in such a way that the restaurant workers may see the results, and thus become convinced of the effectiveness of proper cleaning.

Medium M-113 is used. Keep it in flat one-ounce bottles equipped with screw-caps. Slant 4.5 c.c. of the medium in each bottle. Sand one end of the bottle to permit labeling.

Sterilize cotton-tipped applicators and keep in proper envelopes. Have on hand sterile water to moisten the swabs.

Jamieson devised a traveling laboratory consisting of these utensils and of display racks into which the bottles fit.

In restaurants 3 cups, 3 forks, 3 spoons, 3 tumblers, and 3 cream pitchers are examined. In bars and taverns, 10 glasses ready for filling and one used glass are examined.

For each eating utensil use one swab. Moisten it with sterile water. Squeeze off the superfluous water by pressing the swab against the inner walls of the bottle containing the sterile water.

Swab the inner surface and the rim of the utensils, using the side of the cotton tip and rotating it.

Inoculate with each swab one flat bottle containing the medium by rotating the swab over the surface.

Incubate the flasks in an upside-down position on the display rack at room temperature, in the establishment where the samples were taken, for 3 days.

Evaluation of results:

0 to 10 colonies:	good
11 to 50 colonies:	fair
over 50 colonies:	poor

Microbiologic Examination of Frozen Foods

The Committee on Microbiological Examination of Foods of the American Public Health Association reported[1, 2] their recommendations for methods which have proved workable as a basis for the perfecting of standard methods for frozen foods.

---

*J. Milk Technol. 8: 134, 1945 and Canad. Pub. Health J. 37: 90, 1946.

[1] Am. J. Pub. Health 36: 332-335, 1946.

[2] Report issued under the chairmanship of Harry E. Goresline, Ph.D., U. S. Department of Agriculture, Washington, D. C.

In testing frozen vegetables for microbiologic content, consideration must be given to the fact that freezing storage at temperatures of approximately –10° F. (–23° C.) brings about a reduction in viable microorganisms. This may amount to roughly 50 per cent in 6 months or 75 per cent in 1 year. Thus, while a high bacterial plate count on frozen vegetables may be taken as proof of poor sanitary history, a low or moderate count does not by itself prove the opposite.

It is recommended that in the preparation of samples of frozen fruits and vegetables for microbiologic analysis a mechanical ''blender'' be employed. This has been arrived at after considerable experience with various methods of preparation on a wide variety of frozen products. In comparison with washing or hand grinding the mechanical disintegration will, as a rule, yield higher bacterial counts. However, more uniform results will be obtained, and the method is less laborious. Similarly the choice of tryptone glucose extract agar rests on the demonstrated superiority of this medium over nutrient agar or glucose agar, although glucose agar as a medium for frozen peas appears to be only slightly inferior.

Examination of Frozen Vegetables—Selection, Transportation, and Storage of Samples

Select from the lot to be examined a suitable number of packages, say 3 or 4, from each code lot of the pack. Transport in dry ice to the laboratory for analysis and place the samples in a refrigerated (0° F.) storage chest until they are to be analyzed. The temperature preferably should not rise above 0° F. (-18° C.) in the handling of the material.

Preparation of Sample.—

A. **Peas, Lima Beans, Cut Corn—Whole or Regular Cut Green Beans, etc.:**

1. **Macroscopic Examination.**—Open the package and note condition of the product, especially if ice crystals are present on the inner walls of the package and the vegetables appear to be somewhat shriveled. This condition is indicative of thawing and subsequent freezing. Record observations and any abnormalities, such as unnatural color or odor, or pink colonies of Torulae which are indicative of improper handling practices.

2. **Sampling for Plate Counts.**—The sample, if not loose-frozen, should be broken up into small units. This can be done by tapping the unopened package sharply against the table edge or by sharply striking the package with a dull instrument, being careful not to break open the package. After opening the package remove sample with sterile spoon, taking the sample from various parts of the broken out package, *e.g.*, from the center and corners.

Weigh aseptically a 50 gm. sample into a sterile borosilicate glass mechanical blender jar. Add 450 c.c. of sterile water to the jar and blend the contents for 2 minutes. If a Variac transformer is available it is advisable to increase the speed of the motor gradually and then run the blender for the required time at the 110 V. setting of the transformer.

Allow the sample to stand for 2 to 3 minutes to permit foam to subside.

Pipette 1 c.c. of the mixture into a 99 c.c. sterile water blank. Replace the cap on the dilution bottle and shake the bottle briskly 25 times through a 1 foot arc.

Pipette 1 c.c. aliquots of this mixture into each of two Petri dishes (1:1,000 dilutions) and also 0.1 c.c. aliquots into each of two more Petri dishes (1:10,000 dilution). Make a 1:100 dilution by pipetting 0.1 c.c. aliquots of the original mixture into each of two Petri dishes.

Pour melted tryptone glucose extract agar M-110, pH 7.0, cooled to 45° C., into the Petri dishes immediately, and thoroughly mix the dilution water with the agar by gently rotating the plates in a figure 8 motion with slight tilting of the Petri dish. Cool to harden, invert, and incubate at 32° C. for 4 days.

Dilutions of 1:100, 1:1,000, and 1:10,000 will usually suffice for commercially packed frozen vegetables, although further dilutions should be made if the history or the appearance of the samples warrant it.

It is of prime importance that the agar be poured immediately after the inoculum is introduced; otherwise many bacteria will adhere to the glass and an inaccurate count will result.

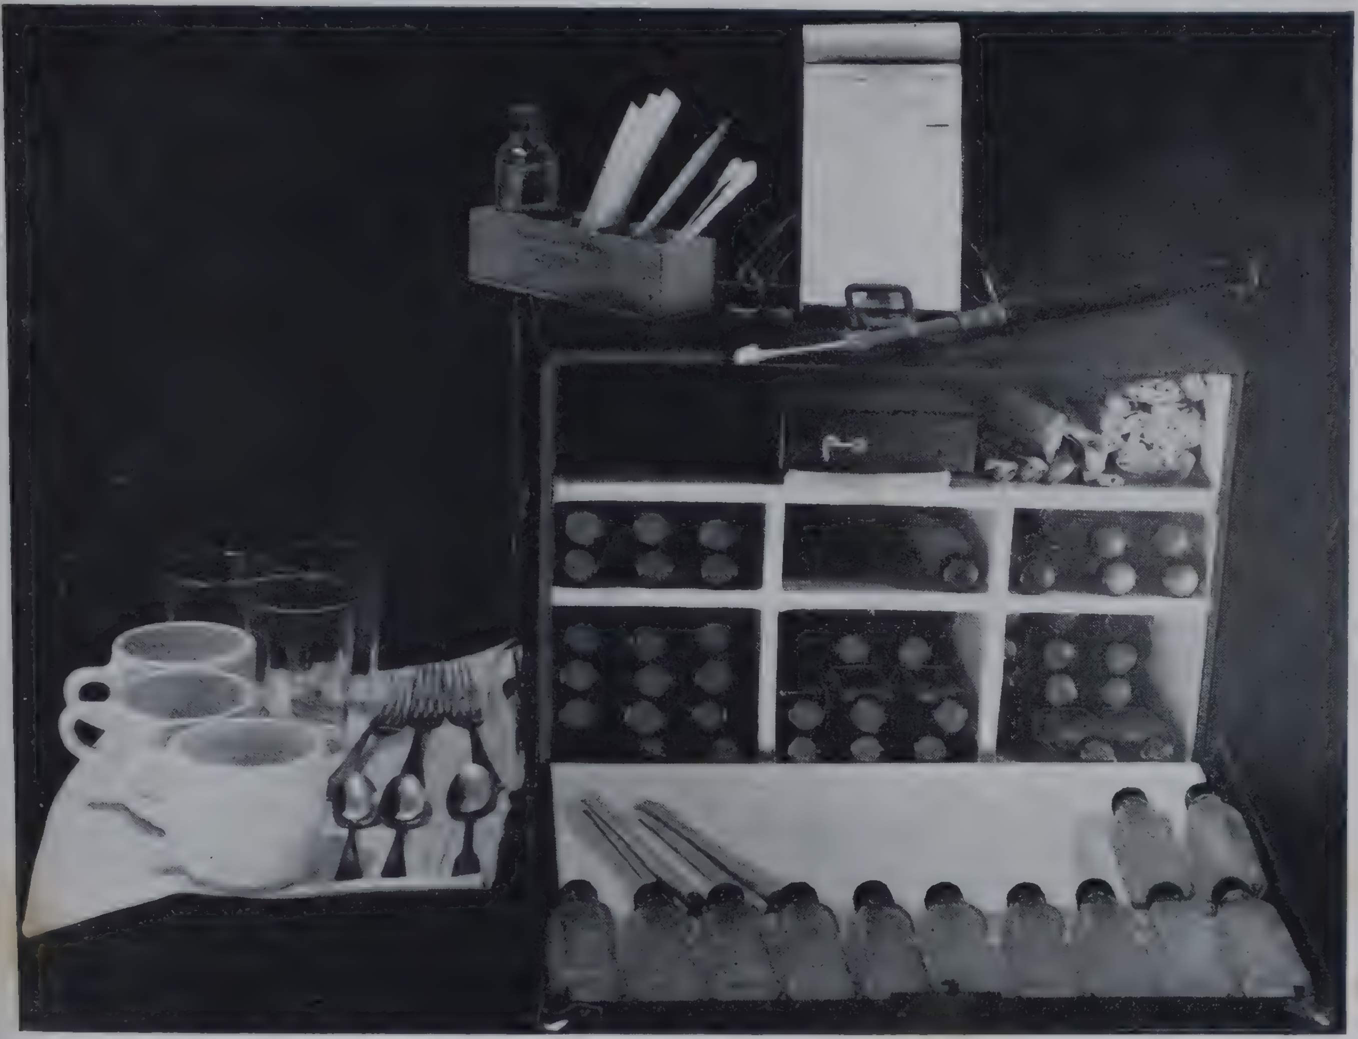

Fig. 398.—The Jamieson traveling laboratory for the "Seeing Is Believing" method of swab-slant cultures for the sanitary examination of restaurants. (Courtesy M. Jamieson.)

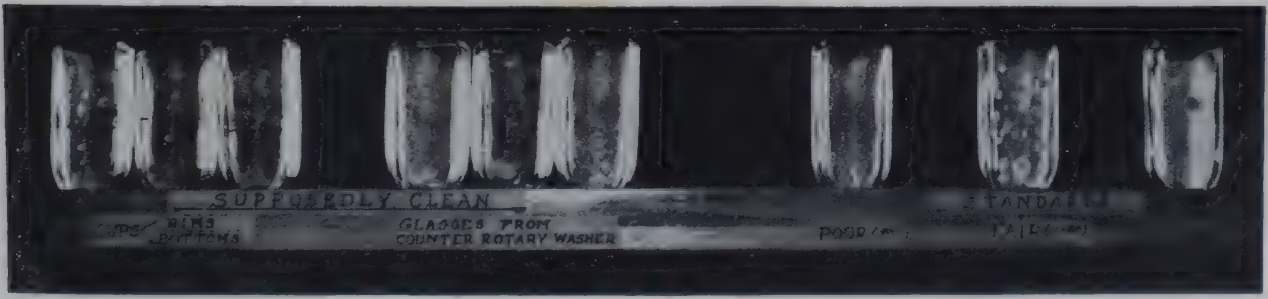

Fig. 399.—Results of examination of glasses. *Left end*, two swabbings showing prevailing conditions in one of the best restaurants. Cups washed in three-compartment machine and not dried. *Below line*, smear from swabbing bottom interior of cups—good. *Above line*, results from swabbing lips of cups—poor. *Middle three cultures* as *regularly* found from glass treated in counter rotary machine, the front of which states, "This sterilizes your glasses." Jamieson has found that this is a false statement. *Right end cultures*, arbitrary sanitary grade standard on glasses. (Courtesy M. Jamieson.)

After the incubation period is complete count the plates, using a suitable colony counter. Record results as "Plate count of microorganisms per gram."

3. **Direct Microscopic Count Method.**—The direct microscopic method has an advantage over the plate count method in that it is quicker and requires less equipment and glassware. Also it detects dead microorganisms, and indicates sanitary history, irrespective of the viable count.

Weigh 50 gm. of the vegetable (peas, lima beans, and cut corn) into a 250 c.c. iodine flask.

Add 100 c.c. water, stopper flask, and shake briskly 50 times through a 1 foot arc. Using a Breed pipette, transfer 0.01 c.c. of the washings to a microscope slide and, using a needle, spread the drop evenly over a 1 sq. cm. area of the slide. Dry and fix with heat or with methyl alcohol. Stain with methylene blue stain S-17, 18, rinse, dry, and examine under the microscope, using oil immersion. Use an ocular micrometer, such as a Whipple disk or Howard disk, with the microscope tube so adjusted that the size of the graduations is equal to 0.1 mm. (area of field 0.01 sq. mm.). Count the cells in 100 fields, and multiply the number by 20,000 to bring to the gram sample basis. Express results as "Direct microscopic estimate, microorganisms per gram."

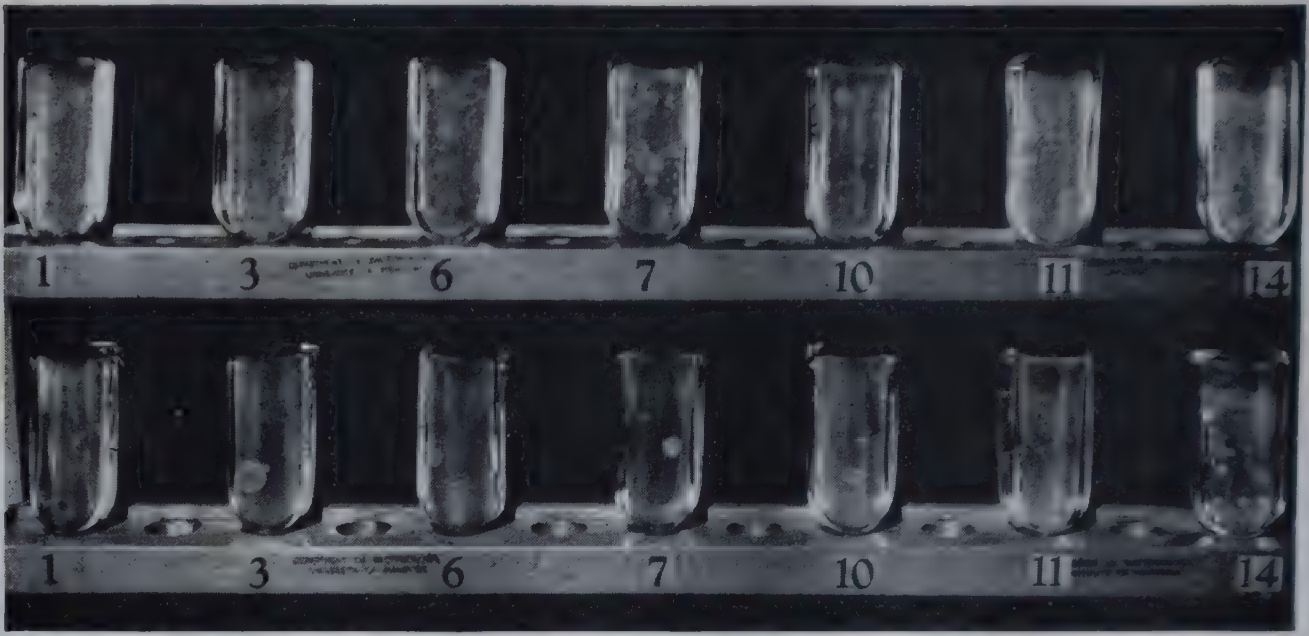

Fig. 400.—Before (top) and after (bottom) the "Seeing Is Believing" test inspired improvements in the cleaning of various types of dairy equipment. (Courtesy M. Jamieson.)

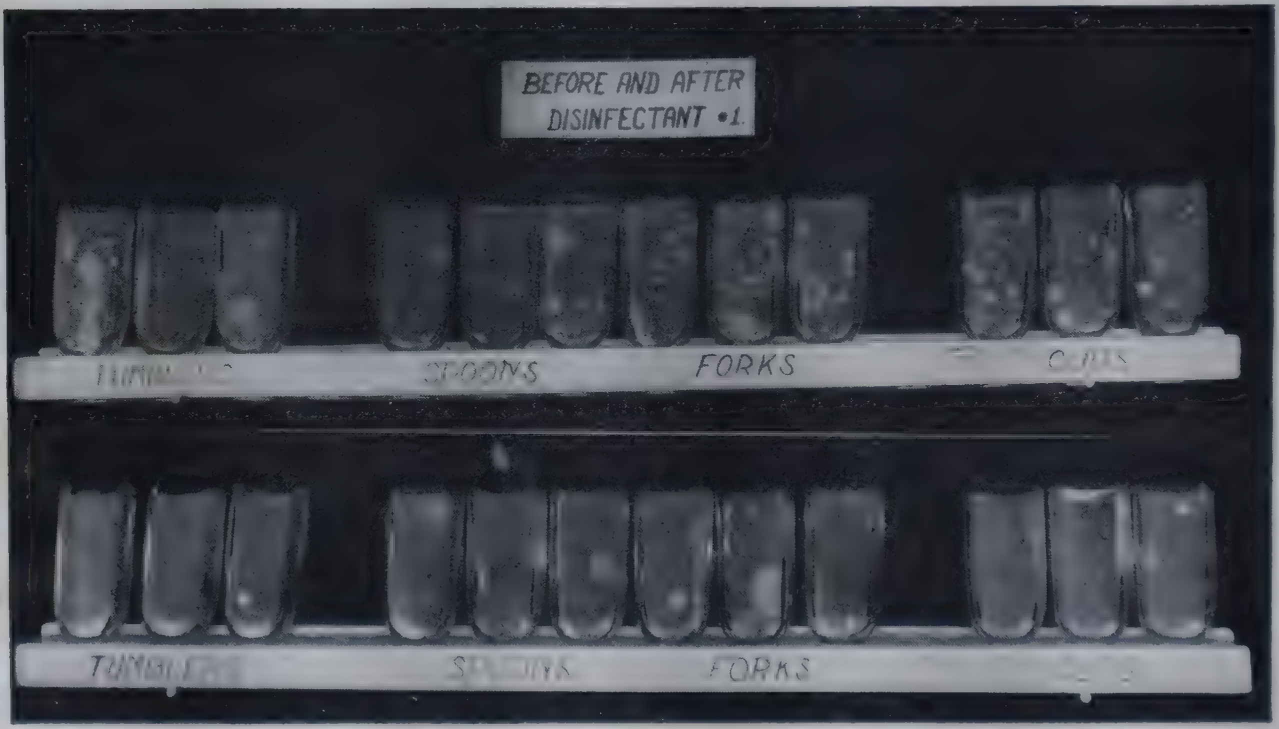

Fig. 401.—Before and after "Roccal" disinfectant and sterilizing treatment. (Courtesy M. Jamieson.)

In the direct method the following assumptions are made: (A) that all the cells are removed from the surface of the vegetable by the washing, (B) that the suspension of bacterial cells is uniform, and (C) that the drop of liquid is evenly spread over 1 square centimeter.

AVERAGE PRIVATE HOME CONDITIONS
SPOONS
FORKS

Fig. 404.—Average private home conditions. (Courtesy M. Jamieson.)

Interpretation of Results.—Plate counts of more than 400,000 per gram of peas or direct microscopic counts of over 1,000,000 per gram may be considered indicative of poor sanitary conditions in the plant, or poor handling practice in transit or in warehousing. In regard to other frozen vegetables it would appear that counts tend to run higher. In vegetable freezing plants plate counts of over 500,000 per gram of newly frozen produce are not encountered unless there is some degree of carelessness in the plant, such as faulty clean-up practice or prolonged holding of the material after blanching.

B. **Frozen Spinach:**

For proper comminution of spinach in a "blender" it is necessary to allow the package of spinach partially to defrost by standing at room temperature for 1½ to 2 hours. Open the package and weigh 50 gm. of the contents into a sterile borosilicate mechanical blender jar. Assemble the sample from various portions of the package, taking care to select petiole and blade portions in about the same ratio as in the sample as a whole. Add 450 c.c. sterile water. Blend for 2 minutes, and proceed as in analysis of A, peas, lima beans, etc.

C. **Frozen Broccoli and Cauliflower:**

Allow partially to defrost at room temperature. Using a sterile scalpel, cut portions from the curd and stem of several representative pieces of the vegetable. Aseptically transfer 50 gm. of these portions into the sterile borosilicate glass mechanical blender jar, add 450 c.c. sterile water, and proceed as directed for A, frozen peas, etc.

D. **Frozen Asparagus:**

Partially defrost at room temperature. Cut spears into short lengths, using sterilized scalpel. Transfer aseptically 50 gm. of the segments into a sterile borosilicate glass mechanical blender jar, add 450 c.c. sterile water, and proceed as in analysis of A, frozen peas, etc. When weighing sample portions, a number of spears should be selected and the proportion of butts and tips maintained.

The "cuts and tips" type of asparagus pack can be weighed directly into the blender cup.

Examination of Frozen Fruits

Preparation of Sample.—

Hold the package of frozen fruit at room temperature for 1 to 2 hours before opening in order partially to defrost the contents. While the fruit is still partially frozen, cut portions from various parts of the contents of the package, using a sterilized scalpel. The proportion of fruit to syrup should approximate that of the whole package. Weigh 50 gm. of fruit and syrup into a sterile borosilicate glass mechanical blender jar. Add 450 c.c. of sterile water, and blend for 2 minutes. Make a 1:1000 dilution by adding 1 c.c. of the blended mixture to 99 c.c. sterile water and make further dilutions in the usual manner. Plate 1 c.c. portions from the various dilutions on tryptone glucose extract agar M-110. Incubate for 3 days at 32° C. Count colonies under a suitable colony counter. Record results as "Plate count of microorganisms per gram."

Direct microscopic counts for molds and yeasts are made according to the methods given in *Official Methods,* A. O. A. C.[3] for microscopic analysis of tomato products. Care must be taken to distinguish between mold hyphae and fruit setae.

BACTERIOLOGIC EXAMINATION OF WATER

A. Bacterial Count

1. **Collecting the Specimen.**—The container should be a colorless glass bottle well stoppered with a cork, or with a ground-glass stopper.

Use ordinary four-ounce wide-mouth bottles with tinfoil-covered corks, and hood of heavier lead foil for collecting samples. Sterilize the bottles as usual in the dry heat oven; 10 gm. of crystallized sodium thiosulphate are dissolved in a liter of sterile water and 0.1 c.c. of the solution is added to each bottle. The bottles are then autoclaved for five minutes at 15 pounds stream pressure. Bottles should be freshly prepared for periods not exceeding two or three days, but the stock solution of sodium thiosulphate may be used over a longer period of time.

---

[3] Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists, ed. 5, 1940.

The bottle is sterilized in the dry heat oven at 170° C. for two hours.

The specimen should be either packed in ice or frozen. If it is frozen, it is placed in a pan of water at room temperature until it has thawed. It is kept in the ice box after the test has been made until the report has been completed.

2. **Preparation of Materials.**—Stabs of nutient agar M-13. Five or more sterile Petri dishes, preferably 5 inches in diameter.

1 c.c. pipettes, graduated in 0.1 c.c., plugged with nonabsorbent cotton, each wrapped separately, and sterilized in the dry heat sterilizer at 170° C. for two hours.

Test tubes of tap water prepared in the following manner:

Place 9 c.c. tap water in each tube. Use 5 × ⅝ inch test tubes. At the bottom of the water meniscus, make a mark with a diamond point pencil. Figure the amount of evaporation in the autoclave at 15 pounds pressure for thirty minutes in a volume of 9 c.c. and add this quantity to each tube. The amount to be added varies from 0.25 c.c. to 0.5 c.c. Plug with nonabsorbent cotton and tie paper over the top. Sterilize in the autoclave at 15 pounds pressure for thirty minutes. After the water has been sterilized, it is cooled to room temperature. If evaporation has left the fluid in each tube at the 9 c.c. mark, the water is ready for use. If the water is above or below the mark, either remove a portion or add more sterile tap water with sterile precautions until each tube contains exactly 9 c.c. sterile tap water. *Do not use distilled water.*

Sterile corks. If 5 × ⅝ inch test tubes are used, a number 5 cork will exactly fit each tube. Wrap each cork separately and sterilize in the dry heat sterilizer at 170° C. for two hours. Prepare one cork for each test tube.

3. **Technic.**—All dilutions of the water specimen must be accurate, and should be made so that no air contamination is allowed to reach the specimen.

Shake the specimen bottle vigorously 25 times before making the dilutions.

Make a 1:10 dilution of the water by adding 1 c.c. of the water specimen to 9 c.c. of sterile tap water.

After adding the 1 c.c. of water specimen, place a sterile cork carefully in the test tube to replace the cotton plug. All sterile precautions are observed during the transfer. Mix the contents of the test tube by turning upside down 25 times.

Make a 1:100 dilution of the water by adding 1 c.c. of the water specimen diluted 1:10 to 9 c.c. of sterile tap water.

Replace the cotton plug with a sterile cork, and mix as above.

Make a 1:1000 dilution of the water by adding 1 c.c. of the water specimen diluted 1:100 to 9 c.c. of sterile tap water.

Replace the cotton plug with a sterile cork, and mix as above.

Make a 1:10,000 dilution of the water by adding 1 c.c. of the water specimen diluted 1:1000 to 9 c.c. of sterile tap water.

Replace the cotton plug with a sterile cork, and mix as above.

A fresh pipette is used for each successive dilution.

Adhesive tape is placed around the side of the plate and the dilution of the water specimen marked on it. When inoculating the plates, the lid of the dish is tilted enough to admit the tip of the pipette, the pipette placed in the center of the dish, and the contents are allowed to run into the Petri dish. Do not blow through the pipette, and do not completely remove the cover of the dish. The entire process of removing the water specimen from each dilution tube, and placing in its respective Petri dish must be done very rapidly to prevent contamination with air bacteria.

Liquefy the agar M-13 and keep in a water-bath regulated at 45° C. In one tube of agar place a thermometer. This tube of agar will have to be discarded at the completion of the test. The temperature of the culture medium must not be greater than 45° C., nor less than 43° C. Higher than 45° C. will kill some of the bacteria, and lower than 43° C. will permit the medium to become solid.

In Petri dish No. I place 1 c.c. undiluted water specimen.

In Petri dish No. II place 1 c.c. of water specimen diluted 1:10.

In Petri dish No. III place 1 c.c. of water specimen diluted 1:100.

In Petri dish No. IV place 1 c.c. of water specimen diluted 1:1000.

In Petri dish No. V place 1 c.c. of water specimen diluted 1:10,000.

Pour the melted agar into each Petri dish, and mix thoroughly by rotating.

Allow to solidify.

Place upside down in the incubator for twenty-four to forty-eight hours. It is our custom to report counts at the end of twenty-four and forty-eight hours.

4. **Count as follows.**—Select the plates in which the colonies of bacteria are most evenly distributed. At least two plates should be counted. Divide the plates into sections by marking the bottoms of the dishes with a wax pencil. Count every colony on the plate.

Multiply the number of colonies counted by the dilution of the water.

Take the average, and report the result as the number of bacteria in each c.c. of undiluted water.

5. **Example.**—There were 343 colonies on the plate containing 1 c.c. of water specimen diluted 1:10.

On the 1:100 dilution of the water specimen, there were 35 colonies.

$$\begin{array}{r} 343 \times 10 = 3430 \\ 35 \times 100 = 3500 \\ 2\,\overline{)\,6930} \\ 3465 \end{array}$$

Each c.c. of undiluted water contains 3465 bacteria.

B. Examination for Evidence of Pollution

Colon bacilli are present in sewage. Examination of water for drinking purposes, therefore, is a test for colon bacilli. If colon bacilli are found there is danger of contamination of the water supply with typhoid bacilli and other intestinal organisms.

1. **Collecting the Specimen.**—The specimen is collected as described above.

2. **Preparation of Materials.**—Have on hand fermentation tubes of lactose broth M-5 made from beef extract, with inverted fermentation vials, 20 c.c. of broth per tube. Lauryl sulphate broth M-109 is preferred. Fifteen such tubes are needed.

Plate of eosin-methylene blue agar M-71, 72.

2-1 c.c. graduated pipettes.

1-10 c.c. volumetric pipette.

3. **Technic of Presumptive Test for Esch. coli.**—Using all sterile precautions, place 0.1 c.c. undiluted water specimen in 5 of the tubes of lactose broth.

Place 1 c.c. of the water in 5 of the tubes.

Place 10 c.c. of the water in 5 of the tubes.

Incubate at 37° C. for 48 hours. Examine each tube at 24 hours, and again at 48 hours. Record gas formation. Note (1) absence of gas formation; (2) formation of gas occupying less than 10 per cent of the inverted tube; and (3) the formation of gas occupying more than 10 per cent of the gas arm of the tube. If, after 24 hours' incubation, the gas formation occupies more than 10 per cent of the gas arm of the tube, this is a positive *presumptive* test for *Esch coli.* If no gas forms within 24 hours, or if the gas formation is less than 10 per cent of the arm of the fermentation tube, continue the incubation for 48 hours. The presence of any gas at all constitutes a *doubtful* presumptive test. This needs confirmation. If no gas forms within 48 hours' incubation, this constitutes a negative test.

4. **Confirmatory Tests for Esch. Coli.**—

To confirm the presence of *Esch. coli,* make transplants from the tubes showing gas formation to plates of eosin-methylene blue agar. Use the tube containing the smallest amount of water which showed gas formation. Incubate the plates at 37° C. for 18 to 24 hours. If typical colonies have developed on the plates within this period, the confirmed test is positive for *Esch. coli.* If no typical colonies develop within 24 hours, reincubate for 24 hours.

Colon bacilli grow black, opaque, and iridescent with metallic sheen on eosin-methylene blue agar.

Confirm results by transferring colonies to differentiating media as listed under "Coliform Organisms," pages 1536 ff.

Report results as: *Esch. coli* present (absent) in five samples of ______ c.c. water.

5. **Culture of Typhoid Bacilli and Other Salmonellae From Water.—**

Inoculate 5 tubes of double-strength selenite-M (M-78) with the water, adding equal amounts to the fluid.

Incubate for 24 hours and make streak inoculations from each tube on one SS plate M-67.

Pour one bismuth sulphite plate M-70 with 1 c.c. of the contents of each tube.

6. **Detection of Cholera Vibrios in Water.—**

Inoculate samples of water into alkaline sea-salt fluid M-98, using inocula of about $\frac{1}{10}$ of the volume of the fluid in the tubes or flasks.

Incubate for 24 hours.

Plate from each tube to Aronson's M-74 and Wilson and Reilly M-75 medium.

7. **Detection of Clostridium Perfringens.—**

This organism, present in nearly every bowel, is a suitable indicator of fecal contamination of the water. Not more than one organism is admissible per 200 c.c. of water.

Add to bismuth sulphite agar M-70, while hot, enough agar to make the agar content 3 per cent.

Cool to 60° C.

Mix equal amounts of water and bismuth sulphite medium.

Pour into large plates, 15 cm. in diameter, in a thick layer.

Allow to solidify and then cover with a layer of medium without water.

Incubate for 72 hours and observe for black, lens-shaped colonies.

C. Membrane Filter Procedure for Testing for Coliform Organisms in Water

This procedure for bacteriologic examination of water makes use of the Millipore filter.* The subcommittee on Standard Methods for the Examination of Water and Sewage of the American Public Health Association found that there is no readily apparent relationship betweeen results obtained by this method and the standard dilution tube procedure. Their investigation indicated that the two procedures do not measure precisely the same group of microorganisms; the sanitary significance of the different results must be determined.

A membrane filter procedure has been developed as a tentative method, but it cannot be considered as an acceptable substitute for the dilution tube method at the present time.

The full tehnic is given on pages 395 to 404 of *Standard Methods for the Examination of Water, Sewage, and Industrial Wastes*, ed. 10, 1955, American Public Health Association, Inc.

D. Chemical Analysis of Water

For the chemical analysis of water, a liberal sample of fresh water should be submitted to the laboratory. This sample, at least one gallon, should be representative of the entire water supply which is to be examined. Procedures described here are largely those recommended by the U. S. Army and the American Public Health Association.

Physical Examination.—

1. Turbidity
2. Color
3. Odor
4. Reaction in terms of hydrogen ion concentration

---

*Obtainable from the Millipore Filter Corporation, Watertown 72, Mass., who also supply a pamphlet with full information for its use.

Chemical Examination.—

1. Total residue
2. Loss on ignition
3. Nitrogen cycle
4. Alkalinity
5. Total hardness
6. Oxygen consuming power
7. Chlorides
8. Sulphates
9. Sodium and potassium
10. Total iron
11. Silica
12. Aluminum
13. Calcium
14. Magnesium
15. Residual chlorine

Most of the equivalents in water chemistry calculations are computed on a parts per million basis. Suggestions for interpreting the quality of the water are given in a chart at the end of this section (page 1674).

Turbidity

Turbidity of water is due to suspended matter in the water. To determine turbidity of the specimen, compare with standard suspensions or standard discs ranging from 5 to 100 parts per million. Report turbidity as less than 5 ppm, or between 10 and 15 ppm, or as 5 ppm, etc.

Standard Suspensions.—

Place 5 grams of Fuller's earth in 1 liter of distilled water.

Agitate intermittently for 1 hour and allow to stand for 24 hours.

Withdraw the supernatant liquid without disturbing the sediment.

Dilute successive portions of the sediment with distilled water to prepare the various standards ranging from 5 to 100 parts per million. Use a candle turbidimeter for standardization.

Standard Disks.—

Permanent turbidity standard disks are available from most large chemical supply houses. The disks may be used in place of the turbidity standard suspensions.

Combination water color and turbidity test sets, U. S. Geological Survey Standard, may be purchased from any large chemical supply company.

Technic.—

The standard unit of turbidity is that produced by 1 part per million of silica in distilled water.

Thoroughly shake the water to be tested. Pour a portion of it into a 125 c.c. glass stoppered bottle and shake.

Shake the standard suspensions and compare in a dark box turbidimeter. Record turbidity in parts per million. Permanent standard disks may be used in place of the standard suspensions. If the Jackson candle method[1] is used, report in turbidity units.

Color

Color disks, calibrated from a platinum-cobalt color scale, may be purchased from any large chemical supply house. Place these glass disks on the end of a metal tube containing distilled water.

Place the water to be tested in a second tube.

Compare and record the color number.

Odor

Odor of water specimens may be described as musty, aromatic, fishy, moldy, etc., and as negative, faint, moderate, strong.

If an odor is detectable in the sample, the odor concentration must be determined.

Place 200 c.c. of the sample in a 500 c.c. flask.

Add 200 c.c. of water free of odor. This is a 1 to 2 dilution.

Mix without unduly exposing to the air. Do not agitate unnecessarily.

Add 200 c.c. of this dilution to 200 c.c. of water free of odor in another 500 c.c. flask. This is a 1 to 4 dilution.

---

[1] Standard Methods for the Examination of Water, Sewage, and Industrial Wastes, ed. 10, 1955, American Public Health Association, Inc., p. 207.

Mix, and continue with the dilutions to obtain 1:8, 1:16, 1:32, and further dilutions, until the second dilution beyond which the odor of the specimen is no longer detectable. If the odor is very strong, omit some of the lower dilutions.

Shake and examine each flask in order, beginning with the strongest dilution and proceeding to the weakest until an odor is just detectable in one of the flasks. This is the threshold odor and is recorded as the odor concentration.

Report the *odor concentration* as the reciprocal of the dilution; e.g., one, two, four, eight.

Hydrogen Ion Concentration

Determine the pH colorimetrically by using a series of indicators and comparing with prepared standards of definite hydrogen ion concentration. The indicators most commonly used are brom thymol blue and phenol red. Use 0.5 c.c. of the indicator to 10 c.c. of the water. See pages 30 ff. for detailed methods of determining hydrogen ion concentration.

Total Residue—Loss on Ignition

Shake the sample thoroughly but do not filter.

Place 100 c.c. of the sample in a weighed platinum dish.

Evaporate on a water or steam bath.

Dry the residue at 103° to 105° C. for 1 hour.

Weigh the crucible and contents. Subtract the weight of the platinum dish from the total weight to obtain the total solids or residue on evaporation. This gives the residue at 103° C. Residues obtained from waters low in organic matter but relatively high in iron may be conveniently used for the determination of iron.

Loss on Ignition and Fixed Residue.—Ignite the residue in the platinum dish at low red heat. Note any significant change in color or odor. Allow the dish to cool.

Moisten the residue with distilled water, then dry at 103° C., cool, and weigh. Subtract this figure from the weight recorded as "residue at 103° C." This figure represents the *loss on ignition*. The weight of the residue is recorded as the *fixed residue*.

For the determination of total solids in waters of high salt concentration, see *Standard Methods for the Examination of Water, Sewage, and Industrial Wastes,* ed. 10, 1955, American Public Health Association, Inc.

Nitrogen Cycle

Ammonia Nitrogen: Albuminoid Nitrogen.—

Distilling Apparatus.—Use a glass flask with a vertical condenser, so arranged that the distillate drops directly into the Nessler tube (50 c.c.). The end of the condenser should be fitted with a glass cup into which the Nessler tubes are inserted when collecting the distillate. Use tin foil to completely cover the rubber stopper.

Reagents.—

Ammonia-Free Water.—

Nessler's Solution.—

Dissolve 50 gm. of potassium iodide
in 35 c.c. of cold ammonia-free water.

Add saturated solution of mercuric chloride until a slight precipitate forms and persists.

Add about 400 c.c. of 9N sodium hydroxide which has been clarified by sedimentation.

Dilute to 1000 c.c. with ammonia-free distilled water. Allow the solution to clarify and decant the clear supernatant fluid.

Stock Ammonium Chloride Solution.—

Dissolve 3.818 gm. ammonium chloride in ammonia-free water in a liter volumetric flask and dilute to 1000 c.c. with ammonia-free water. 1 c.c. contains 1 mg. N.

Standard Nitrogen Solution.—

Dilute 10 c.c. of the stock ammonium chloride solution to 1000 c.c. in a liter volumetric flask, using ammonia-free water.

1 c.c. contains 0.01 mg. of N, equivalent to 0.01288 mg. of NH_4.

Phosphate Buffer Solution, pH 7.4.—

Dissolve 14.3 gm. of monobasic potassium phosphate (KH_2PO_4)
and 90.15 gm. of dibasic potassium phosphate ($K_2HPO_4.3H_2O$) in distilled water in a liter volumetric flask and dilute to 1000 c.c. with distilled water.

Alkaline Potassium Permanganate Solution.—

Boil 1,200 c.c. of distilled water for 10 minutes to expel the ammonia. Add 16 gm. of potassium permanganate and stir until dissolved.

Add 800 c.c. of a clarified 9N sodium or potassium hydroxide solution.

Dilute to 2,500 c.c. with ammonia-free water.

Concentrate to 2 liters.

Determine the ammonia in this reagent using Nessler reagent. Use this figure as a correction factor.

Technic.—

Free the apparatus from ammonia by boiling the water until the distillate shows no signs of ammonia by the Nessler test.

Empty the flask and measure into it 500 c.c. of the water to be tested.

Add 10 c.c. of phosphate buffer.

Distill at the rate of not more than 10 c.c. nor less than 6 c.c. per minute.

Collect in 50 c.c. portions in four Nessler tubes and dilute to 50 c.c. with ammonia-free water.

Prepare standards in similar tubes. Standards must contain 0.0, 0.1, 0.3, 0.5, 0.7, 1.0, 1.4, 1.7, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, and 6.0 c.c. of the standard nitrogen solution, covering the range of nitrogen expected in the water sample. Dilute the standards to 50 c.c. with ammonia-free water.

Now add 50 c.c. of alkaline potassium permanganate solution to the contents of the distillation flask, after the ammonia has been removed, and continue distillation until five 50 c.c. portions are recovered.

Nesslerize both the standards and the nine portions of distillate by adding 1 c.c. of Nessler's reagent to each tube.

Allow the tubes to stand not less than 10 minutes.

Compare with the standard tubes.

Calculation.—

The sum of the readings of the first four tubes × 2 × 0.01 = the ammonia nitrogen content in parts per million.

The sum of the readings of the last five tubes × 2 × 0.01 = the albuminoid nitrogen content in parts per million.

Nitrate and **Nitrite Nitrogen.—**

Nitrite N.—

Reagents.—

Sulphanilic Acid Solution.—

Dissolve 8 grams of sulphanilic acid in 5N acetic acid and dilute to 1 liter with 5N acetic acid in a liter volumetric flask.

a-**Naphthylamine Hydrochloride** (or **Acetate**).—

Dissolve 5 grams of *a*-naphthylamine hydrochloride or acetate in 5N acetic acid in a liter volumetric flask and dilute to 1 liter with 5N acetic acid.

Stock Sodium Nitrite Solution.—

Dissolve 1.1 gm. silver nitrate in nitr*ite*-free water. Precipitate the silver with sodium chloride solution. Dilute to 1000 c.c. with distilled water.

Nitrogen Standard.—

Dilute 100 c.c. the stock sodium nitrite solution to 1000 c.c. in a liter volumetric flask.

Mix and transfer 50 c.c. to a liter volumetric flask.

Dilute to 1 liter with sterilized nitrite-free water.

Add 1 c.c. of chloroform and store in a sterilized bottle.

1 c.c. contains 0.0005 mg. N and is equivalent to 0.001642 mg. NO_2.

Aluminum Hydroxide.—

Electrolize ammonia-free water with aluminum electrodes. Wash the precipitate until it is free from chlorides, ammonia, and nitrite.

Or, dissolve 125 gm. of potassium of ammonium alum in one liter of distilled water. Precipitate the aluminum by adding the ammonium hydroxide cautiously. Wash until free from chlorides, nitrites, and ammonia.

Technic.—

Place in a standard Nessler tube 50 c.c. of the sample, decolorized, if necessary, with aluminum hydroxide.

At the same time prepare standards in Nessler tubes covering the range of the suspected nitrite N. Use 0.0, 1, 2, 3 c.c., etc., of the standard solution.

Add 1 c.c. of sulphanilic acid solution

and 1 c.c. of *a*-naphthylamine hydrochloride solution to the sample and the standards.

Mix thoroughly.

Allow to stand not less than 10 minutes.

Compare the unknown with the standard solutions. If the color of the sample is deeper than that of the highest standard prepared, repeat the test using diluted samples.

Nitrate N.—

Reagents.—

Phenoldisulphonic Acid Solution.—

Dissolve 25 gm. of pure white phenol
in 150 c.c. of concentrated sulphuric acid.
Add 75 c.c. of fuming sulphuric acid (15% free SO_3).
Stir well.
Heat for 2 hours at 100° C.

Potassium Hydroxide Solution, Approximately 12N.—

See pages 23 ff. for normal solutions.

10 c.c. of this solution should neutralize 4 c.c. of phenoldisulphonic acid.

Standard Nitrate Solution.—

Dissolve 0.7216 gm. of pure recrystallized sodium nitrate in 1 liter of distilled water.

Evaporate 50 c.c. of this solution to dryness on the water bath. Moisten the residue quickly and thoroughly with 2 c.c. of phenoldisulphonic acid and rub with a glass rod to insure intimate contact.

Dilute to 500 c.c. with distilled water.

1 c.c. contains 0.01 mg. of N, equivalent to 0.04427 mg. NO_3.

Standard Silver Sulphate Solution.—

Dissolve 4.397 gm. of silver sulphate in distilled water in a liter volumetric flask and dilute to 1 liter with distilled water.

1 c.c. is equivalent to 1 mg. of Cl.

Technic.—

If nitrite N is present in excess of 1 part per million, remove it by heating the water specimen with a few drops of hydrogen peroxide. Subtract the nitrite N equivalent from the final reading.

If the color is greater than 10 (see under *Color*), decolorize with 2 or 3 c.c. of aluminum hydroxide solution.

Filter and add enough sulphuric acid to make neutral to phenolphthalein.

If chlorides are present in concentrations above 3 mg. in the sample (see *Chloride* results), remove all but 0.1 mg. of chlorine by adding standard silver sulphate. Excess silver sulphate will cause loss of nitrite N.

Filter and evaporate to dryness.

Heat the dish for a few minutes.

Add 2 c.c. of phenoldisulphonic acid and rub with glass to insure intimate contact.

Dilute with distilled water.

Add potassium hydroxide solution slowly until the maximum yellow color is developed.

Transfer the solution to a Nessler tube, filtering if necessary, and dilute to 50 c.c. with distilled water.

Prepare standards using varying quantities of the standard nitrate solution (0.01 mg. of N, 0.02, etc.). Treat the standards in a similar manner.

Compare the unknown solutions with the standards and record the results.

Alkalinity

Reagents.—

Phenolphthalein Indicator.—

Dissolve 5 gm. of phenolphthalein in 1 liter of 50 per cent alcohol. Neutralize with N/50 sodium hydroxide. The alcohol should be diluted with distilled water which has been boiled and cooled quickly.

Methyl Orange Indicator.—

Dissolve 5 gm. of methyl orange in 1 liter of distilled water. Keep the solution in the dark.

Technic.—

With Phenolphthalein.—

Add 4 drops of phenolphthalein indicator to 50 or 100 c.c. of the water sample in a white porcelain casserole or in an Erlenmeyer flask over a white surface. If the solution becomes colored, hydroxide or normal carbonate is present.

Titrate with N/50 sulphuric acid from a buret until the color disappears. This is the end point.

Calculation.—C.c. of N/50 sulphuric acid used × 20 = the phenolphthalein alkalinity in parts per million of calcium carbonate if 50 c.c. of the water sample were used. If 100 c.c. were used, multiply by 10 instead of by 20.

With Methyl Orange.—

Use 2 drops of methyl orange indicator to 50 or 100 c.c. of the water sample. The solution develops a yellow color in the presence of hydroxide, normal carbonate, or bicarbonate. Titrate with N/50 sulphuric acid to the first faint pink color; that is, until the yellow color is no longer a pure yellow. Calculate as for phenolphthalein.

Bicarbonate (HCO_3) is present if the alkalinity to phenolphthalein is less than one-half of the alkalinity to methyl orange. The alkalinity to methyl orange is due entirely to bicarbonate if there is no phenolphthalein alkalinity. The bicarbonate in terms of $CaCO_3$ is equal to the methyl orange alkalinity minus twice the phenolphthalein alkalinity; or if no phenolphthalein alkalinity exists, it is equal to 1.22 times the bicarbonate expressed in terms of $CaCO_3$ (methyl orange alkalinity).

Carbon dioxide (CO_2) as bicarbonate is equal to 0.88 times the bicarbonate expressed in terms of $CaCO_3$.

Half-bound CO_2 is equal to 0.44 times the bicarbonate expressed in terms of $CaCO_3$.

Total Hardness

(Soap Method)

Reagents.—

Stock Standard Soap Solution.—

Dissolve 100 gm. of pure powdered castille soap in 1 liter of 80 per cent alcohol. Allow to stand overnight. Decant. This solution is approximately ten times stronger than needed for the working solution.

Working Soap Solution.—

Titrate the standard soap solution against a standard calcium chloride solution, 1 c.c. of which is equivalent to 1 mg. of calcium carbonate. Dilute the stock standard solution with 80 per cent alcohol in accordance with the titer so that 1 c.c. is equivalent to 1 c.c. of the standard calcium chloride solution.

Standard Calcium Chloride Solution.—

Dissolve 0.5 gm. of pure calcite with a small amount of dilute hydrochloride acid. Wash down with carbon-dioxide-free distilled water and neutralize with ammonium hydroxide. Add a small amount of ammonium hydroxide to produce slight alkalinity. Dilute with carbon-dioxide-free distilled water to 500 c.c. 1 c.c. is equivalent to 1 mg. of calcium carbonate.

Technic.—

Place 50 c.c. of the water to be examined in an 8 ounce glass-stoppered bottle.

Add from a buret the working standard soap solution, using small amounts (0.5 c.c.) at a time. Shake vigorously after each addition. Continue adding the soap solution until a strong permanent lather, which stands 5 minutes with the bottle laid on its side, is secured. This is the end point. When approaching the end point, reduce the addition of the soap solution to 0.1 to 0.2 c.c. at a time.

A blank titration should be made using distilled water against the soap solution. The result of this titration is referred to as the "lather factor."

Calculations.—Subtract the lather factor from the titration results and multiply by 20 to obtain the total hardness in terms of calcium carbonate in parts per million.

If a hardness test requires more than 15 c.c. of soap solution, dilute an aliquot of the water to 50 c.c. with carbon-dioxide-free distilled water so that the final lather point will be less than 15 c.c. Deduct the lather factor (blank) and multiply the result by 20 then by the dilution factor to obtain the correct hardness value.

If the water is acid, render it neutral to methyl orange using N/50 sodium carbonate solution before determining the total hardness.

Oxygen Consuming Power

Reagents.—

Dilute Sulphuric Acid.—

Add 1 part of concentrated sulphuric acid to 3 parts of distilled water, cooling under running water while adding the acid.

Ammonium Oxalate Solution.—

Dissolve 0.888 gm. of ammonium oxalate, c.p., in distilled water in a liter volumetric flask and dilute to 1 liter with distilled water.

1 c.c. is equivalent to 0.1 mg. of oxygen. This solution is stable for about one month.

Standard Potassium Permanganate Solution.—

Dissolve 0.4 gm. potassium permanganate in 1 liter of distilled water.

Add 10 c.c. of this solution and 10 c.c. of dilute sulphuric acid solution to 100 c.c. of distilled water in a flask.

Digest for 30 minutes in boiling water.

Add 10 c.c. of ammonium oxalate solution.

Titrate to a pink color with the standard potassium permanganate solution to destroy the oxidizing capacity of the distilled water.

Again add 10 c.c. of the oxalate solution and titrate with the potassium permanganate solution.

Adjust the permanganate solution so that 1 c.c. is equivalent to 1 c.c. of the oxalate solution, or to 0.1 mg. of available oxygen. Preserve in a dark glass bottle.

33 Per Cent Sodium Hydroxide Solution.—

Dissolve 500 gm. of sodium hydroxide in 1 liter of distilled water. Allow to settle and decant the clear supernatant fluid.

Technic.—

If the water to be tested is relatively pure, use 100 c.c.

If sewage is being examined, dilute 1 to 10 c.c. quantities of the sample to 100 c.c. with distilled water.

The volume of the sample plus the diluent must be 100 c.c. and the quantity of the sample must be such that an excess of not less than 5 c.c. of the permanganate remains after digestion.

Add 10 c.c. of permanganate solution to the sample in a flask.

Add 10 c.c. of dilute sulphuric acid solution.

Digest for 30 minutes in a hot water bath in such manner that the entire amount of sample plus reagents is submerged.

Add 10 c.c. of the oxalate solution.

Titrate with permanganate solution to a faint pink color.

Digest a blank of distilled water and the reagents used, decolorize with the oxalate, and titrate back with the permanganate.

Calculations.—

$$\frac{\text{Titration results} - \text{blank}}{\text{c.c. sample used}} \times 100 = \text{oxygen consumed, expressed in parts per million.}$$

Chlorides

Reagents.—

Standard Sodium Chloride Solution.—

Dissolve 16.4858 gm. of pure fused sodium chloride in distilled water in a liter volumetric flask and dilute to 1 liter with distilled water.

Transfer 100 c.c. of this solution to a liter volumetric flask and dilute to 1000 c.c. with distilled water.

1 c.c. contains 1 mg. of chloride radical.

Standard Silver Nitrate Solution.—

Dissolve 2.4 gm. of silver nitrate crystals in distilled water in a liter volumetric flask and dilute to 1000 c.c. with distilled water.

Titrate against the standard sodium chloride solution using potassium chromate indicator. Adjust so that 1 c.c. of the solution is exactly equivalent to 0.5 mg. of Cl radical.

Potassium Chromate Indicator.—

Dissolve 50 gm. of neutral potassium chromate in a small amount of distilled water. Add silver nitrate solution to produce a slight red precipitate. Allow to stand for 1 or 2 days and filter and dilute the filtrate to 1 liter with distilled water.

Aluminum Hydroxide.—

See page 1666.

Technic.—

If the sample has a color value greater than 30 (see *Color*), decolorize by shaking it thoroughly with aluminum hydroxide, 3 c.c. to 500 c.c. of the sample. Filter. Make the determination in aliquot portions of the clarified sample.

Before titrating the chloride, add 2 drops of phenolphthalein indicator. If a red color appears, neutralize with 0.02 N sulphuric acid. If the water is acid to methyl orange, neutralize with 0.02 N sodium carbonate. If the sample contains hydrogen sulphide, acidify with sulphuric acid, boil a few minutes, cool, neutralize with sodium bicarbonate, and restore the original volume of the sample. If the amount of chloride appears to be more than 50 parts per million, use 25 c.c. or less of the sample and dilute to 50 c.c. with distilled water.

If the chloride is less than 10 parts per million, add a previously measured amount of standard sodium chloride solution and make corrections accordingly in the final calculations.

Add 1 c.c. of potassium chromate indicator to 50 c.c. of the prepared sample in a 6-inch white porcelain dish.

Titrate with standard silver nitrate solution. The end point is very sharp when viewed by yellow electric light. The first very faint reddish color is the end point.

Calculations.—

$$\frac{1000}{2 \times \text{c.c. sample titrated}} \times \text{c.c. silver nitrate solution used} = \text{chloride in parts per million.}$$

Sulphates

Evaporate 250 c.c. of sample to dryness. Before the sample is completely dry add 1 c.c. of 1:2 hydrochloric acid. Remove the silica as previously described.

Add a hot solution of barium chloride to the hot filtrate and warm it, stirring at intervals, for one-half hour or until the precipitate settles readily and leaves a clear supernatant fluid.

The precipitate is barium sulphate.

The filtrate can be used to determine sodium and potassium.

Filter, dry, ignite the precipitate as barium sulphate, of which 41.14 per cent is equal to the content of SO_4.

Sodium and Potassium (as Sodium)
By Calculation

To determine sodium and potassium by calculation, all basic and acid radicals must have been determined. Multiply these by the following factors:

BASIC RADICALS	FACTOR	ACID RADICALS	FACTOR
Calcium	0.04991	Bicarbonates	0.01639
Magnesium	0.08224	Sulphates	0.02082
		Chlorides	0.02828

If the sum of the products of the basic radicals is greater than that of the acid radicals, sodium and potassium are not present. But if acid radicals are greater than the basic radicals, divide the difference by the factor for sodium, 0.04348. The quotient represents the amount of sodium as Na and K in parts per million.

Total Iron

Reagents.—

Standard Ferric Iron Solution.—

Dissolve 0.7022 gm. of crystallized ferrous ammonium sulphate ($FeSO_4(NH_4)_2SO_4.6H_2O$) in 50 c.c. distilled water and 20 c.c. of concentrated sulphuric acid.

Warm the solution and add potassium permanganate solution until the iron is completely oxidized. Dilute to 1 liter with distilled water.

1 c.c. contains 0.1 mg. Fe.

Dilute Hydrochloric Acid.—

To 2 volumes of distilled water add 1 volume of concentrated hydrochloric acid, specific gravity 1.2. This is an approximate 3N solution.

Potassium Permanganate Solution.—

Dissolve 6.3 gm. of potassium permanganate in distilled water in a liter volumetric flask and dilute to 1 liter with distilled water. This is an approximate N/5 solution.

Potassium or Ammonium Thiocyanate.—

Dissolve 2 gm. potassium or ammonium thiocyanate in distilled water in a 100 c.c. volumetric flask and dilute to 100 c.c. with distilled water.

Hydrochloric Acid.—

Concentrated hydrochloric acid free from iron.

Nitric Acid.—

Nitric acid, specific gravity 1.42, free from iron.

Nitric Acid.—

Nitric acid, specific gravity 1.195. Use 382 c.c. of this concentrated nitric acid per liter of solution. This is approximately a 6N solution.

Technic.—

Evaporate 100 c.c. (or less) of the sample to dryness, or use the residue on evaporation. With silt-bearing samples of water the quantity of iron is sometimes so great that it is necessary to use as little as 10 c.c. of the sample. In such cases add 5 to 10 c.c. of concentrated hydrochloric acid to the sample. If the sample contains much organic matter, destroy the organic matter by ignition so that the iron dissolves only with difficulty.

Heat the dish to drive off excess of acid if the residue was not ignited.

Cool and add 0.8 to 1.0 c.c. of 3N hydrochloric acid.

Warm on the water bath taking care to avoid evaporation to dryness by adding small quantities of distilled water from time to time.

Rinse the hot solution into a 50 c.c. Nessler tube, filtering if necessary.

Add 1 to 2 drops of potassium permanganate solution. If the color of permanganate does not persist for at least 5 minutes, add more permanganate solution, drop by drop.

Cool and dilute to the mark with distilled water.

Prepare iron standards by placing in matched Nessler tubes 0.05 c.c., 0.10 c.c., etc., up to 4 c.c. (or more), of standard iron solution covering the range of standards required for the determination at hand. Dilute each to about 40 c.c. with distilled water.

Add 0.5 c.c. of 3N hydrochloric acid and 1 or 2 drops of potassium permanganate solution to each tube. Dilute to the mark.

Add 5 c.c. of thiocyanate solution to the unknown and to the standards. Mix each tube thoroughly and compare immediately.

If the sample is low in organic matter, boil 50 c.c. with 5 c.c. of 6N nitric acid for 5 minutes, add 3 drops of permanganate solution, and cool. Add 5 c.c. of thiocyanate solution and compare immediately with standards prepared from the standard iron solution with 6N nitric acid instead of with 3N hydrochloric acid.

Silica

Gravimetric Method

Evaporate 500 c.c. of the sample in a platinum crucible. When the residue is nearly dry add 1 c.c. of dilute hydrochloric acid (1:2), moisten the sides of the dish, and evaporate to dryness. If much organic matter is present, char in a radiator.

Add a few drops of hydrochloric acid, dissolve in hot water, and filter.

Ignite and weigh the insoluble residue.

Add 2 drops of concentrated sulphuric acid and a little hydrofluoric acid, volatilize the acids, ignite, and weigh again.

Report the loss in weight as silica (SiO_2). A weight of nonvolatile matter exceeding 0.5 mg. should be analyzed.

Aluminum

Use the filtrate from the insoluble residue. Heat to boiling, oxidize with concentrated nitric acid or bromine, and concentrate to 100 c.c.

Add ammonium hydroxide in slight excess, boil one minute, and filter.

Ignite the precipitate and weigh as ferric and aluminum oxides.

Calculate the iron determined in terms of ferric oxide and subtract this from the weight of the ignited oxides. Aluminum is 53 per cent of the remainder.

If much phosphate is present, it must be determined in a separate sample, and the amount of P_2O_5 subtracted from the ignited oxides.

Calcium

Concentrate the filtrate obtained from the determination of aluminum to 100 c.c.

Add an excess of fresh saturated solution of ammonium oxalate, little by little, to the hot ammoniacal solution. Keep the solution warm.

Stir at intervals until the precipitate settles readily and leaves a clear supernatant liquid.

Filter and save the filtrate for the determination of magnesium.

Ignite the precipitate and weigh it as calcium oxide, 71.46 per cent of which is equivalent to Ca.

Magnesium

Use the filtrate from the separation of calcium. Acidify with hydrochloric acid.

Concentrate to about 100 c.c.

Add 20 c.c. of a saturated solution of sodium ammonium phosphate solution ($NH_4NaHPO_4.4H_2O$). Cool and make slightly but distinctly alkaline by adding ammonium hydroxide, drop by drop.

Allow the solution to stand four hours, then filter and wash with 3 per cent ammonium hydroxide.

Ignite the precipitate and weigh as magnesium pyrophosphate, 21.84 per cent of which is equivalent to magnesium. If manganese is present it is precipitated with the magnesium.

Correct for manganese after determining the quantity in a separate sample. The weight of manganese pyrophosphate is equivalent to 2.586 times the weight of manganese.

Calculation of Total Hardness.—Total hardness may be computed from the results of the determinations of calcium and magnesium in the sample. Iron and other metals must be included in the calculation if they are present in significant amounts. Total hardness as $CaCO_3$ is equal to $2.495 \times$ calcium $+ 4.115 \times$ magnesium.

Noncarbonate Hardness.—If the total hardness is greater than the carbonate and bicarbonate alkalinity, the amount of hardness equivalent to the alkalinity is called ''carbonate hardness.'' The amount of hardness in excess of this is called ''noncarbonate hardness.''

Residual Chlorine

Reagents.—

Orthotolidine Solution.—

Weigh 0.5 gm. of orthotolidine.

Grind to a thin paste in a mortar with 5 c.c. of dilute hydrochloric acid solution (below).

Add 150 to 200 c.c. distilled water. The orthotolidine should dissolve immediately.

Transfer to a liter graduate and dilute to 505 c.c. with distilled water. Add dilute hydrochloric acid to a final volume of 1000 c.c. Store in dark amber bottles for no longer than 6 months and do not expose to high or low temperatures.

Dilute Hydrochloric Acid.—

Add 150 c.c. concentrated hydrochloric acid, sp. gr. 1.18 to 1.19,
to 350 c.c. distilled water.

Sodium Hydroxide Solution, 4.5 N.—

Magnesium Sulphate Solution.—

Dissolve 20 gm. of magnesium sulphate in 100 c.c. distilled water. If necessary, eliminate any large chlorine demand in this and in the sodium hydroxide solution by treating to a slight residual with calcium or sodium hypochlorite solution.

Potassium Chromate-Dichromate Solution.—

Weak.—Dissolve 0.25 gm. of potassium dichromate
and 0.75 gm. of potassium chromate
in 1000 c.c. of distilled water.

Strong.—Dissolve the same quantities of chemicals in 100 c.c. of distilled water.

Boric Acid-Borax Buffer, pH 6.5.—

Dissolve 12.4 gm. boric acid in distilled water and dilute to 1000 c.c. with distilled water. This is approximately a 0.2 M solution and has a reaction of pH 4.6±.

Dissolve 3.8 gm. of borax ($Na_2B_4O_7$) in distilled water and dilute to 1000 c.c. with distilled water. This is a 0.01 M solution with a reaction of about pH 9.2.

Add sufficient borax solution, usually about 80 c.c., to a liter of the boric acid solution to prepare a buffer solution of pH 6.5.

Note.—The reagent used for detection and estimation of chlorine is not specific, but gives similar reactions with oxidizing agents and chlorine addition products. Exercise care, therefore, in interpreting the results. Nitrites, ferric compounds, manganic compounds, organic coloring matter, and chlorates are examples of interfering substances; these must be considered in evaluating the results. Turbidity interferes with the test. Do not confuse orthotolidine with orthotoluidine.

Technic.—

Place 100 c.c. of the sample in a 100 c.c. Nessler tube.

Warm to 20° C.

Add 2 c.c. of the orthotolidine solution, mix, and place in the dark for not less than 5 or more than 15 minutes.

Small amounts of chlorine give a yellow color. Larger amounts give an orange color. Compare the color with permanent standards, below. All tubes should match as to height of graduation mark.

Permanent Standards.—

Permanent standards for testing residual chlorine are available from many chemical supply houses. They may be made as follows:

Use 100 c.c. Nessler tubes. Place the proper volumes of dichromate-chromate solutions in the tube and dilute to the 100 c.c. mark with the boric acid-borax buffer.

CHLORINE STANDARDS, SCOTT FORMULA

CHLORINE PPM	C.C. WEAK DICHROMATE-CHROMATE	CHLORINE PPM	C.C. STRONG DICHROMATE-CHROMATE
0.01	0.4	0.50	2.6
0.02	0.8	0.70	3.6
0.03	1.3	1.00	5.2
0.05	2.2	1.50	8.0
0.07	3.1	2.00	11.2
0.10	4.4	3.00	18.0
0.15	7.4		
0.20	10.0		
0.25	13.0		
0.30	16.0		
0.40	21.0		

If the water contains over 1 part per million of iron or 0.01 part per million of manganic manganese, flocculate 200 c.c. with 2 c.c. of the magnesium sulphate solution and 2 c.c. of 4.5 N sodium hydroxide, clarify by centrifugalizing, and follow the standard procedure.

Interpretation of Chemical Analysis of Drinking Water

The following are ordinarily considered safe limits of impurities in drinking water of good quality from a *chemical* standpoint. Drinking water must never be considered safe, however, without a satisfactory *bacteriologic* analysis. The results below are expressed in *parts per million.*

IMPURITY	DESIRABLE	LIMIT
	Less than:	Not greater than:
Odor	None	Free from odor
Color	5	20
Turbidity	5	10
Ammonia nitrogen	0.04	0.9
Albuminoid nitrogen	0.05	0.1
Nitrite nitrogen	None	0.7
Nitrate nitrogen		0.5
Oxygen consuming power	1	2
Chlorides	50	250
Free residual chlorine	At least 0.2 (at tap)	Must not cause objectionable odor or taste
Total hardness (as $CaCO_3$)		250
		10.2
Noncarbonate hardness	Relative to total hardness	
Acidity	Free mineral acids must be absent	
Total solids	500	1000
Loss on ignition	Is a relative, not a precise, determination Represents not only organic matter but volatile decomposition products from carbonates, nitrates, and other components of the residue	
Alkalinity (as $CaCO_3$)	It is desirable to have the total alkalinity below 400 ppm; however, alkalinity is usually of no significance unless there is phenolphthalein alkalinity In the case of nontreated waters, the phenolphthalein alkalinity should not be greater than half of the total alkalinity In chemically treated waters, the phenolphthalein alkalinity (calculated as $CaCO_3$) should not be greater than 15 mg./L. plus 0.4 times the total alkalinity. In the case of waters softened by the lime soda process, the total alkalinity produced should not exceed the hardness by more than 35 ppm (calculated as $CaCO_3$)	
Minerals		
Silica		250
Magnesium	30	100
Calcium	Unimportant	250
Iron	0.1	0.3
Sulphates	100	500
Sodium and potassium	0	50
Aluminum		0.3
Manganese		0.5
Toxic Ions:		
Arsenic	None	0.05
Lead	None	0.1
Copper	None	3.0
Zinc	None	15.0
Fluorides	None	1.0
Selenium	None	0.05
Barium	None	None
Molecularly dehydrated phosphates (chem. treatment)	Less than 10.0	10.0

Bacteriologic Examination of Water from Swimming Pools and Bathing Places

For some time it has been the custom to disinfect swimming pools and bathing places with some form of chlorination. This method is highly efficient provided it is properly controlled. In order to test the efficiency of chlorination, bacteriologic examination of water from these pools is made daily in some places. It has been discovered that when water is taken from the pool and examined at once, a given bacteriologic result will be obtained which is quite different from that obtained when the water is examined several hours later. This is due to the fact that the residual chlorine present in the water continues to act after the water is taken from the pool; therefore, a sample examined later will show less pollution. The presence of even a minimum chlorine residue by chemical test shows the presence of germicidal chlorine. If germicidal chlorine is present, it necessarily follows that any bacteria present are going to be affected, and if a period of time elapses between sampling and testing, a reduction of the bacteria must result. If we have a sufficient period and a sufficient amount of residual chlorine, an otherwise polluted sample would be sterile when tested.

Mallmann and Schalm[1] demonstrated in a series of laboratory experiments that increasing alkalinities in water caused a decreased activity or delayed killing action of chlorine. It was also found that during periods of use, swimming pool water showed marked pollution as measured by colon bacilli and streptococci indices in the presence of residual chlorine contents of 0.2 to 0.5 p.p.m. and that during rest, the pollution evidenced during use disappeared, the rate of disappearance depending upon the type of treatment used.

Water taken at the pool-side and immediately examined will give an accurate picture of the bacterial content of said water. In order to examine water and get accurate results at a later period, it is necessary to treat the sample in such way that the residual chlorine will not continue to act upon the sample after it is collected.

Extended studies of Mallmann and Cary[2] and Fletcher and Link[3] have demonstrated that samples collected in sodium thiosulphate-treated bottles give an actual picture of the water at the time of the sample; therefore, this type of bottle should be used.

BACTERIOLOGIC EXAMINATION OF MILK

Macroscopic Colony Count—Petri Dish Method

Phosphate Buffered Distilled Water for Dilutions.—

Stock Solution of Phosphate Buffer.—

Dissolve 34 gm. of monobasic potassium phosphate (KH_2PO_4)
in 500 c.c. distilled water.
Adjust the reaction to pH 7.2 with N/1 sodium hydroxide.
Dilute to 1,000 c.c. with distilled water.

For Use.—

Add 1.25 c.c. of the stock phosphate buffer to distilled water, and dilute to 1,000 c.c. with distilled water.

Preparation of Bottles.—

Use resistant glass bottles, 4 ounce capacity, closed with rubber stoppers or preferably screw caps.

Place a mark at 99 c.c. with a diamond point pencil.

Fill with the phosphate buffered distilled water to the 99 c.c. mark, and sterilize in an autoclave at 15 pounds pressure for 30 minutes, after closing with the stopper. Do not use cotton plugs.

When cool, check for evaporation. Measure the quantity of fluid which must be added to make up the quantity to 99 c.c.

When preparing the bottles for use, add the 99 c.c. of buffered solution and the excess which is to be allowed for evaporation, before sterilizing.

If desired, prepare bottles marked also at 9 c.c.

Preparation of Dilutions of Milk.—

To make a 1:10 dilution, add 11 c.c. of the milk, in the manner described under Water Analysis, page 1661, to the bottle containing 99 c.c. of phosphate buffered distilled water. Replace cap and mix thoroughly.

---

[1] Michigan Eng. Exper. Sta. Bull. 44, 1932.
[2] Am. Pub. Health A. 23: 35, 1933.
[3] Am. Pub. Health A. 23: 1255, 1933.

To make a 1:100 dilution, add 1 c.c. of distilled water to 99 c.c. of phosphate buffered distilled water. Mix as above.

Make a 1:1,000 dilution by transferring 1 c.c. from the 1:10 dilution to 99 c.c. of phosphate buffered distilled water.

To make a 1:10,000 dilution, transfer 1 c.c. from the 1:100 dilution to 99 c.c. of phosphate buffered distilled water.

In preparing the plates, measure 1 c.c. of the respective dilutions in sterile 1 c.c. pipettes, letting the column drain into the Petri dish and then blowing out the last drop. Do not rinse the pipette in the dilution waters.

Each plate is inoculated with 1 c.c. of its respective dilution of milk. Use milk agar M-111, melted and kept at a temperature of 45° C. Do not guess at the temperature, but keep the media in a regulated water bath, the thermometer being in one of the tubes (which will be discarded at the end of the test).

After solidifying, the plates are placed, upside down, in the incubator at 35° C. for forty-eight hours.

If, among the various dilutions, there are plates containing 30 to 300 colonies, these are selected for making the count.

The number of bacterial colonies on the plate is multiplied by the dilution of the milk in the plate for the number of bacteria in 1 c.c. of undiluted milk.

Several plates are counted. The average counts are taken.

If no plates show bacterial growth within these limits, the plates with bacteria numbering closest to 300 colonies are counted.

No plate that contains less than twenty colonies should be counted.

Counting should be done with a hand-lens, and all recognizable colonies included. In case any particles visible by this method are of doubtful nature, they should be examined with a compound microscope, to determine their true nature.

Microscopic Count of Bacteria (Breed Method)

Standardization of Microscope

A stage micrometer and mechanical stage are needed.

Place the stage micrometer on the stage of the microscope.

Use the oil immersion objective, and by adjusting the ocular and the draw tube, bring the diameter of the field to 0.16 mm. When so adjusted each field of the microscope covers an area of approximately 1/5000 sq. mm.

Record the number of the microscope, the number of the ocular, the objective used, and the length of the draw tube.

Counting the Bacteria

Cleanliness of glassware is more important than sterilization.

Slides must be thoroughly cleaned so that there is no fat present.

On a piece of white paper, rule off an area exactly 1 sq. cm.

Shake the sample of milk thoroughly.

Withdraw 0.01 c.c. in a 0.01 c.c. pipette.

Deposit on a clean slide.

Spread the drop uniformly over an area of 1 sq. cm. by means of a stiff needle. This is accomplished by placing the slide over the previously ruled square, and using it as a guide.

Dry the preparation in a warm place, upon a level surface, protected from dust. This drying should be accomplished within five to ten minutes. Excessive heat should be avoided, or the dry films will crack and peel from the slide in later handling.

Dip in xylol to remove fat. Usually one minute.

Drain, and dry.

Immerse in 90% alcohol for one or more minutes.

Transfer to a jar of Loeffler's methylene blue.

The slides are left in the stain until overstained.

Rinse in water and decolorize in alcohol.

This requires from several seconds to a minute or more. Observe the slide carefully during the process in order not to decolorize too long. When properly decolorized, the background of the film should show a faint blue tint. Poorly stained slides may be decolorized and restained without injury.

Examine the slides with the microscope adjusted so that the field covers an area of approximately 1/5000 sq. cm., as described above. The diameter of the field is 0.16 mm.

Each organism in a field represents 500,000 bacteria per c.c.

Count the number of bacteria in 10 fields.

Multiply the total by 50,000 to obtain the number of bacteria per c.c. of sample.

Count 100 fields when the number of bacteria is moderate, or when more accurate results are desired. Multiply the total in this case by 5,000 to obtain the number of bacteria in each c.c. of sample.

Tests for Control of Milk

Coliform Organisms

One of the most simple and effective methods for the control of pasteurized milk was devised by Mickle and Borman.[1] It is known as the ''Connecticut Three Point Program.'' This consists of the determination of the bacterial count by the Breed method (not more than 20,000 organisms in grade ''A'' milk, not more than 50,000 organisms in grade ''B'' milk); phosphatase determination (less than 0.05 mg. phenol liberated, see below); and the absence of colon bacilli in 0.1 c.c. of the milk.

The presence of colon bacilli in milk is tested by inoculating a series (3 to 5) of lauryl sulphate broth M-109 or brilliant green lactose bile broth M-108 with 0.01, 0.1, and 1.0 c.c. of milk.

Incubate all tubes for 48 hours at 37° C. and observe for gas formation. If the gas occupies more than 1/10 of the inverted vials in the test tubes containing the broth, streak on eosin-methylene blue agar M-72 from the broth and proceed as under ''Water Examination.''

Tests for Other Bacteria in Milk

Brucella.—

Centrifuge samples of milk.

Collect cream and sediment and mix both.

Inoculate tryptose agar plates M-16 or liver infusion agar plates M-26 with this mixture. Incubate in carbon dioxide atmosphere for a week.

Inoculate two guinea pigs with 5 c.c. of the cream-sediment mixture.

If the animals do not die in 7 weeks, sacrifice them and examine the liver and spleen for typical lesions. Inoculate plates with the material from these organs as above.

Testing Milk Sera for Brucellosis.—

This test may be carried out with milk from cows for the detection of those carrying *Brucella abortus* in the udders. Collect several samples of the fore milk from each quarter, using clean, sterilized vials of about one-half-ounce capacity. Before collecting the samples, place in each vial a small amount of rennin powder, about the amount that would go on the tip of a small knife blade. Draw the milk into the vial and place in a slanting position. The serum will separate out in about an hour at room temperature. Conduct the test with the milk sera in exactly the same manner as previously described for blood sera, p. 1573.

Typhoid and Other Salmonellae—

Use methods described under Water Examination, page 1663.

Tubercle Bacilli.—

The only reliable method is to centrifuge the milk; collect the cream and the sediment and inoculate guinea pigs with this mixture.

---

[1] J. Milk Technol. 6: 231, 1943.

Streptococci.—

(a) **Hotis Test.—**

Add 9.5 c.c. of milk to 0.5 c.c. of a 0.5% sterile aqueous solution of brom cresol purple in sterile test tube.

Incubate overnight at 37° C.

Decolorization and curd formation indicates mastitis.

(b) **Plating.—**

Plate samples of milk on sodium azide blood plates M-21.

Carry out tests for further identification as described under "Streptococci," pages 1487 ff., and 1490 ff.

Acid-Producers, Molds, Yeasts.—

Use dextrose agar M-19 for their detection.

Brucella Abortus Ring Test

The ring test for diagnosis of brucellosis in dairy cattle was first described by Fleischhauer and Hermann[1] in 1937 and 1938. It is sufficiently sensitive to permit its use on pooled milk samples from individual herds, collected at the receiving platform in a dairy plant.[2] It has been found positive in pooled samples of milk where the milk from one infected animal had been mixed with that of as many as 5 to 15 noninfected or negative cows.

The present ring test is not a reliable method of diagnosing infection in individual animals, but it will identify approximately 80 per cent of the infected herds.

A number of factors may influence the results[3]: period of lactation, nonlactating infected animals, adult vaccination with strain 19 vaccine, method of collecting milk samples, souring and freezing of milk, amount of cream on the sample; and uniformity of antigens, procedures, and interpretation of results.

The antigen is deep blue. In milk from infected animals, the stained antigen agglutinates and collects on the fat droplets or cream, and as the cream rises, the antigen is carried with it. It therefore produces a deep blue cream line or ring when whole milk is tested. The skim milk fraction is white in strongly positive samples; in negative samples, the antigen remains and gives the skim milk fraction a light blue color, the cream ring being white.

The test is sometimes designated as A.B.R., meaning "*abortus* Bang ring" test.

Collection of Specimen.—

Approximately 3 c.c. of milk are collected from each of 2 or 3 milk cans of a producer, using a small long-handled dipper on the receiving line. For a dairy herd producing 5 or 6 cans of milk per day, this represents 2 such composite milk samples to be tested. For cream, approximately 5 c.c. are secured from each can on the receiving line, or taken from the vial containing the cream specimen normally collected by the creamery operator for butter-fat analysis.

Antigen.—

Obtain the parent antigen from the U. S. Bureau of Animal Industry, official *Brucella abortus plate antigen*, about 8% by volume; *or* the stock *tube antigen*, approximately 4% cells.

---

[1] Berlin. tierärztl. Wchnschr. **53**: 527, 1937; **54**: 333, 1938.
[2] Roepke: Brucellosis, AAAS, 1950.
[3] Manthei: Brucellosis, AAAS, 1950.

Centrifuge the stock antigen in weighed centrifuge tubes.

Wash once by centrifugation with physiologic saline.

Discard the supernatant fluid and reweigh the tubes. This gives the weight of the bacterial paste.

Stir this paste thoroughly with a glass rod, adding a few drops of saline at a time, until a smooth thick creamy suspension of the cells is obtained in a small volume of saline.

The suspension of the cells must be stable at the low pH and high salt concentration of the staining solution used to stain the antigen. It must also be stable at pH 4.0, the pH of the wash fluid used to remove the excess dye, and the approximate pH of the final preparation.

The Staining Solution:

1. Dissolve 9 gm. of ammonium aluminum sulphate
   in 100 c.c. of distilled water.
   Add 30 c.c. of glycerin.
2. Dissolve 1 gm. hematoxylin
   in 2 c.c. of 85% ethyl alcohol by heating at 50° C.
   Add distilled water to a total volume of 100 c.c.
3. Mix the two solutions.

Add 0.17 gm. sodium iodate dissolved in 2 c.c. distilled water.

Wait 15 minutes for oxidation of the dye.

Dilute the dye 1:4.5 or 1:5 with 10% ammonium aluminum sulphate solution (a less deeply stained antigen may be made at this point if desired).

Allow to stand at room temperature for 12 to 20 hours.

Filter through a small filter paper to remove insoluble substances.

The final reaction should be pH 2.8 to 2.9.

This is the staining solution.

The Stained Antigen:

Add the concentrated suspension of washed cells to the staining solution in the proportion of 10 gm. of paste to 1,200 to 1,400 c.c. of the diluted stain.

Allow to stand at room temperature for 36 to 48 hours.

Collect the stained cells by centrifugation at 2,800 to 3,000 r.p.m. for 90 minutes.

Remove excess dye by suspending the stained cells in a wash fluid. (**Wash Fluid.**—This is composed of 0.4% sodium chloride and approximately 0.001 M lactic acid, the reaction adjusted to pH 3.8 to 4.0, using dilute sodium hydroxide solution.)

Centrifuge the suspension.

Repeat the washing process to a total of three washings, using a volume of wash fluid each time of approximately one-fourth to one-fifth the original volume of the staining solution.

Suspend the washed cells in a solution of 0.5% phenol in a mixture of equal parts of glycerin and physiologic saline, in a proportion of 1 gm. of the stained bacterial paste to 20 c.c. of the diluting fluid.

Adjust the final cell concentration to 4% cells by volume, as determined by the centrifuge method with the Fitch-Hopkins vaccine tube. In an emergency, a graduated centrifuge tube may be used.

Adjust to a final reaction of pH 3.8 to 4.0 preferably by means of the glass electrode method.

Technic of the Ring Test.—

(a) Milk:

Mix the specimens by gently inverting the collecting vials several times.

Pour sufficient milk, about 2 c.c., into a small test tube, 10 by 100 mm., to produce a column of milk approximately ¾ inch deep.

Add 2 drops of saturated solution of sodium bicarbonate to a test specimen, if it is poor quality milk, before adding the antigen.

Add the stained antigen to the milk in the proportion of 1 drop or 0.03 c.c. of antigen to each c.c. of milk.

Mix well for 1 minute by gently inverting the tube a number of times, in such manner as to thoroughly wash the antigen down the wall of the tube.

Examine the specimen after it has stood a few minutes, to check for adequate mixing. If not mixed enough, the process must be repeated. Avoid forming a foam.

Allow to stand at room temperature for 75 to 90 minutes, depending upon the temperature.

Results.—

–	cream line or ring that is white or nearly white; skim milk contains essentially all the stained antigen.
+	cream ring color approaches or equals that of the skim milk fraction.
++	cream ring color slightly greater that that of the skim milk fraction.
+++	cream ring significantly deeper blue than the skim milk layer.
++++	cream ring very dark blue and the skim milk fraction essentially white.

(b) Cream:

Place 1 c.c. of physiologic saline containing 1% sodium carbonate in a small tube (10 by 100 mm.) and add 12 drops of cream, using a dropper.

Add 1 drop of antigen.

Mix thoroughly.

Allow to stand at room temperature.

Read as in the milk test.

The Reductase Test[1]

(Methylene Blue Reduction Test of Milk)

The reductase test of milk is based on the fact that the color imparted to milk by a small quantity of methylene blue will disappear more or less quickly due to the activity of growing bacteria, presumably by their consumption of the oxygen dissolved in the milk.

The value of the methylene blue reduction test is the rapidity with which the quality of milk can be observed where laboratory facilities are limited.

Apparatus.—

10 c.c. pipettes.

1 c.c. pipettes with a small opening.

Test tubes 12 to 15 mm. in diameter.

Water-bath regulated at 37° C.

All glassware used should be sterilized in the dry heat sterilizer at 170° C. for two hours. Test tubes should be plugged with nonabsorbent cotton.

Reagent.—

Use standard tablets of methylene blue thiocyanate, certified by the Biological Stain Commission. These can be purchased from most biological supply houses.

Using sterile forceps, pick up one methylene blue tablet and place it in a flask containing 200 c.c., or slightly more, of boiling distilled water. When cool, the total quantity must be 200 c.c. Cool rapidly when the tablet has dissolved. The solution is not stable.

Technic.—

Place 1 c.c. of the methylene blue solution in a sterile test tube, using a buret.

Add 10 c.c. of the milk to be tested.

Insert sterile cork and invert gently. The color of the milk is now a robin's egg blue. The intensity of color will not be the same in all milk because of differences in milk fat dispersion.

Place the tubes in the water-bath at 37° C. and observe at stated intervals. The end point is reached when the blue color has disappeared and the milk has regained its normal color. In most cases, the color disappears uniformly throughout the entire mass of milk. If the color disappears in an uneven manner, the end point is taken as the time when the milk, after mixing, shows no blue color.

---

[1] Abstracted from "Standard Methods of Milk Analysis," 6th Edition, 1934, published by the American Public Health Association.

Interpretation of Results.—

Class 1. *Good milk,* not decolorized in five and one-half hours.

Class 2. *Milk of fair average quality,* decolorized in less than five and one-half hours but not less than two hours.

Class 3. *Unsatisfactory milk,* decolorized in less than two hours but not in less than twenty minutes.

Class 4. *Very unsatisfactory milk,* decolorized in twenty minutes or less.

The Phosphatase Test for Pasteurization*

It is a matter of great importance for public health officials to know whether milk that is labeled "pasteurized" really has received sufficient heat treatment to make it safe. The phosphatase test is the first means the health officer has had to determine whether a sample of milk has been adequately heat treated.

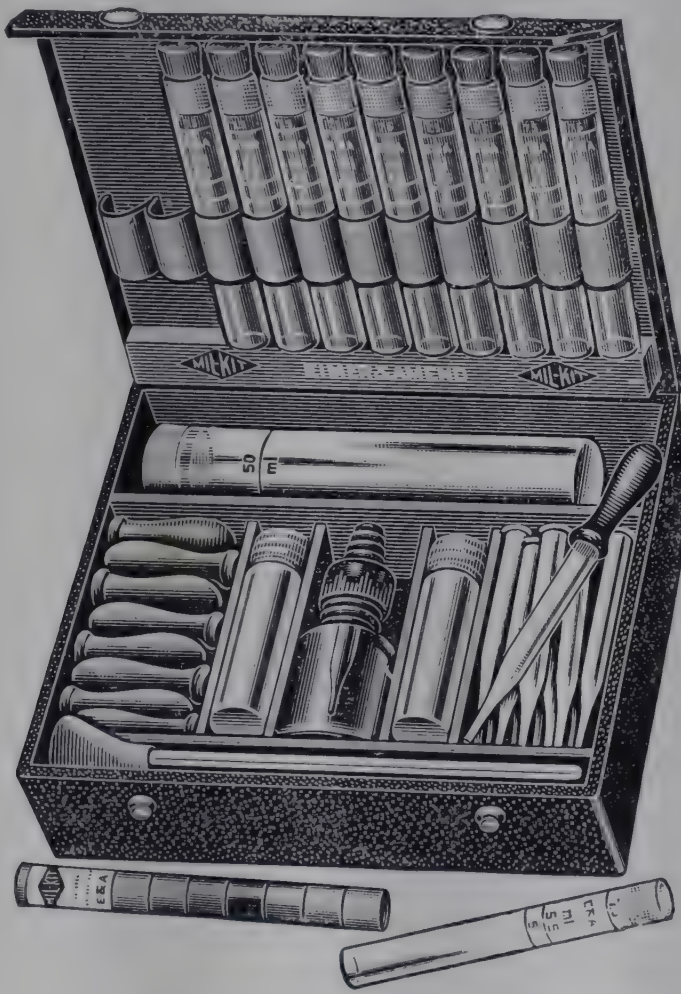

Fig. 405.—Milk kit, Eimer and Amend.

Numerous attempts have been made to cover this question in the past thirty years. The method devised by Rothenfusser[1] was designed to measure the effect of heat on the enzyme peroxidase. Various modifications of this test have been developed but were unsuccessful. Other tests for heated milk including the microscopic cellular test[2, 3] have failed to differentiate between pasteurized milk and milk undertreated in pasteurization.

---

*The Mil-Kit by Eimer and Amend, New York, is recommended. It contains all the necessary equipment and is assembled in a portable leatherette case. It is especially adapted to field work or plant operation, as shown in Fig. 405. The reagents and chemicals for making these reagents may be procured from the Paul Lewis Laboratories, Inc., manufacturing chemists, 918-922 N. 4th St., Milwaukee, Wisconsin.

[1] Milchwirtschaftliches Zentr. 6: 468, 1910.

[2] J. A. M. A. 64: 821, 1915.

[3] J. Dairy Sc. 2: 189, 1919.

The phosphatase test is based upon the fact that this enzyme is always present in raw milk in abundance and is almost completely devitalized by the heat treatment required for the pasteurization of milk. The test was developed by Kay and Graham.[4] The method, as modified by Gilcreas and Davis,[5] is as follows:

Collection of Sample.—Proceed as directed in Methods of Analysis, A. O. A. C., *Standard Methods for the Examination of Dairy Products,* 1953, p. 258, except that no preservative shall be present and not more than 48 hours shall have elapsed between the time of sampling and receipt at the laboratory. If samples are refrigerated, observe precautions to prevent freezing.

The quantity of sample required depends upon the number of determinations to be made. For the usual analysis collect 250-500 c.c.; for the fat determination only, 5-60 c.c. will suffice.

In the case of bottled milk collect one or more bottles as prepared for sale. In sampling bulk milk, thoroughly mix by pouring from one clean vessel to another 3 or 4 times. If this procedure is impracticable, thoroughly stir the milk for at least 30 seconds with a suitable appliance long enough to reach to the bottom of the container. If cream has formed on the milk, continue the mixing until all cream is detached from the sides of the vessel and evenly emulsified through the liquid.

Place the samples in nonabsorbent, air-tight containers and keep them in the cold, but at a temperature above freezing until ready for examination. When transported by mail, express, or otherwise, completely fill the containers, tightly stopper, and mark for identification. A suitable quantity of preservative (mercuric chloride, potassium dichromate, or formaldehyde) may be used unless the presence of the preservative is objectionable in connection with physical or chemical tests to be applied in addition to the determination of fat.

Reagents.—

(a) *Buffer Substrate.*—Dissolve 1.09 gm. of disodium phenyl phosphate[6] and 11.54 gm. of sodium Veronal in water saturated with chloroform and dilute to 1 liter. Add 10 c.c. chloroform per liter and store the reagent in a refrigerator.

(b) *Folin-Ciocalteu Phenol Reagent.*—Dissolve 100 gm. sodium tungstate, according to Folin, and 25 gm. sodium molybdate in 700 c.c. water in a 1500 c.c. flask connected by a ground-glass joint to a reflux condenser. Add 50 c.c. 85% phosphoric acid and 100 c.c. hydrochloric acid and reflux gently 10 hr. Cool, add 150 gm. lithium sulphate, 50 c.c. distilled water and 4 to 6 drops liquid bromine. Boil the mixture without a condenser 15 min. to remove excess bromine. Cool, transfer to a 1 liter flask, dilute to volume with water, and filter. (The finished reagent should have a golden yellow color; reject it if it has a greenish tint.) Keep the reagent in the refrigerator, protected from dust. For use dilute 1 volume of this stock reagent with 2 volumes of water.

(c) *Sodium Carbonate Solution.*—Prepare a 14% or 1.32 M solution of anhydrous sodium carbonate.

(d) *Filter Paper.*—Whatman No. 40, 11 cm. diameter. (Use only this grade as interfering substances are at times extracted from other grades.)

Permanent Phenol Standards.—

(a) *Color Solution, Gray.*—Dissolve in distilled water, 31.9 gm. of cobaltous chloride ($CoCl_2.6H_2O$), 67.5 gm. of cupric sulphate ($CuSO_4.5H_2O$), and 75 gm. of nickel sulphate ($NiSO_4.6H_2O$). Add 32 c.c. hydrochloric acid and 45 c.c. sulphuric acid and dilute to 500 c.c.

(b) *Color Solution, Red.*—Dissolve 476 gm. cobaltous chloride in distilled water and filter. To the filtrate add 100 c.c. hydrochloric acid and dilute to 1 liter.

---

[4] J. Dairy Res. 6: 191, 1935.

[5] 25th Ann. Rpt. Intern. Assoc. Milk Sanitarians 5: 15, 1936; 11th Ann. Rpt., New York State Assoc. Dairy and Milk Inspection, 1937.

[6] The disodium phenyl phosphate *must* be absolutely free of phenol. No soap-containing phenol must be used in cleaning the glassware used in this test. Check the paraffin used on milk caps for traces of phenol.

(c) *Color Solution, Blue.*—Dissolve 300 gm. cupric sulphate in distilled water, add 20 c.c. sulphuric acid, and dilute to 1 liter. (Should crystals appear when solution is cooled to below 20°, warm slightly before using to insure complete solubility.)

Prepare permanent color standards equivalent to phenol concentrations of from 0.01 to 0.15 mg. per 0.5 c.c. of sample by combining the quantities of color solutions a, b, and c indicated in the table and diluting to 10 c.c. with distilled water in each case; e.g., 0.3 c.c. solution a + 0.106 c.c. solution b + 0.96 c.c. solution c + distilled water to make a volume of 10 c.c. is equivalent to a phenol concentration of 0.01 mg. in 0.5 c.c. of samples.

These color standards are suitable for use only in natural daylight. If, however, a turquoise blue, unglazed, opaque glass plate is used to deflect the light from a daylight lamp through the tubes of standards and sample, accurate color comparisons can be made in the absence of daylight. Since the standards are prepared for use only at 13 mm. depth of color, tubes of different diameter cannot be used for accurate work.

PREPARATION OF PERMANENT PHENOL STANDARDS

PHENOL	COLOR SOLUTIONS			
	GRAY (A)	RED (B)	BLUE (C)	H_2O (DISTILLED) (D)
mg. per 0.5 c.c. (μg/c.c.)	c.c.	c.c.	c.c.	c.c.
0.01 = 20	0.30	0.106	0.96	8.634
0.02 = 40	0.40	0.140	1.16	8.3
0.03 = 60	0.55	0.180	1.65	7.62
0.04 = 80	0.65	0.216	2.10	7.032
0.06 = 120	0.92	0.286	3.00	5.794
0.09 = 180	1.30	0.326	4.40	3.974
0.12 = 240	1.70	0.360	5.70	2.24
0.15 = 300	2.50	0.396	7.10	0.004

Determination.—Transfer 10 c.c. of the buffer substrate solution into a test tube 20 mm. x 160 mm. and add 0.5 c.c. milk to be tested. Add a few drops chloroform, mix thoroughly by rotating the tube, and cover to protect contents from dust. (Do not use rubber or cork stoppers; paper toweling placed over the open end of the tube is satisfactory.) Warm to 37-39° C. in a water-bath and incubate at 34-37° C. for not less than 18 and not more than 24 hours. After incubation add 4.5 c.c. of the diluted Folin-Ciocalteu reagent. Mix, and allow to stand for 3 minutes. Filter, and transfer 5 c.c. of the filtrate to a test tube of 13 mm. diameter. Add 1 c.c. of the sodium carbonate solution and mix thoroughly by rotating the tube. Place the tube in a boiling water-bath for 5 minutes and filter. Cool, and estimate the color of the filtrate by comparison with the permanent color standards in 13 mm. outside diameter tubes, or with photometer and 650 mμ filter.

Control Test.—

(To check deterioration of the reagents and the presence of interfering substances in the milk sample.)

To 10 c.c. of the buffer substrate solution, add 4.5 c.c. of the Folin-Ciocalteu reagent, and 0.5 c.c. of the milk sample. (Do not incubate.) Mix thoroughly, allow to stand 3 minutes, and filter. To 5 c.c. of the filtrate add 1 c.c. of the sodium carbonate solution, mix thoroughly by rotating the tube, heat in a boiling water-bath 5 minutes, and filter. Cool, and compare the color of the filtrate with the permanent color standards in 13 mm. outside diameter tubes, or with photometer and 650 mμ filter. If the phenol value obtained is greater than 20 μg subtract the excess from the phenol value of the incubated sample to obtain the phenol value indicative of pasteurization treatment.

A phenol value of 80 μg phenol per c.c. sample generally indicates milk heated to 143° F. for 30 minutes. A value greater than this indicates progressively inadequate heat treatment. In reporting results, give the μg of phenol per c.c. of sample as well as an interpretation as to whether the milk is pasteurized or underpasteurized.

False Positive Phosphatase Tests.—

In connection with the performance of phosphatase tests to determine whether or not milk has been properly pasteurized, attention must be called to an occasional ''false positive.'' Buck,[1] using the Gilcreas modification of the Kay and Graham technic, described above, has found in the past five years in the Baltimore Health Department examinations of pasteurized milk and ice cream from plants where the equipment and pasteurizing inspection showed everything in order, twenty-one instances of these so-called ''false positives.'' Leahy and others[2] have shown that certain strains of bacteria are capable of hydrolyzing the substrate used in the phosphatase test. Therefore, a word of caution must be uttered in interpretation of this test where great numbers of bacteria are present in milk. Buck found a certain thermophilic bacillus present in milk that would give such a false positive. This organism was isolated from the products of four Baltimore dairies. Buck suggested the name *Lactobacillus enzymothermophilus* for this organism. He found that this organism produced an enzyme which was destroyed by heating at 185° F. for one minute. He found that production of the bacterial phosphatase in milk at pasteurizing temperatures of 142° to 144° F. began after a 90-minute holding period. The factors governing the production of the bacterial phosphatase are the inoculum number, the temperature, and the time period.

False positives are due to bacterial phosphatase enzyme production from thermophilic organisms, and not to inefficiency in pasteurization.

CHEMICAL MILK ANALYSIS

Reagents

N/10 Sodium Hydroxide.—

To about 50 c.c. distilled water in a 100 c.c. volumetric flask
Add 10 c.c. N/1 sodium hydroxide solution.
Dilute to 100 c.c. with distilled water.

Benedict's Volumetric Solution.—

The method of preparing and titrating Benedict's volumetric solution will be found on page 54.

Bogg's Reagent for Protein.—

(1) Phosphotungstic acid	25 grams
Distilled water	125 c.c.
(2) Concentrated hydrochloric acid	25 c.c.
Distilled water	125 c.c.

When the phosphotungstic acid is completely dissolved, mix the two solutions. This reagent is quite stable if kept in a dark glass bottle.

1% Alcoholic Phenolphthalein.—Dissolve 1 gram phenolphthalein in 100 c.c. 95% alcohol.

Milk-Fat Mixture.—Equal parts of concentrated hydrochloric acid and amyl alcohol.*

75% Sulphuric Acid.—

Distilled water	25 c.c.
Sulphuric acid, c.p., conc.	75 c.c.

Caution: Add the sulphuric acid slowly to the distilled water in a Pyrex flask, cooling it under running tap water.

Reaction

Technic.—

Make a preliminary determination of the reaction with litmus paper. If the milk is alkaline, the degree of alkalinity is determined by titration with N/10 hydrochloric acid; if it is acid, the degree of acidity is determined by titration with N/10 sodium hydroxide solution. The reaction of milk is usually amphoteric; that is, it reacts red to blue litmus, and blue to red litmus. Frequently, however, it is alkaline.

Fill a buret with N/10 sodium hydroxide (if the milk is acid).

---

*Make fresh each day.

[1] Am. J. Pub. Health 32: 1224, 1942.

[2] J. Milk Tech. 3: 183, 1940.

Place 10 c.c. of milk in a casserole.

Add about 50 c.c. distilled water, and 2 drops of 1% alcoholic phenolphthalein.

Add the sodium hydroxide drop by drop from the buret, stirring constantly, until the first permanent pink color is obtained. This is the end-point.

Read from the buret the number of c.c. of N/10 sodium hydroxide used. Multiply this number by 10 to obtain the degree of acidity.

Example.—If 1.5 c.c. of N/10 sodium hydroxide were used to neutralize 10 c.c. of milk, the degree of acidity is 10 × 1.5, or 15 degrees. The degree of acidity is equal to the number of c.c. of N/10 sodium hydroxide required to neutralize 100 c.c. milk An acidity of 15 to 25 degrees may be observed within six hours after milking; forty-eight hours after, the acidity is generally between 100 and 125. This applies more to cow's milk than to human milk.

Specific Gravity

Take the specific gravity with a urinometer. If a bacteriologic examination is to be made, enough milk is transferred to a sterile container for that purpose before the urinometer is admitted. Normal specific gravity is 1.028-1.032. The milk should be cooled to 60° F. before taking the specific gravity.

Color

The normal color of human milk is pale bluish white.

Lactose

Fill a buret, graduated in 0.1 c.c., with milk. Place 25 c.c. Benedict's volumetric solution in a casserole. Add 5-10 grams sodium carbonate, and a pinch of powdered pumice.

Bring the solution in the casserole to a boil and continue boiling until the end-point is reached.

Add the milk to the Benedict's solution in the casserole, a drop at a time, stirring after the addition of each drop. The milk should be added very slowly to the solution in the casserole, and some time allowed to pass before the addition of each drop, as reduction of the copper takes place very slowly.

Continue adding the milk, and boiling, until the blue color of the copper sulphate has entirely disappeared, and is replaced by a gray color. This is the end-point.

Read from the buret the number of c.c. of milk used. Twenty-five c.c. Benedict's volumetric solution are reduced by 67 mg. lactose.

The number of c.c. of milk that were used to bring about the reduction of the copper sulphate, therefore, contained 67 mg. of lactose. From this figure, the number of grams of lactose per 100 c.c. milk, or the percentage of lactose, can be computed according to the following example.

Example.—It required 4.0 c.c. of milk to reduce 25 c.c. Benedict's volumetric solution. 4.0 c.c. milk, therefore, contain 67 mg. lactose. 1 c.c. milk contains 67 divided by 4, or 16.75 mg. lactose. 100 c.c. milk contain 16.75 × 100, or 1675 mg. lactose. 1675 mg. = 1.675 grams (1675 ÷ 1000). The percentage of lactose in the milk is, therefore, 1.675.

Normal percentage of lactose in human milk is 6 to 7; in cow's milk, 4.3 to 7.

Fat

Leffmann-Beam Method

Use the modified Babcock tube, made for 5 c.c. quantities of milk. Place 5 c.c. milk in the Babcock tube.

Add 1 c.c. milk-fat mixture. Mix thoroughly by rotating.

Add 75% sulphuric acid to the mixture, mixing thoroughly as the acid is added, until the meniscus stands at the 0 mark on the stem. The solution becomes quite hot, and must be centrifuged before it cools.

Centrifuge immediately at 1,000 revolutions per minute for three minutes. The fat will be separated, and may be read in percentage on the stem. Each mark on the stem is 0.2% of fat. Read the percentage of fat from the stem and record. Read from the top of the meniscus.

Normal percentage of fat in human milk is 3 to 5; in cow's milk, it is 3.5 to 4.

Protein

Bogg's Modification of the Esbach Method

If human milk is to be examined, dilute, accurately, 1:10 with distilled water. If cow's milk is being tested, dilute 1:20 with distilled water. Place the milk in an Esbach tube until the bottom of the meniscus stands at the mark "U."

Fill to the mark "R" with Bogg's reagent.

Mix by inverting several times, taking care to prevent the formation of air bubbles.

Allow to stand in an upright position for 24 hours. Read from the graduation marks the number of grams of dried protein per 1,000 c.c., or the height of the coagulum. Divide this result by 10 to obtain the number of grams in 100 c.c. Multiply this by the dilution of the milk. This gives the number of grams of protein in 100 c.c., or the percentage.

Example: Human milk was used, and the dilution was 1:10. The reading on the Esbach tube is 1.25. 1.25 ÷ 10 gives 0.125, or the number of grams of protein in 100 c.c. diluted milk. 0.125 × 10 = 1.25 grams of protein in 100 c.c. milk, or 1.25% protein.

Normal protein content of human milk is 1.0 to 2.25%; of cow's milk is 1.5 to 4%.

Total Solids

Total solids are roughly calculated from the lactometer readings according to the following formula:

Let "L" equal the last two figures of the specific gravity.

Let "F" equal the percentage of fat found in the milk.

Total solids equals:

$$(L \div 4) + (0.2 \times F) + F.$$

Example.—Specific gravity was 1.028. Percentage of fat was 4. 28 ÷ 4 is 7; 0.2 × 4 (F) is 0.8; 7 + 0.8 + 4 = 11.8, the total solids.

Total Protein

Compute the total nitrogen by the method described for total nitrogen in urine (page 144). Report "total nitrogen found." Human milk contains 9% nonprotein nitrogen. Subtract 9 from the total nitrogen found, and multiply the result by 6.34, which will give the total protein present.

Formaldehyde in Milk

Place 5 c.c. sulphuric acid, c.p., concentrated, in a test tube.

Add to it 15 drops of 10% ferric chloride solution. Great caution must be taken in the addition of the ferric chloride solution to the sulphuric acid. Do not add it too rapidly, and avoid undue agitation of the contents. The proportion of ferric chloride is 3 drops to each c.c. of sulphuric acid.

Fill a large test tube to within about 1 inch of the top with the milk to be tested.

Allow 1 or 2 c.c. of the sulphuric acid and ferric chloride mixture to run slowly down the side of the tube so that it will collect on the bottom of the tube without mixing with the milk.

Allow to stand about 5 minutes.

The development of a permanganate ring at the point of contact indicates the presence of formaldehyde.

Care must be taken not to use too much reagent, which may obscure the reaction.

FOOD POISONING

The term "food poisoning" is a very broad one. Illnesses included under it are caused by a variety of factors in which bacteria play a very important part. A number of metallic compounds may produce poisoning. Certain foods are poisonous due to the presence of alkaloids or more obscure but related substances. Attention, too, must be called to the fact that food allergy may be responsible for certain cases of so-called food poisoning. Finally, there are certain outbreaks in which no definite causative factor can be found. Epidemiologic evidence and clinical symptoms may give us a clue, but at other times this information is of no assistance. In this chapter we shall concern ourselves only with the bacteriologic examinations of suspected food. There are three groups which must be investigated: (1) *Clostridium botulinum;* (2) certain members of the Salmonella group; and (3) Staphylococci. In a few instances members of the dysentery group and streptococci as well as Proteus have been accused of being responsible for these attacks. Recently *Clostridium perfingens* type *F*, which is nonhemolytic, has also been implicated.

The Koser[3] procedure, detailed here, is recommended. It is as follows:

Laboratory Procedure

A. First Examination.—

1. Prepare a stained smear (Gram stain) directly from the foodstuff, preferably the liquid portion.

2. With a loopful of the foodstuff,[4] streak in succession two agar plates, preferably a meat infusion agar M-15. With another loopful streak two plates of eosin-methylene blue agar M-71, 72. Incubate for eighteen to twenty-four hours at 37° C.

3. Inoculate a tube of broth, preferably prepared from meat infusion M-4, with a small amount of the sample. Incubate at 37° C.

4. In order to determine the presence of Staphylococcus, use the agar plate medium described above under (2) and follow this up by the usual test for identification of staphylococcus, such as coagulase test (R-4), etc. Also make stain to determine whether the coccus is gram-negative or gram-positive. Special Petri dish with special anaerobic cover (see special plate made by Baltimore Biological Company, page 1470) is recommended. This plate should contain thioglycollate agar M-49. Staphylococci associated with food poisoning are often found to be facultative anaerobic; that is, they will grow on anaerobic cultures and also on this special medium.

If the poisoning is suspected or definitely known to be botulism the following steps should be included:

5. Inoculate each of three tubes of chopped meat medium M-12 with approximately a gram or 1 c.c. of the sample.

Immediately after inoculation two of the three tubes should be heated to 80° C. for twenty minutes to destroy vegetative cells. If an anaerobic jar is not available, the three tubes should be layered with about 1 c.c. of sterile petrolatum to form a seal. Incubation should be 35° to 37° C.

6. A portion of the sample should also be used to test for the presence of toxin. Inject subcutaneously at least two guinea pigs or two white mice with a portion of the food. In most cases it will be necessary to centrifuge the sample before injection to eliminate gross contamination. Use 0.5 to 1.0 c.c. of the supernatant fluid for injection. Where abundant toxin formation is suspected, and a sufficiently large sample is available, it is desirable to feed portions to two guinea pigs.

---

[3] Am. J. Pub. Health 24: 203, 1934.

[4] If the only sample submitted is an empty jar or can, the interior should be thoroughly washed out with a few c.c. of sterile salt solution or sterile broth. The washings can then be used for the examination.

Should death of any of the animals occur, controls with antitoxin of types A and B should be included. Inject subcutaneously two more animals with a protective dose of type A antitoxin (usually 1 c.c. is sufficient) and an additional two with type B antitoxin. These four animals should then be injected with the foodstuff in the same way as the original two which did not receive antitoxin. If the antitoxic sera are not at hand, these controls should be performed as soon as they are available.

B. Subsequent Examinations.—

1. Microscopic examination of the stained smear will give an idea of the relative abundance of bacteria in the product and of the morphologic types present.

2. Examine the eosin-methylene blue plates for the presence of colorless colonies. If suspicious looking colonies are found, fish several to Kligler medium M-79 or T.S.I. medium M-80. The identification of suspected intestinal pathogens requires additional procedure and is described on pages 1632 ff.

Examine also the nutrient agar plates and make Gram stains of several representative colonies. Note especially if Staphylococcus or Streptococcus colonies are present in considerable numbers. Proceed with the identification as recommended on pages 1485, 1487 ff.

3. The purpose of using a tube of broth is to detect by enrichment and subsequent plating any Salmonella, Staphylococci, or other types which might have been missed by direct plating. If the steps listed under A2 and B2 have yielded no information of value, streak eosin-methylene blue plates and nutrient agar plates from this broth culture. The examination of these plates should then proceed as given under item B2.

4 and 5. (If suspected botulism.) The condition of the animals which were injected under item A5 will afford preliminary evidence of the presence or absence of botulinum toxin in the food. This should now be supplemented by examination of the meat medium tubes inoculated under item A4.

These tubes should be incubated for at least three to four days. Note any macroscopic evidence of growth and prepare Gram stains from each tube. Note whether gram-positive bacilli, with or without subterminal spores, are present. Select one or more tubes for a toxicity test similar to that carried out with the original sample under item A5. The result of this will serve to confirm that secured with the food sample and at times it may be of great value in affording some additional information. In the event of a positive test the meat medium may be used for further purification and isolation of the culture, if this is desired.

C. Examination of Feces.—

Samples of excreta are often of value, particularly in those instances where the suspected foodstuff has been consumed or destroyed. If fecal specimens are taken, especial endeavor should be made to procure them during the acute stages of illness. It is believed that no detailed laboratory procedure need be given here, since the examination would follow the usual steps employed for isolation of organisms of the enteric group from feces (see pp. 1629 ff.).

D. Examination of Necropsy Material.—

If such material is available following acute gastrointestinal illness which might have been caused by Salmonella or dysentery organisms, cultures can be made from contents of the colon, spleen, and mesenteric lymph nodes. Positive cultures, which are definitely identified as Salmonella or dysentery types, may be of value in determining the cause of the illness. Positive cultures are usually not obtained from the blood, but where a definite Salmonella type has been isolated from the blood it is often of value when taken in connection with the other findings.

In cases of botulism, toxin can sometimes be demonstrated in blood or in bowel contents by animal injection along with the use of specific antitoxins. It is necessary to centrifuge or filter bowel contents to get rid of the numerous miscellaneous bacteria which are present.

Interpretation of Results

Since some outbreaks of food poisoning are due to other than bacteriologic causes, perhaps the first duty of the bacteriologist is to realize that his part of the examination may at times prove to be fruitless and that he should not feel obligated to attach blame to any organism which happens to be conspicuous.

The laboratory is often asked for proof that the actual organism obtained is in reality the cause of the trouble. Unfortunately, symptoms of typical acute gastrointestinal illness can rarely, if ever, be reproduced in the ordinary laboratory animals by feeding. Results obtained by the injection of suspected cultures are open to question and should not be advanced as sole proof of an etiologic role of the organism in question.

However, if a member of the Salmonella group has been isolated from the suspected food, one may rest assured that beyond reasonable doubt he has obtained the causative agent. This conclusion seems justified since these organisms are not ordinarily encountered in foodstuffs and since there is now good evidence that they are a definite cause of food poisoning. In the event that it has been possible to isolate a similar Salmonella type from specimens of feces or from necropsy material, additional confirmation is thereby obtained.

CAT TEST TO DETERMINE STAPHYLOCOCCIC FOOD POISONING

In the case of Staphylococcus findings in connection with food poisoning, it is considered that this food poisoning is due to the presence in the material of staphylococcus enterotoxin. Dolman and his associates[1] first described the kitten intra-abdominal test. This test consisted in injecting specially prepared culture filtrates into the abdominal cavity of very young kittens after inactivation of the lethal exotoxins by heat, Formalin, or neutralization by specific antitoxin. After a variable period of time, toxic filtrates containing the Staphylococci will produce vomiting and diarrhea in these kittens.

The method for preparation of the staphylococcus toxin has been described by Hammon and Favorite.*

Use trypticase soy agar M-18 in Petri dishes or Kolle flasks. Inoculate plates and incubate at 37° C. for 40 hours in 30% carbon dioxide. Put plates in an anaerobic jar, evacuate the air, and introduce carbon dioxide 30%. Squeeze the culture through cheese cloth, centrifuge at high speed, decant the supernatant fluid, and put through a Seitz filter. This is used to inoculate cats.

Chapman[2] suggested a rapid presumptive test for the examination of foods suspected of having caused food poisoning.

The food is triturated with a small amount of sterile broth M-1. To 0.5 c.c. of the filtrate of this extract add 0.5 c.c. citrated or oxalated human plasma. Incubate and observe for coagulation.

---

*J. Bact. 41: 305, 1941.

[1] Canad. Pub. Health J. 27: 489, 1936.

[2] Food Research 9: 377, 1944.

A similar shortened method to be used with Staphylococcus colonies was described by Lominski and Grossfeld.[3] These authors suggested the addition of 2 to 3 loopfuls of the material to 0.5 c.c. of citrated or oxalated plasma which was diluted 4 to 8 times with saline. The mixture is incubated at 37° C. and read after ½ hour, 1, 6, and 12 hours. This method permits the saving of plasma.

Cat Technic: Place the cat, without anesthesia, on its back on animal board and shave the inner aspect of one thigh to a point just below the knee. Slight pressure over the vein near the inguinal region enables one easily to see and enter the saphenous vein at about the level of the knee, or just above, with a sharp 26 gauge needle. After releasing the pressure above, grasp the syringe and leg together with one hand and make the injection slowly. Depending on the toxin, from 0.5 c.c. to 5 c.c. may be required. The toxin must first be heated for thirty minutes in a boiling water bath. The precipitate should be sedimented and the supernatant liquid used as inoculum. When heat is used, the supernatant liquid from well-centrifuged cultures may be safely used without filtration. Sterility, in practice, appears to be unnecessary.

The train of **symptoms** observed after an intravenous inoculation of enterotoxin is as follows: In from 15 minutes to 2 hours, most frequently in about 30 minutes, vomiting occurs, preceded by nausea. Coarse tremors are usually noted and the hair stands erect. This is interpreted as a chill because the temperature rises, sometimes to 106°, after 2 to 4 hours.

Diarrhea is conspicuous but may be mild. It persists for several hours. Vomiting may recur at intervals of from 5 minutes to 1 hour over a period of 2 to 3 hours. After 3 to 4 hours, the cat is noticed to be less ill, and 24 to 48 hours later it appears to be normal. Since vomiting and occasionally diarrhea are symptoms of the very common and highly infectious type of feline epizoötic panleukopenia, it is quite important to use cats known to be in good health. A moderate-sized meal eaten shortly before the inoculation of enterotoxin has been found to increase the effectiveness of the vomiting stimulus, and noted refusal of the offered meal aids distinctly in the elimination of sick animals.

In the case of botulism there is fortunately direct evidence in the injection and feeding of animals and the protection afforded by a specific antitoxic serum.

TABLE 164.—DIFFERENCES BETWEEN BOTULISM AND FOOD INFECTIONS

COMPILED BY BURKE AND MAY*

	BOTULISM	FOOD INFECTIONS
Cause	Botulinus toxin	Salmonellae
Fever	Not characteristic; temperature usually subnormal	Characteristic; acute
Occurring	Mainly in winter	Mainly in summer
Associated with	Preserved foods	Fresh foods, or freshly contaminated foods, usually meat or milk
Condition of bowels	Constipation, rarely diarrhea	Diarrhea
Visual disturbances	Double vision; ptosis of lids	Absent
Abdominal pain	Absent	Present
Onset	Usually gradual	Sudden
Incubation period	Variable, usually from twelve hours to several days	Short, usually from six to twelve hours
Throat	Swallowing difficult	Normal
Treatment	Antitoxin	Systemic
Mortality	From 60 to 70%	From 1 to 2%

There is considerable difference of opinion as to the different media and methods which should be employed; the outline, page 1687, however, is serviceable.

SPECIAL TESTS IN CONNECTION WITH EXAMINATION OF FOOD CONTAMINATION BY CHEMICALS AND SPOILAGE*

There are a number of tests advocated for the control of products coming within the scope of health department activities. These products are spoilage of certain fragile food materials, cyanide in metal polish, etc.

Korff and Kaplan[1] have been particularly active in developing testing outfits and providing their inspectors with simple and proper equipment for gathering material for making these tests. With their permission, the method and equipment used by Baltimore City Health Department to make certain analytical examinations in the field are here presented.

Field Equipment.—Each inspector is equipped with a leather case containing the usual detention cards, violation notices, copies of laws, educational forms and leaflets, sample identification cards, and such conventional equipment as flashlights, thermometer, can opener, and meat trier. They have paper bags and paper spoons for collecting food samples; sterile 4 oz. bottles for water samples, and sampling vials for food utensil swabbing. They are also supplied with portable apparatus for detecting fluorides, cyanides, cadmium, arsenic, sulphites; also equipment for testing strength of chlorine solutions used as disinfectants and for the detection of spoilage of shucked oysters and crab meat. Where possible, reagents are kept in uniform glass vials, each case being fitted with a wooden rack to hold the apparatus. All solutions, test papers, and other equipment are periodically replaced and reconditioned by the Bureau of Laboratories.

Analytical Procedures

1. Detection of Spoilage of Shucked Oysters.—According to Korff and Kaplan, pH measurements of oyster liquor is a useful adjunct to organoleptic examination in the detection of spoilage of shucked oysters. This has been demonstrated by several investigators.[2, 3] The pH of the fresh oysters varies between 6.0 and 7.0. Hydrogen ion concentrations between pH 5.4 and 5.8 are suspicious, with decomposition indicated when the pH values lie below this range.

Technic of the Field Examination for Spoilage of Shucked Oysters.—

Transfer 5 c.c. of oyster liquor to a test tube graduated at 5 c.c.

Add 0.5 c.c. of methyl red indicator solution (0.02% methyl red in 50% alcohol).

Mix. Compare the color with the methyl red color standards. These color standards range from pH 5.4 to 6.0 and are kept in sealed ampules. If the oysters appear to have been recently washed, place several drops of the indicator solution directly on the oyster. Production of a red color which persists indicates spoilage.

---

[3] Baldwin, W. H., Puncochar, J. F., and Pottinger, S. R.: Fishery Market News 3: 3, 1941, U. S. Department of the Interior, Fish and Wildlife Service.

2. Detection of Spoilage of Crab Meat.—Decomposition of crab meat involves a progressive proteolysis, with an accompanying rapid rise in the ammonia content of the meat. The Nessler ammonia test as a means of differentiating fresh from spoiled crab meat was suggested in 1932 by Harris.[4]

Technic of Test Made by Inspectors.—

Transfer about 1 gm. of crab meat to a test tube.

Add several c.c. of distilled water and shake thoroughly.

Add 2 or 3 drops of Nessler's reagent (see page 244).

Spoilage of meat is indicated if a deep yellow or brown color develops immediately. This test is used only as an aid to organoleptic examination of the suspected crab meat.

3. Detection of Cyanide in Metal Polish.—Williams, in 1930,[5] pointed out the possible role of cyanide-containing metal polish in cases of gastroenteritis. The Maryland State Department of Health in 1938 adopted regulations governing retail sale or use of cyanide-containing preparations. Many other communities have similar legislation.[5]

Sodium picrate test papers[6] are used conveniently for qualitative detection of cyanide in metal polishes in the field. Moisten the test paper with water, then suspend it in the container of suspected polish. Take care that the paper does not come in contact with the material. If the concentration of cyanide (as KCN) exceeds 0.5 per cent, the paper will turn orange and then brick red in 5 to 10 minutes. This reaction is not wholly specific for cyanide; nevertheless, it serves as a ready screening test in the field.

4. Cadmium.—There has been a tendency on the part of equipment manufacturing companies to use cadmium for plating utensils and equipment. This was brought about because of difficulty in obtaining aluminum and stainless steel. A number of food poisoning outbreaks attributed to consumption of acid foods stored in cadmium-plated vessels have been reported.[7] Warnings of the dangers of the use of cadmium-lined utensils have been issued to the newspapers by the Federal Security Agency.

Modified Field Test for Cadmium.*—

Reagents.—

1 oz. dropping bottle containing 10% nitric acid.

1 oz. dropping bottle containing 40% sodium sulphide.

Technic.—

Place 1 drop of 10% nitric acid on the surface to be tested.

Wait 5 to 10 seconds, then add a drop of 40% sodium sulphide solution to the drop of acid on the metal. A bright yellow color indicates the presence of cadmium.

If the surface is such that it is not feasible to use the liquids directly, dip a cotton swab into the nitric acid, and rub over a small area for about 5 to 10 seconds. Then place a drop of the sodium sulphide reagent on the swab. Instantaneous appearance of a canary yellow color on the swab indicates presence of cadmium.

Note: Reagents should be renewed at least once a month.

5. Available Chlorine in Disinfectant Solutions.—Regulations of the Maryland State Board of Health require that all food containers (drinking glasses, plates, forks, etc.) used in establishments dispensing food or drink, after cleaning and rinsing, must be disinfected either by immersing in water at 180° F. or above, or by immersion in a solution containing not less than 100 p.p.m. of available chlorine.

---

[7] Cadmium Poisoning, Pub. Health Rep. 17: 601, 1942.

Strength of chlorine rinse waters is determined by a modified orthotolidine test.[8] Inspectors carry in their kit a 2 oz. dropping bottle of orthotolidine solution, a 100 p.p.m. permanent chlorine standard in a sealed ampule, a test tube of the same diameter as the standard ampule and graduated at 10 c.c. and a medicine dropper calibrated to deliver 20 drops of water per c.c.

Technic.—

(*a*) Add 10 c.c. of tap water to the tube.
Follow by 4 drops (0.2 c.c.) of the rinse water being tested.
Add 1 c.c. of the orthotolidine solution.

Wait 5 to 10 minutes, then compare with the standard. The permanent standard actually corresponds to 2 p.p.m. of chlorine. The sample is diluted 1 to 50 in the test (0.2 to 10). Permanent standards are prepared by the method of Scott,[9] which permits color matching irrespective of the tube length.

(b) A compact portable iodimetric testing outfit for residual chlorine has been prepared for dairy inspectors. This consists of Barnes dropping vials containing potassium iodide-starch solution, lactic acid solution, and standard sodium thiosulphate solution. Transfer the rinse water to a vial graduated at 10 c.c. Adjust the standard solution so that one drop is equivalent to 20 p.p.m. of available chlorine when 10 c.c. of rinse water is titrated.

This iodimetric method gives a more exact evaluation of the strength of chlorine rinse water than the orthotolidine test. It may be used with chloramine preparations, whereas the orthotolidine test does not function well in the presence of chloramine compounds.

6. Fluoride-Containing Insecticide Powders.—Accidental poisoning from white sodium fluoride is not uncommon. The Maryland State Board of Health, in 1941, adopted regulations requiring insecticides containing sodium fluoride to be colored Nile blue as a warning. These regulations were adopted because of the widespread use of insecticides containing uncolored sodium fluoride in hotel, restaurant, and hospital kitchens in Maryland.[10]

Fluoride test paper is used. In the presence of strong acids, soluble fluorides decolorize the zirconium lake of sodium alizarin sulphonate.

Impregnate strips of filter paper with fluoride reagent.[11] Dry.

Moisten a test paper with dilute hydrochloric acid (the orthotolidine solution carried by the inspectors for the residual chlorine test may be used).

Touch the moist strip to the suspected powder.

In the presence of a large amount of soluble fluoride, decolorization of the paper will occur in about 5 seconds. Decolorization is evident in about 30 seconds when a 1 to 1,000 dilution of sodium fluoride powder in flour is used. Allow a reaction time of 5 minutes for traces of fluoride. Phosphates and oxalates may yield false tests. Positive findings, therefore, should be confirmed in the laboratory.

7. Detection of Sulphites in Meat Products.—Sulphites in ground meat serve partly as a preservative, but are used chiefly to deodorize and to restore the bright red color of fresh meat.[12] The A.O.A.C. qualitative test for sulphurous acid[13] has been adapted as a field test. Sulphite detection depends upon the evolution of hydrogen sulphide when material containing sulphide is treated with zinc and dilute mineral acid. The evolved hydrogen sulphide blackens a cotton dental roll moistened with lead acetate and contained in a Gutzeit scrubber tube.[14]

---

[8] Standard Methods for the Examination of Water and Sewage, ed. 8, 1936, p. 20. American Public Health Association, New York, N. Y.

[9] Scott, R. D.: Water Works & Sewerage **82**: 399, 1935.

[10] Baltimore Health News **18**: 153-154, 1941.

[11] Snell, F. D., and Snell, C. T.: Colorimetric Methods of Analysis, 1936, p. 581, Van Nostrand.

Technic.—

Transfer about 10 gm. of ground meat to a wide mouth bottle containing 30 c.c. of 10 per cent sulphuric acid.

Stopper the bottle and shake moderately for 10 seconds. Allow several minutes for foam to subside.

Add 3 gm. of 30 mesh granulated zinc (arsenic- and sulphur-free).

Insert immediately a stopper containing a Gutzeit scrubber tube[14] previously fitted with a No. 2 cotton dental roll impregnated with 20 per cent lead acetate solution.

The cotton roll will become black in 5 to 10 minutes. After about 10 minutes, open the bottle. There will be a decided odor of hydrogen sulphide if sulphites are present. The test will detect as little as one grain of sodium sulphite in a pound of ground meat. Traces of sulphides in foods may yield false positive tests. Because of this, field outfits are intended for screening tests only. All samples which show positive reactions are submitted to the laboratory for confirmatory analyses.

8. **Arsenic Spray Residue.**—Presence of excessive amounts of spray residue on fruits and vegetables is suspected when there are unusual deposits on the foods. In order to eliminate the detention of truck, boat, or railroad shipments pending laboratory examination, testing for arsenic is done in the field. The test used is an adaptation of the official Gutzeit method for arsenic of the A.O.A.C. Similar modifications have been used by others.[15]

Use the equipment designed for the sulphite determination in ground meat. Fit a piece of glass tubing to the Gutzeit scrubber tube to hold a strip of sensitized mercuric bromide paper.

In addition, add 15 c.c. of 40 per cent stannous chloride solution to each liter of 10 per cent sulphuric acid reagent. In practice the acid used for the sulphite test contains the stannous chloride addition and is thus also suitable for the arsenic examination.

Directions are essentially the same as in the case of the sulphite examination. Introduce scrapings of suspected material into the generator. Add the acid and zinc. Allow the reaction to proceed for 30 minutes. A decided yellow to dark brown coloration of the sensitized mercuric bromide paper indicates the presence of arsenic.

9. **Food Utensil Swabbing.**—The Baltimore City Health Department food inspectors use the improved vials described by Buck[16] in 1941 to secure bacteriologic samples from drinking glasses and food utensils. These vials have a plastic screw type closure which holds a wooden applicator with cotton attached.

[14] Ibid. p. 390.

[15] Mayo, N., and Taylor, J. J.: Florida Quart. Bull. 42, 2: 12, 1933.

[16] Buck, T. C.: Baltimore Health News 18: No. 7 (July), 1941.

Sterilize salt solution or broth directly in the vials. Numbers of vials may be carried by the inspectors in their carrying cases without danger of contaminating them. For more complete information refer to pages 1654 ff.

10. Other Tests.—Other equipment may be added to the inspectors' kits as needed. The Scharer modification of the phosphatase test for the detection of proper pasteurization of milk and cream[17] is adaptable to field use. Inspectors in soft drink bottling plants may use an outfit for testing alkalinity of wash waters. The foam test[18] for renovated butter and oleomargarine may be carried out in the field by means of a spoon and an alcohol lamp.

Discussion.—More than 6,000 field tests were made by the staff of the Bureau of Food Control of the Baltimore City Health Department during the years 1941 and 1942. The majority of these tests were examinations of chlorine rinse waters and food utensil swabbings. Other tests revealed that metal polish containing cyanide was in use in more than 200 food establishments, which led to regulations prohibiting its use. Field testing resulted in the condemnation of at least 50 lots of incipiently decomposed shucked oysters which could not have been readily detected by organoleptic means. Sulphite in ground meat is now rarely encountered, largely because meat dealers know that the Health Department has ready means of its detection.

The field test is never used as a basis for prosecution. The purpose and the intention of the field tests are to assist the inspectors' organoleptic senses; they are not meant to supplant the more critical examination of foods by trained chemists. Inspectors are cautioned to use the field methods for information and screening purposes only and to submit samples to the Bureau of Laboratories for confirmatory analyses.

EXAMINATION OF FLOUR FOR "ROPE" SPORE CONTENT

Method:[19]

Preparation of Special Broth:

Peptone	10 gm.
Beef extract	5.4 gm.
Sodium chloride	9 gm.
Distilled water	1 liter

pH = 7.2-7.3

Place in 5 c.c. quantities in $5/8$ inch diameter test tubes. Steam for 10 minutes on three successive days.

Sterilize bottles, pipettes, and measuring cylinder by heating at 150° C. for two hours.

Sterilize sodium chloride solution (0.5%) by boiling in a plugged flask for an hour.

Measure 400 c.c. of the sodium chloride solution into a sterile 16 ounce glass-stoppered bottle, and 100 c.c. into a sterile 8 ounce glass-stoppered bottle.

Heat 20 grams of purified silver sand to redness in a platinum capsule for some minutes and then pour, while hot, into the liquid in the 16 ounce bottle.

Weigh 20 grams of the flour on a sterile watch glass and transfer by means of sterile paper to the 16 ounce bottle. Then shake this bottle vigorously for two minutes and immediately transfer 1 and 2 c.c. quantities of the suspension to 5 c.c. tubes of broth.

---

[17] Scharer, H.: J. Dairy Sci. **21**: 21-34, 1938.

[18] Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists, ed. 5, 1940, p. 300.

[19] Amos, A. J., and Kent-Jones, D. W.: The Analyst **56**: 572, 1931.

Reshake the bottle and add 20 c.c. of the suspension at once to the liquid in the 8 ounce bottle; then shake it well. Transfer volumes of 4, 3, 2.5, 2, 1.7, 1.5, 1.3, 1.2, and 1 c.c. respectively of this dilution to 5 c.c. tubes of broth.

Thoroughly mix the contents of each tube, taken individually, and place the tube in a bath of boiling water, for 20 minutes. The water level must be above the level of the liquid in the tubes. Then thoroughly mix the contents of the tubes and place them in an incubator at 37° C. for 48 hours. Contents of tubes must be well mixed several times during the first 24 hours of incubation. After 48 hours, report the tube as positive or negative, according to whether or not the contained broth exhibits a pellicle. The number of rope spores (*Bacillus mesentericus)* is taken as the reciprocal of the smallest fraction of a gram of flour giving a positive test.

2 c.c. of primary suspension = 1/10 gram flour
1 c.c. of primary suspension = 1/20 gram flour
4 c.c. of 20:100 dilution = 1/30 gram flour
3 c.c. of 20:100 dilution = 1/40 gram flour
2.5 c.c. of 20:100 dilution = 1/48 gram flour
2 c.c. of 20:100 dilution = 1/60 gram flour
1.7 c.c. of 20:100 dilution = 1/70 gram flour
1.5 c.c. of 20:100 dilution = 1/80 gram flour
1.3 c.c. of 20:100 dilution = 1/92 gram flour
1.2 c.c. of 20:100 dilution = 1/100 gram flour
1 c.c. of 20:100 dilution = 1/120 gram flour

B. subtilis, another organism sometimes found in flour, forms a pellicle on the broth. This organism will not cause ropy bread. If the spore count is high, determine whether the pellicles are due to *subtilis* or *mesentericus,* by transplanting to agar slants.

B. mesentericus vulgatus forms a grayish-white growth which is at first moist and ''blister''-like in appearance, but later becomes dry and finely wrinkled.

B. subtilis gives a whitish, spreading growth, the edges of which appear as an interwoven mass of fine hairs.

The rope spore content of flour, unless particularly high, is of little significance in outbreaks of rope in commercial practice. The systems of fermentation, baking, and bread cooling employed by the baker are of greater significance.

When ropiness occurs, the following rules should be observed in fermenting the doughs:

(1) Avoid a long system of fermentation.
(2) Use a liberal quantity of yeast.
(3) Avoid low temperatures in the dough.
(4) Avoid slack doughs.

The dough should be well baked, and cooled as rapidly as possible in a well-ventilated place.

It is desirable to use flour of low rope spore content.

For the examination of thermophilic organisms in flour, and also in other foods, use dextrose agar M-19. It must be incubated at higher temperatures (45° and 50° C.).

EXAMINATION OF CANNED FOOD, DRESSINGS, NEEDLES, ETC., FOR STERILITY

Simple Rapid Test

The examination for sterility is made by placing a portion of the material to be tested in four fermentation tubes of chopped meat medium M-12. One is to be incubated aerobically at room temperature, one aerobically at 37° C., one anaerobically at room temperature, and one anaerobically at 37° C. The material from the canned food is obtained in the following manner:

Place about 5 c.c. of alcohol on the top of the can. Ignite. Flame the can opener to free it of bacteria. Cut a hole in the top of the can with the sterilized can opener. Using a piece of glass tubing which has been previously sterilized, remove a portion of the contents of the can, and using all sterile precautions, place in 4 tubes of chopped meat medium M-12. Two tubes are incubated at room temperature, the other two at 37° in the incubator. Both aerobic and anaerobic cultures should be made.

For dressings, use sterile scissors and sterile forceps to remove a portion of the material. Select a part of the material from the center of the package.

Flame the mouth of the fermentation tube, and drop the material into the broth, taking care not to touch the glass of the tube.

Needles, etc., are examined in the same manner as surgical dressings. For the examination of catgut, see below.

If no growth appears after ten days' incubation the material examined was sterile.

If a growth is obtained before ten days' incubation, make an examination to determine the type of bacteria present.

No report that the material was sterile may be given under ten days' incubation. A growth may be reported at once.

Evidence of growth is a cloudy medium. Smears may be made to confirm the evidence. Proceed in the usual manner to identify the bacteria.

Test for Sterility of Catgut

(Frank L. Meleney, M.D., and Mabel Chatfield, New York.)[1]

Run at least two tests on each sample; one aerobic, the other anaerobic. Seize the catgut from the container with a pair of long "alligator" forceps previously dipped into alcohol and flamed.

Transfer with sterile precautions to a test tube containing 40 c.c. sterile distilled water.

Place this tube in the incubator for twenty-four hours.

Transfer the catgut to a tube containing 1% sodium thiosulphate and 1% sodium carbonate solutions. Incubate for twenty-four hours.

Transfer to fermentation tubes containing thioglycollate broth M-48.

Incubate both cultures fifteen days before reporting sterile.

Tests should be made on the medium (1) for sterility, and (2) for growth-producing ability.

Tubes of the medium should be incubated, uninoculated, along with the sterility tests on the catgut.

Test organisms, such as anthrax and tetanus bacilli, should be planted in tubes of broth and incubated during the fifteen-day period.

Tests for Determination of Sterility of Solids, Such as Gauze, Surgical Dressing, and Related Products*

Method of Choice

Broth for Sterility Tests Under Aerobiosis.—

Use formula M-4 to which glucose has been added in 1 per cent concentration.

Do not use culture medium which has been kept longer than two weeks at room temperature or four weeks under refrigeration.

Broth for Sterility Tests Under Anaerobiosis.—

Litmus solution	10 c.c.
Gelatin	20 gm.
Broth for sterility tests under aerobiosis, a sufficient quantity to make	1,000 c.c.

The broth prepared for aerobiosis need not be filtered or sterilized before the addition of the other ingredients. Dissolve the gelatin in the broth by the aid of gentle heat, add the litmus test solution, and adjust the preliminary reaction to pH 7.6. Then, if necessary, add the albumen of two fresh eggs or its equivalent in desiccated egg albumen, heat to coagulate, and add distilled water to make 1,000 c.c.; filter until clear and distribute the filtrate in quantities of 40 c.c. each, as described under the broth for testing aerobic organisms. Sterilize in an autoclave at from 15 to 20 pounds pressure (121° to 125° C.) for from twenty to thirty minutes, or by any other suitable method. The final reaction should be between pH 7.2 and pH 7.4.

---

*This material is taken from The Second Supplement to the Pharmacopoeia of the United States of America, Eleventh Decennial Revision (U. S. P. XI-1939 Supplement). Proper acknowledgment of this is seen on the reverse side of the title page of this book.

[1] Surg. Gynec. & Obst. 52: 430, 1931.

The 10 c.c. of litmus test solutions may be replaced by 0.2 gm. of azolitmin if preferred.

Do not use culture medium which has been kept longer than two weeks at room temperature or four weeks under refrigeration.

Honey Medium for Molds and Yeasts.—

Peptone	10 gm.
Honey	60 c.c.
Distilled water, a sufficient quantity to make	1,000 c.c.

Dissolve the peptone in the distilled water with gentle heat, add the honey, and adjust the preliminary reaction to pH 6.0. Filter if necessary and sterilize in an autoclave at from 15 to 20 pounds pressure (121° to 125° C.) for from twenty to thirty minutes or by any other suitable method. The final reaction should approximate pH 5.6.

Sterilized Distilled Water.—

Distribute distilled water in quantities of 40 c.c. each in chemically clean, preferably sterile, test tubes. Plug the tubes with gauze-wrapped, nonabsorbent cotton, and sterilize in an autoclave.

Inactivating Fluids for Inactivating Bacteriostatic Agents.—

Fluids A or B are used for removing the various chlorine, iodine, or mercury compounds which are employed as bacteriostatic agents in the tubing fluids used in the packaging of surgical gut. Fluid C is necessary as a preliminary inactivating fluid if the chemical analysis shows that the sutures contain copper salts. If bacteriostatic agents, other than those already designated, are used, appropriate sterile inactivating fluids and appropriate sterile washing agents must be employed so as to remove effectively the bacteriostatic and inactivating agents, which if present would interfere with bacterial growth in the subsequent test for sterility.

Inactivating Fluid A

Sodium thiosulphate	10 gm.
Sodium carbonate	10 gm.
Distilled water, a sufficient quantity to make	1,000 c.c.

Mix, filter if necessary, and distribute in quantities of 40 c.c. each, in chemically clean, dry, sterile test tubes. Sterilize in an autoclave at from 15 to 20 pounds pressure (121° to 125° C.) for from twenty to thirty minutes.

Inactivating Fluid B

Sodium thiosulphate	100 gm.
Distilled water, a sufficient quantity to make	1,000 c.c.

Mix, filter if necessary, and distribute in quantities of 40 c.c. each, in chemically clean, dry, sterile test tubes. Sterilize in an autoclave at from 15 to 20 pounds pressure (121° to 125° C.) for from twenty to thirty minutes.

Inactivating Fluid C

Ammonium chloride	50 gm.
Stronger ammonia water	15 c.c.
Distilled water, a sufficient quantity to make	1,000 c.c.

Dissolve the ammonium chloride in enough distilled water to make 1,000 c.c., filter if necessary and sterilize in an autoclave at from 15 to 20 pounds pressure (121° to 125° C.) for from twenty to thirty minutes. Add 15 c.c. of stronger ammonia water, and distribute the solution aseptically in quantities of 40 c.c. each, in chemically clean, dry, sterile test tubes.

Petrolatum-Paraffin Mixture for an Anaerobic Seal.—

Petrolatum, having a melting point of 48° C.	50 gm.
Paraffin, having a melting point of 57° C.	50 gm.

Liquefy the ingredients by gentle heat and distribute preferably in quantities of 50 or 100 c.c. each in chemically clean, dry test tubes or other containers. Sterilize in a dry heat oven at 170° C. for two hours or by any other suitable method.

Suggested Technic for Conducting Tests for Sterility

Carry out all bacteriologic tests under the most rigid aseptic conditions. Wherever possible, tests should be carried out by two operators working together. The outside wearing apparel of the operators should consist of sterile caps, gowns, and face masks to cover the nose and mouth, and all manipulations should be conducted in a small, dust-proof room supplied with filtered air under positive pressure. The air in the testing room should be sprayed with water and the room itself washed down with a disinfectant each time transfers are to be made, or at least once daily when in use, the room being allowed to remain closed for fifteen minutes thereafter.

Opening Packages and Containers

For Purified Cotton, Gauze, Surgical Dressings, and Related Products.—Flame with care the carton, package, container, or one of the margins if in an envelope, to remove adhering dust particles. Remove material from the package with sterile forceps. Sterilization of the latter is effected in an autoclave or by wrapping the forceps and heating them in a hot-air oven at 170° C. for two hours. Between successive transfers thoroughly flame the forceps. If scissors are needed, sterilize them by the technic directed for forceps.

For Sutures.—If necessary make a file line in the center of the tube or about 10 mm. above any tubing fluid. Then place the tubes in a suitable, active disinfecting solution for 24 hours. Remove the tubes with sterile forceps and place them between sterile towels. As an alternative method of sterilization, flame the tubes, preferably in a wing flame, avoiding the heating of the contents.

Removing and Culturing Contents.—Take portions of the substance in triplicate from the cartons, wrapped packages, envelopes, and similar containers. The material to be tested should be taken from various locations within the roll of purified cotton, gauze, surgical dressing, or related material, preferably from the outer end, center, and core, using sterile instruments and equipment. Transfer these portions of the material, as rapidly as possible, to the necessary number of tubes of medium for aerobic and anaerobic culturing, and also to tubes of honey medium for detecting molds and yeasts. Before use, heat the culture medium for anaerobiosis at 100° C. for fifteen minutes and cool quickly. Seal the inoculated anaerobic medium with a thick (3 cm.) layer of sterile petrolatum-paraffin mixture. Place the sealed tubes immediately in a 37° C. incubator or in a cool water bath to solidify the seal. The time between the removal of the medium from the steam bath and the pouring of the seal should not exceed 15 minutes when examining sutures, and 30 minutes when examining other solids. Cultures of sutures are incubated at 37° C. for 15 days before negative results are recorded. Other products are to be incubated as directed above for 7 days before negative results are recorded. The cultures in honey medium for yeast and fungi are to be incubated for 15 days at from 22° to 25° C. before negative results are recorded.

In the case of sutures, break the tube at the filed line preferably by holding against it a red-hot, curved wire. Transfer the entire suture or loop or strand of gut, with the points of the sterile forceps, to the test tube containing 40 c.c. of sterile distilled water, replace the cotton plug, and incubate the tube at 37° C. for 24 hours. Then transfer the gut to a test tube containing 40 c.c. of sterile inactivating fluid A, using the necessary precautions to prevent contamination, and again incubate at 37° C. for 24 hours.

If a chemical analysis of at least 4 sutures of any lot reveals that the sutures are impregnated with more than 2 per cent of a mercury compound or more than 5 per cent of chlorine or iodine, use sterile inactivating fluid B instead of the above. If the sutures upon chemical analysis have been found to contain copper, transfer the suture, after treatment with 40 c.c. of sterile distilled water to 40 c.c. of sterile inactivating fluid C and again incubate at 37° C. for 24 hours.

It may also be necessary at this point to employ other appropriate sterile inactivating fluids if bacteriostatic agents other than mercury, iodine, or chlorine have been used. If inactivating fluid B or inactivating fluid C, or special inactivating fluids are used, follow by placing the suture in 40 c.c. of sterile inactivating fluid A. That the inactivating fluid used may not interfere with bacterial culturing, an additional step is necessary before the transfer of the suture to the culture medium. This is to wash the suture, after treatment with the inactivator, in another tube of 40 c.c. of sterile distilled water. Finally place the gut in each of the three tubes of medium to test for aerobes, anaerobes, and for molds and yeasts as detailed above.

Confirm all positive cultures showing growth by a microscopic examination of stained smears.

At the end of the period of incubation inoculate at least 5 per cent of all negative aerobic suture cultures showing no growth with 1 c.c. of a 1:100,000 dilution of an eighteen- to twenty-four-hour broth culture of *Esch. coli* and incubate at 37° C. for three days. Inoculate at least 5 per cent of all negative anaerobic suture cultures showing no growth with 1 c.c. of a 1:100,000 dilution of an eighteen- to twenty-four-hour broth culture of *Cl. novyi* and incubate at 37° C. for three days. Inoculate at least 5 per cent of all negative yeast and mold suture cultures showing no growth, with 1 c.c. of a 1:1000 dilution of a seventy-two-hour honey medium culture of *Monilia albicans* and incubate at from 22° to 25° C. for three days. Failure of growth is evidence that bacteriostatic agents which may have been carried over in the transfer are present.

Controls

Tubes of media, distilled water, and inactivating fluid are preferably placed in cans or baskets before sterilization and then covered by paper hoods. Incubate all tubes of culture media immediately after their preparation, for 48 hours at 37° C. and then for 48 hours at room temperature. Discard tubes showing growth. Culture aerobically and also anaerobically 10 c.c. of the distilled water used in these tests and also each of the inactivating fluids, immediately after their preparation. If any of the tubes used in testing show growth the entire stock of material they represent must be discarded.

When testing any material for sterility, the following controls are to be conducted simultaneously:

(a) Inoculate two tubes of each of the culture media to be used with 10 c.c. of the distilled water used and incubate for fifteen days.

(b) Carry out a similar test as in (a) but replace the distilled water with the inactivating fluid used. If more than one inactivating fluid is to be employed, each one must be tested separately.

(c) Seal two tubes of the anaerobic culture medium with a 3 cm. layer of the petrolatum-paraffin mixture and incubate for fifteen days to determine the sterility of the anaerobic seal.

(d) The culture medium to be used for anaerobic culturing should support growth upon inoculating 40 c.c. with 1 c.c. of a 1:100,000 dilution of an eighteen- to twenty-four-hour broth culture of *Cl. novyi.* The culture medium to be used for aerobic culturing should support growth upon inoculating 40 c.c. with 1 c.c. of a 1:100,000 dilution of *Esch. coli.* Incubate inoculated tubes for 72 hours at 37° C. The culture medium used for molds and yeasts should support growth upon inoculating 40 c.c. with 1 c.c. of a 1:1000 dilution of a seventy-two-hour honey medium culture of *Monilia albicans* and incubating at 22° to 25° C. for three days.

Testing for Sterility of Biologic Products

Fluid thioglycollate medium M-48 is used.

Prepare according to the label on the bottle, by suspending 29.5 grams in 1000 c.c. of cold distilled water, heating to boiling to dissolve the medium completely, and distributing into test tubes. Sterilize in the autoclave at 15 to 17 pounds pressure for 18 to 20 minutes.

The final reaction of the medium will be pH 7.1. Store the tubes in the dark at room temperature. Do not use if more than 30 per cent of the uppermost portion of the medium has changed to a pink color. However, one reheating in a boiling water bath is permissible to drive off the absorbed oxygen.

To test for sterility of preparations containing a preservative, the amount of medium used must be sufficient to dilute the inoculum beyond the bacteriostatic limits of the preservative. On the basis of a 1 c.c. inoculum, Difco suggests the amounts of medium to be used for the various types of preservative commonly used in biological preparations, Table 165.

If sterility tests are to be made of certain biologic products which are turbid or otherwise cannot be cultured satisfactorily in fluid thioglycollate medium because of their viscosity, use the formula listed below:

Bacto-N.I.H. Thioglycollate Broth or BBL Sterility Test Broth

Casitone or Trypticase	15 gm.
Yeast extract	5 gm.
Dextrose	1 gm.
Sodium chloride	2.5 gm.
l-Cystine	0.05 gm.
Sodium thioglycollate	0.5 gm.

Suspend 24 gm. in 1000 c.c. cold distilled water. Distribute in Smith fermentation tubes and sterilize in the autoclave for 18 to 20 minutes at 15 to 17 pounds pressure. The final reaction will be pH 7.1±.

In those instances where a solid agar medium is needed for the maintenance of cultures isolated in connection with the sterility testing of a biologic product, or for use as a solid sterility test medium, use BBL or Bacto-N.I.H. agar, dehydrated.

N.I.H. Agar

Casitone or Trypticase	15 gm.
Yeast extract	5 gm.
Dextrose	1 gm.
Sodium chloride	2.5 gm.
l-Cystine	0.05 gm.
Agar	15.0 gm.

Suspend 38.5 gm. of N.I.H. agar in 1000 c.c. cold distilled water. Heat to boiling to dissolve and distribute into tubes or flasks. Sterilize in the autoclave at 15 to 17 pounds pressure for 18 to 20 minutes. Final reaction will be pH 7.1±.

Table 165 gives the minimum quantities of medium for use in sterility tests.

TABLE 165.—MINIMUM QUANTITIES OF MEDIUM FOR USE IN STERILITY TESTS*

PRESERVATIVE USED	TYPE OF BIOLOGIC PRODUCT	AMOUNT OF PRESERVATIVE PRESENT	MINIMUM VOLUME OF CULTURE MEDIUM TO USE PER 1 C.C. OF INOCULUM
Phenol	Sera and vaccines	0.5%	40 c.c.
Cresol, U.S.P.	Serum	0.35%	60 c.c.
Merthiolate	Toxoids Human plasma	1:10,000 1:35,000	10 c.c.
Phenyl mercuric acetate	Human plasma Normal saline	1:50,000 1:100,000	10 c.c.
Phenyl mercuric borate	Human plasma Normal saline	1:50,000 1:100,000	10 c.c.
Phenyl mercuric nitrate	Human plasma Normal saline	1:50,000 1:100,000	10 c.c.
Merthiolate + phenol	Serum	1:10,000 +0.2%	20 c.c.
Chlorbutanol	xxx	0.5%	40 c.c.
Formalin	xxx	0.4%	40 c.c.

*Manual of Dehydrated Culture Media and Reagents, ed. 9, revised 1953, Difco Laboratories, Inc., Detroit, Mich.

THE TESTING OF DISINFECTANTS

The Reddish Method of Testing Solutions for Antiseptic Action

Prepare a twenty-four-hour broth culture of *Staphylococcus aureus*, FDA.

Have on hand No. 2 Whatman filter paper, previously cut into pieces about 0.5 cm. square, and sterilized in the dry heat sterilizer at 170° C. for two hours.

Prepare numerous sterile test tubes with cotton plugs, and sterilize in the dry heat sterilizer. These are to be used for the 5 c.c. of diluted antiseptic used in the test.

Have on hand tubes of nutrient broth M-2, previously tested for sterility. If the material to be tested is oil, and is to be diluted, have sterile mineral oil on hand.

If the material is to be diluted with water, have on hand sterile distilled water.

Prepare 5 c.c. pipettes, graduated 10 c.c. pipettes, and 1 c.c. pipettes, and sterilize.

Technic.—Transfer the sterile paper squares to the twenty-four-hour broth culture of *Staphylococcus aureus*.

Prepare the various dilutions of the disinfectant to be tested, placing 5 c.c. of each dilution into properly marked sterile test tubes.

Determine the time intervals of exposure of the organism to the disinfectant before making the test.

Assume that time intervals are to be thirty seconds, one minute, two minutes, three minutes, four minutes, and five minutes. Each dilution of antiseptic will require 6 transplants. If there are to be three dilutions (undiluted, 1 to 2, and 1 to 10), 18 tubes of nutrient broth are arranged 6 in a row in test tube racks.

18 more tubes of broth are arranged in test tube racks. These are used to shake off the disinfectant. All tubes are properly labeled with the dilution and the time interval.

Proceed with the test:

1. Fish a piece of the paper from the *Staphylococcus aureus* broth culture by means of a flamed platinum wire.
2. Place this immediately in 5 c.c. undiluted disinfectant.
3. At the end of 30 seconds, transfer the paper to a tube of sterile broth.
4. Shake in this broth for 5 minutes to remove the disinfectant.
5. Transfer the paper to a second tube of sterile broth, labeled with the dilution and time interval, and incubate at 37° C. for three days.

Carry out similar tests at different time intervals and different dilutions, incubating all tests at the same time.

At the end of the three-day incubation period, report the results in each tube, as either sterile or growth.

If more than one test organism is to be used, manifestly more material must be prepared.

Food and Drug Administration Methods of Testing Antiseptics and Disinfectants[1]

The Food and Drug Administration method is applicable to the testing of phenol-like disinfectants, such as coal-tar and cresylic acid compounds and other phenolic preparations, and gives results quite comparable to those obtained with the Hygienic Laboratory method which is limited only to phenol-like compounds. It must be distinctly understood that this method is not well adapted for the testing of chlorine compounds or for oxidizing agents in general since the presence of organic matter adversely affects the germicidal effectiveness of such preparations under practical conditions. Therefore, a phenol coefficient figure for chlorine compounds would be misleading to the consumer since such a figure would not indicate the actual germicidal efficiency of such disinfectants under practical conditions in the presence of organic matter.

---

[1] Ruehle, G. L. A., and Brewer, C. M.: Circular No. 198, December, 1931, United States Department of Agriculture, Washington, D. C.

Apparatus and Technic

''**Test Organism and Culture Medium.**—The test organism is a 22- to 26-hour culture of *Salmonella typhosa* (Hopkins strain) incubated and grown in nutrient broth at 37° C. The broth contains the following ingredients: 5 gm. of Liebig's beef extract, 5 gm. of chemically pure sodium chloride, and 10 gm. of Armour's peptone (for disinfectant testing) in 1,000 c.c. of distilled water. The mixture is boiled for 20 minutes, made up to original weight (or volume) with distilled water, and adjusted with NaOH to pH 6.8 using the colorimetric method. It is then filtered through paper, tubed (10 c.c. to each tube), and the tubes are plugged with cotton and sterilized at 15 pounds pressure for 40 minutes. The test culture is transferred daily in this medium for not more than one month. At the end of each month, a fresh transfer is made from the stock culture. The stock culture is carried on agar slants of the same composition as the broth medium plus 1½ per cent Bacto-Agar (Difco), adjusted to pH 7.2 to 7.4. This medium is also filtered, tubed, plugged with cotton, sterilized, and slanted. The stock culture is transferred once a month, and the test organism is taken from the month-old stock culture. When the test organism has not been transferred daily, it is advisable to make four or five consecutive daily transfers in broth before using it for testing purposes, to be reasonably sure of its conforming to the phenol resistance requirements. When only one transfer has been skipped the following transfer from the 48-hour culture is usually satisfactory for use after 24 hours. Transfers are made with the platinum loop used in the test. Only cultures giving readings within the following limits are considered satisfactory:

Phenol:	5 minutes	10 minutes	15 minutes
1- 90	+	+	0
1-100	+	+	+
or			
1- 90	0	0	0
1-100	+	+	0

''The following reading is that most usually obtained and is the most convenient:

Phenol:	5 minutes	10 minutes	15 minutes
1- 90	+	0	0
1-100	+	+	+

''**Phenol.**—The phenol used must meet the requirements of the United States Pharmacopoeia, and in addition the congealing point must not be below 40° C. A 5 per cent solution may be used as a stock solution if kept in a relatively cool place in well-stoppered amber-colored bottles protected from the light. This 5 per cent solution should be standardized with decinormal bromine or with sodium bromide and bromate solution.

''**Apparatus.**—Besides a number of accurately graduated pipettes, 100 c.c. glass-stoppered graduates or volumetric flasks are almost essential for the making of correct dilutions. All pipettes and graduates should be standardized. The test tubes for containing the dilutions should be large enough to permit transfers being made without touching the sides with the transfer needle. Lipped Pyrex (to withstand constant flaming) test tubes 25 by 150 mm. serve very well as these seeding or medication tubes. A water bath for holding the dilutions at the desired temperature must be provided. To maintain the temperature practically constant during the period of the test, the bath should be made so as to contain a relatively large volume per surface area, and should be insulated. The lid is made with well-spaced holes admitting the 25-mm. tube, but not the lip. The most convenient form of subculture tubes (tubes containing medium for incubating the tested organisms, as well as for growing the test culture) are ordinary nonlipped bacteriological test tubes 20 by 150 mm. The racks for holding the subculture tubes may be any convenient style. Blocks of wood with a series of holes bored in them are quite satisfactory. Dimensions depend somewhat on the size of the incubator, but the holes should be well spaced to insure quick selection and easy manipulation during the test. It is an added convenience to have the holes large enough to admit the medication tubes while dilutions are being made. The transfers are made with a 4-mm.

(inside diameter) single loop of number 23 B. & S. gauge platinum wire, 1½ to 3 inches long, set in a suitable holder such as an aluminum or glass rod approximately 0.5 cm. in diameter.

"**Procedure.**—One per cent stock dilutions of the substance to be tested (or any other convenient dilution of the disinfectant, depending on the strength) are made up, usually in the glass-stoppered cylinders or volumetric flasks from which the individual dilutions are then prepared. For rapid routine work, the final dilutions may be made directly in the medication tubes. In this case all excess over 5 c.c. must be removed. For more precise work and when high dilutions are required or volatile substances are dealt with, it is preferable to make up all of the dilutions in volumetric flasks and then transfer 5 c.c. of the final dilution to the medication tubes. These tubes containing 5 c.c. of each dilution (including the phenol control) are placed in the water bath at 20° C. for five minutes until the temperature of the bath is reached. Even slight variations in temperature may affect the results. The dilutions should cover the range of the killing limits of the disinfectant within 5- and 15-minute periods and should at the same time be spaced sufficiently close together to insure the desired accuracy. Five-tenths of a cubic centimeter of the test culture is then added to each of the dilutions at a time interval corresponding to the interval at which the transfers are to be made. Thus by the time 10 tubes have been seeded at 30-second intervals, four and one-half minutes will have elapsed and a 30-second interval intervenes before the transference to the subcultures is commenced. The culture is added from a graduated pipette holding sufficient culture to seed all the tubes in any one set. The pipette may be loosely plugged with cotton at the mouth end before sterilizing, as a precautionary measure. Unfiltered culture is used, but it should be thoroughly shaken 15 minutes before use and allowed to settle. The temperature of the culture should be practically that of the water bath before being added.

"In inoculating the medication tubes they should be held in a slanting position, after removal from the bath, and the culture run in without the tip of the pipette touching the disinfectant. The tip may be allowed to rest against the side of the tube just above the surface of the liquid. The tubes are agitated gently but thoroughly after the addition of the culture to insure even distribution of the bacteria. Five minutes from the time of seeding the first medication tube, transfer 1 loopful of the mixture of culture and diluted disinfectant from the medication tube to the corresponding subculture tube. To facilitate transfer of uniform drops of the medication mixture, the loop is bent to form a slight angle with the stem and the medication tube is held at an angle of 60°. In other words, as the loop is withdrawn, its plane should be parallel with the surface of the liquid. At the end of 30 seconds, a loopful is transferred from the second medication tube to the second subculture tube and the process is continued for each successive dilution. Five minutes from the time of making the first transfer, a second set of transfers is begun for the 10-minute period and finally repeated for the 15-minute period. Before each transfer the loop is heated to red heat in the Bunsen flame and the mouth of every tube is flamed. Sterilization of the loop is effected immediately after making the previous transfer (before replugging the tubes) to allow time for sufficient cooling. Time does not permit flaming the tubes after making the transfer. For this reason, care in transferring and seeding is necessary. Due caution is observed to prevent either the seeding pipette or the transfer needle from touching the sides or mouth of the medication tube; neither should cotton threads be found adhering to the sides or mouth of these. After completion of the transferring, the subculture tubes are incubated at 37° C. for 48 hours and results are read. Macroscopic examination usually suffices for this, but occasionally agglutination with antityphoid serum will aid in reading doubtful results. A 3-day incubation period or agar streak or microscopic examination may be resorted to in determining feeble growth, especially when organisms other than *Salmonella typhosa* are used.

"There are certain types of germicidal agents, such as many of the mercury compounds, which give very high results by phenol coefficient tests.[2] Due to the high inhibitory value of such substances in preventing growth in the subcultures these figures are frequently misleading. For germicides used in the disinfection of such objects as surgical instruments, this is of particular importance and must be taken into account. Failure to appreciate this characteristic of certain compounds is much more likely to lead to error when *Staphylococcus aureus* is used rather than *Salmonella typhosa* as the test organism. That false values may not be obtained for products of this type, or for any other disinfectant giving suspiciously high results, the subcultures should contain very large amounts of medium (not less than 200 c.c.) or they should be retransferred by carrying at least 4 loopfuls from the first subculture to a second tube of broth, as recommended by Shippen.*

---

[2] Am. J. Pub. Health 18: 1231, 1928.

''Other groups of disinfectants in common use, for which the phenol coefficient method of testing is not well adapted, are those compounds containing chlorine as the active agent as well as oxidizing agents in general. These are affected so materially by the presence of organic matter that a phenol coefficient statement may grossly misrepresent their value under practical conditions of use and is very apt to be misleading to the consumer when placed on the label.''

Calculation of the Phenol Coefficient

''The results of the test are expressed in terms of the *phenol coefficient.* This represents the germicidal value of the diluted disinfectant as compared with the diluted phenol control. It is a figure obtained by dividing the numerical value of the greatest dilution (the denominator of the fraction expressing the dilution) of the disinfectant capable of killing *Salmonella typhosa* in 10 minutes but not in 5 minutes, by the greatest dilution of phenol showing the same results; that is, by the phenol control. Thus, if the results were as follows:

	5 minutes	10 minutes	15 minutes
Disinfectant (X):			
1-300	0	0	0
1-325	+	0	0
1-350	+	0	0
1-375	+	+	0
1-400	+	+	+
Phenol:			
1- 90	+	0	0
1-100	+	+	+

the phenol coefficient would be $\frac{350}{90} = 3.89$.

''If none of the dilutions shows growth in 5 minutes and killing in 10 minutes, the hypothetical dilution may be estimated in certain cases. This may be done only when any three consecutive dilutions show the following results:

''The first, no growth in 5 minutes; the second, growth in 10 minutes but not in 15 minutes; and the third, growth in 15 minutes; for example:

''If the results were as follows:

	5 minutes	10 minutes	15 minutes
Disinfectant (X):			
1-300	0	0	0
1-350	+	+	0
1-400	+	+	+
Phenol:			
1- 90	0	0	0
1-100	+	+	0

the estimated phenol coefficient would be $\frac{325}{95} = 3.42$.

''To avoid giving an impression of fictitious accuracy, the phenol coefficient is calculated to the nearest 0.1 unless the coefficient is less than 1.0. Thus, in the examples cited above, the phenol coefficients would be reported as 3.9 and 3.4 instead of 3.89 and 3.42.

''In the preceding description, *S. typhosa* has been mentioned as the test organism. Wherever any expression of phenol coefficient occurs in literature, on labels, etc., it is assumed to mean the *S. typhosa* phenol coefficient, unless otherwise stated. It is, however, the distinct intention of this department* not to limit the test to the use of one organism. In fact, the test has been found adaptable to the use of a wide variety of bacterial species in the determination of phenol coefficients. In cases where some of the more strictly parasitic bacteria are used, modifications in media are necessitated, and, of course, a change in the phenol dilutions. The writers are not in a position at this time to prescribe the limits of resistance for many of the organisms that might be used. Therefore discussion of the exact technic is here omitted, with the exception of that for *Staphylococcus aureus.* Suggestions for the use of certain representative types may, however, be found in a paper by Reddish.† When any test organism other than *S. typhosa* is used it should be distinctly designated when stating the phenol coefficient.

---

*Loc. cit., p. 1704

''*Staph. aureus* has been found to be an extremely useful organism for testing disinfectants and antiseptics and has been used for this purpose for a number of years. When substituted in the above test the technic remains exactly the same. The phenol dilutions, however, must be changed. The resistance of any strain of *Staph. aureus* used in this test must come within the following limits: At 20° C. it must survive a 1:60 dilution of phenol for 5 minutes and a 1:70 dilution for 15 minutes. The following is the minimal resistance that would be acceptable:

	5 minutes	10 minutes	15 minutes
Phenol:			
1-60	+	0	0
1-70	+	+	+

''In the bacteriological examination of disinfectants, the *S. typhosa* and the *Staph. aureus* phenol coefficients give, in general, sufficient information to render tests with other organisms unnecessary, except in special instances. The commonly accepted criterion that disinfectants for general use be employed at a dilution equivalent to the germicidal efficiency of 5 per cent phenol against *S. typhosa* (that is, 20 times the *S. typhosa* phenol coefficient) allows a reasonable margin of safety for the destruction of infective agents likely to be the object of general disinfection about premises with the possible exception of *Mycobacterium tuberculosis. Staph. aureus,* due to its ubiquity, resistance and ever-ready tendency to cause infection, should always be employed in testing those substances recommended for personal use or as applications for wounds. If the disinfectant is recommended for use externally the temperature of test should be 20° C., but where such substances are recommended for use in the body cavities, such as for mouth washes, gargles, douches, etc., this test should be conducted at 37°. In such case the test should be designated 'The F.D.A. method (special) *Staph. aureus,* 37° C.' At body temperature the *Staph. aureus* should show the following resistance to phenol:

	5 minutes	10 minutes	15 minutes
1-80	+	0	0
1-90	+	+	+

Or

	5 minutes	10 minutes	15 minutes
1-80	+	0	0
1-90	+	+	0

''

Reddish emphasizes that antiseptics are chemical agents used to kill or inhibit infectious bacteria on the human and animal body, and that the phenol coefficient test is not suitable for testing antiseptics and should never be used for this purpose. A figure showing germicidal activity against *S. typhosa* does not indicate the effectiveness of antiseptics against pus-producing and other infectious bacteria which are present in and on the body. It is obvious that antiseptics should be tested against the kind of bacteria which they are expected to kill under practical conditions. Reddish in 1925[1] published a method for testing soluble liquid antiseptics against *Staphylococcus aureus* of known normal resistance to phenol. In this test 0.5 c.c. of a 24-hour F.D.A. broth culture of *Staphylococcus aureus* is added to 5.0 c.c. of antiseptic at 37° C., and transfers are made from this mixture to 10 c.c. of sterile broth after 5 minutes (officially designated as the F.D.A. method *Staphylococcus aureus* 37° C., 18). If all of the microorganisms (approximately 350,000,000) in the 0.5 c.c. of culture are killed by 5.0 c.c. of antiseptic in 5 minutes, the product is an effective antiseptic. The culture of *Staphylococcus aureus* employed in this test must not be killed by 1:80 phenol in 5 minutes nor by 1:90 phenol in 10 minutes at 37° C. under the conditions of the test as just outlined. (No comparison of any kind is made to the results obtained with phenol, the phenol test being only a control on the resistance of the culture.) Such antiseptics are approximately equal in germ-killing power to the 1:40 solution of carbolic acid used in antiseptic surgery. Antiseptics which pass this test are effective germicides when used in practice, as has been proved in the case of antiseptics for oral use.[2]

---

*United States Department of Agriculture, Washington, D. C.

†Am. J. Pub. Health 17: 320, 1927.

The classes of preparations to which this test is applicable are the various germicidal solutions ordinarily used for first aid, for oral use, and for general applications about the body for the prevention of infections. Tincture of iodine, liquor antisepticus, aqueous solutions of iodine, solutions of phenol, mercury compounds, essential oils, halogen compounds, etc., should be tested by this method. Solutions of antiseptic dyes, however, should be tested by the agar cup plate method.[3] The test is not especially applicable for the testing of antiseptics for skin disinfections, as has been shown by Tinker and Sutton,[4] Reddish and Drake,[5] and Simmons.[6] The F.D.A. method *Staphylococcus aureus* 37° C. is applicable to those soluble liquid antiseptics which are employed for short periods of contact, and for this purpose it has proved both practical and satisfactory.

Interference of Phospholipids With Phenol Coefficient Results

There are certain pitfalls in all the methods for determination of phenol coefficients of disinfectants, as pointed out by Brewer.[7] He definitely proved that the peptone component of the medium for culturing phenol coefficient test organisms may seriously affect the phenol coefficient figure obtained. This effect on the test culture is not detectable from the results of the phenol coefficient. This work is based upon certain preceding observations. For instance, Petroff and Schain[8] showed that the bactericidal properties of germicides are enhanced by the addition of detergents. For this reason, many manufacturers have been adding detergents or wetting agents to disinfectants, with a consequent increase in the phenol coefficient figure. The result of the killing power against *S. typhosa* depends upon the type of peptone used in the test. The phospholipid content in the peptone is the pivotal point in this matter. Some peptones, for instance, contain a certain amount of phospholipid, others little or none. Their presence and amount determine the results of the test.

What is the answer? What can we do to make accurate and reliable and trustworthy phenol coefficient test results in testing disinfectants containing a detergent? This phospholipid factor, which is the determining point, according to Brewer's work, is present in the standard or recommended peptone (the F.D.A. method prescribes Armour peptone) in favorable amounts. Brewer states "the problem is not easy of solution." He concluded that when tested against *S. typhosa* the germicidal activity of disinfectants containing synthetic detergents is greatly altered by the phospholipid content of the culture medium.

DISEASES DUE TO RICKETTSIAE

A number of diseases, most of which are typhus-like, have been shown to be due to the type of organisms which have been given the name of Rickettsiae. These organisms have been shown in the tissues of many insects and also in the tissues of animals or human beings during certain specific diseases of which they are suspected of being the causative factors. Rickettsiae are small, nonmotile, coccoid-like bodies, about 0.5 micron in diameter, occasionally seen in pairs of bacillary and filamentous forms. They may be demonstrated by using diluted Giemsa stain, 1 c.c. to 50 c.c. distilled water, after fixation for one-half hour in alcohol. The organisms take on a reddish purple coloration with this stain.

Pinkerton* states that present evidence indicates that the rickettsiae, although they are as strictly dependent upon intracellular conditions as the smaller viruses, have a somewhat more complex enzyme system than the latter, and are therefore able to maintain a certain amount of independent metabolic activity within their host cells. He believes that we may consider rickettsiae both from the point of view of size and from the point of view of independent metabolic activity as occupying a position intermediate between certain cytotropic bacteria and the viruses.

Using the criteria suggested by Cowdry† and Wolbach,‡ Pinkerton* defines rickettsiae as small, often pleomorphic, gram-negative, bacterium-like organisms, living and multiplying in arthropod tissues, behaving as obligate intracellular parasites, and staining lightly with aniline dyes. With but a few exceptions, criteria adequate for classification on the basis of biologic properties are available only for those members of the group which are pathogenic for mammals.

The most important diseases which have been shown to be associated with rickettsiae are typhus on the European continent and Rocky Mountain spotted fever on this continent. Ricketts and Wilder[1] first pointed out the etiologic agent of typhus in lice fed upon typhus patients. This was confirmed by da Rocha-Lima,[2] who called the organism *Rickettsia prowazeki*. Wolbach, Todd, and Palfrey[3] experimentally confirmed this etiology by showing

[3] Harvard University Press, Cambridge, Mass., 1922.

that lice, originally free from rickettsiae, acquired numerous rickettsiae which distended the intestinal lining cells, when fed on typhus patients. They showed intracellular rickettsiae in the lesions of man and experimental animals, and, further, when the intestines of lice, containing intracellular rickettsiae, were emulsified and injected into guinea pigs, typhus resulted, whereas injection of the intestines of rickettsia-free stock lice produced no illness. The hosts for *Rickettsia prowazeki* are *Pediculus humanus, Xenopsylla cheopis,* and *Ceratophyllus fasciatus.* Rocky Mountain spotted fever, found so frequently in this country, is due to rickettsiae called *Dermacentroxenus rickettsii.* The hosts for this rickettsia are *Dermacentor andersoni, Dermacentor variabilis, Haemaphysalis leporis-palustris, Amblyomma americanum,* and *Rhipicephalus sanguineus.*

Rickettsia Prowazeki (Typhus Rickettsiae).—In paraffin sections, *R. prowazeki* are always intracellular. In smears, extracellular organisms are often seen, as a result of the rupture of cells in the process of making the preparation. They appear frequently as minute diplobacilli, each member of the diploid form averaging about $0.6 \times 0.3\ \mu$. Short chains are not uncommon; sometimes, long chains are seen in tissue culture.

They stain poorly with most aniline dyes. They are gram-negative. They can be stained by the Giemsa method, by Macchiavello's (S-46), or by the Castañeda's stain (S-49).[4] With the Giemsa stain, the rickettsiae are stained blue or purple, with the cytoplasm a pale blue. With the last method, the rickettsiae are stained red and stand out sharply against a blue cytoplasmic background. Stains for Rickettsiae are discussed on pages 1413 and 1711.

Typhus rickettsiae multiply exclusively in the cytoplasm of cells in tissue cultures, and are never seen in nuclei. This behavior is in striking contrast to that of spotted fever rickettsiae as pointed out by Pinkerton and Hass.[5] During mitotic division of their host cells, the organisms are markedly reduced in number and tend to collect at the poles of each cell.[6] When fat droplets appear within cells in tissue culture, the rickettsiae are never seen within these droplets, but crowd the cytoplasm around the droplets.

R. prowazeki are readily killed by heat, drying, or chemical agents. At −20° C., a brain or spleen from a typhus guinea pig, if sealed in a test tube, retains its virulence with a gradual loss of titer for periods ranging up to eight months.[7] Nigg[8] showed that typhus rickettsiae in sealed Maitland cultures at 37° C. are virulent for periods ranging up to several months.

According to Pinkerton[9] the most satisfactory animal for the study of typhus is the guinea pig, in which both murine and human typhus causes a febrile but nonfatal illness. Two distinct types of *R. prowazeki* are recognized. Pinkerton believes that the differences between these two types are of subspecific magnitude and the two types should be given the variety names *R. prowazeki* var. *prowazeki* and *R. prowazeki* var. *mooseri.* The former is the etiological agent of louse-borne human typhus, of the type which has occurred in great epidemics on the European continent, and has been called European or epidemic typhus. *R. prowazeki* var. *mooseri* is the name applied to the etiological agent of a somewhat milder, usually endemic, form of the disease occurring in various parts of the world, and apparently enzootic in rats. This form of the disease is carried from rat to rat by the rat louse (and by the rat flea) and from rat to man by the rat flea. It is called murine typhus.

[4] Zinsser, H.: Harvard Symposium, Harvard University Press, p. 896, 1940.

[5] J. Exper. Med. **56**: 151, 1932.

[6] J. Exper. Med. **54**: 307, 1931.

[7] Pinkerton, H.: Unpublished observations.

[8] J. Exper. Med. **61**: 17, 1935.

[9] Bact. Rev. **6**: 37, 1942.

Pinkerton states that the difference between these two types of *R. prowazeki* may be summarized as follows:

1. *R. prowazeki* var. *mooseri* after intraperitoneal injection in rats causes a febrile illness, while *R. prowazeki* var. *prowazeki* produces only an inapparent infection. Male rats infected with *R. prowazeki* var. *mooseri* suffer a mild inflammation of the tunica vaginalis with many serosal cells laden with rickettsiae while *R. prowazeki* var. *prowazeki* causes no such reaction.
2. *R. prowazeki* var. *mooseri,* when introduced per anum into *Pediculus humanus,* kills this arthropod in a few days, while *R. prowazeki* var. *prowazeki* requires about three weeks.
3. If injected intraperitoneally in male guinea pigs, *R. prowazeki* var. *mooseri* almost constantly induces an acute inflammation of the scrotal sac with numerous visible organisms, while *R. prowazeki* var. *prowazeki* either fails to cause such a reaction at all or produces it irregularly and in a milder, more transient form.
4. Zinsser's studies with Castañeda brought out certain minor immunologic differences between the two varieties.
5. The most important of all distinguishing features from a practical point of view is the fact that *R. prowazeki* var. *prowazeki* multiplies much less luxuriantly, not only in living experimental animals with resistance reduced by various methods, but also in the various media containing living or surviving cells.

Agglutination Reactions.—There is no true biologic relationship between rickettsiae and *Proteus vulgaris.* Castañeda[10] believes that the production of agglutination of *Proteus vulgaris* by rickettsial sera depends on the possession of a common carbohydrate antigen by the two organisms. In typhus, agglutination is usually found in relatively high titer with the OX19 strain of *P. vulgaris,* and in low titer with the OX2 strain. This enables one to differentiate typhus from tsutsugamushi disease, since in the latter the agglutination titer is characteristically high with OXK. In spotted fever, agglutination occurs with OX19 *or* OX2. Complement fixation is the preferred method.

Diagnostic Methods.—

The complement fixation test gives excellent results. Intraperitoneal injection of 5 c.c. of the patient's blood into each of two guinea pigs during the first few days of illness will result in a febrile disease with involvement of the scrotum or scrotal sac. This is a diagnostic test of typhus or spotted fever. After sacrificing the pigs and making smears from the scrotal sac, a presumptive diagnosis can usually be made, since in typhus we find cells packed with rickettsiae, while in spotted fever the organisms are fewer and larger, and tend to have the characteristic lanceolate form. The nature of the infection can further be proved by carrying out cross-immunity tests with known strains of typhus and spotted fever rickettsiae.

---

[10] J. Exper. Med. 62: 289, 1935.

Diagnosis can be made also by cross-protection tests with the patient's serum.

Dermacentroxenus Rickettsi (Spotted Fever Group).—*Dermacentroxenus rickettsi* is the etiologic cause of a number of diseases of the spotted fever group. Wolbach[11] assigned it to a different genus although it resembles in many respects *Rickettsia prowazeki.* Originally it was thought that the disease was localized to the general region of the Rocky Mountains and so it was called Rocky Mountain spotted fever. It has since been found that diseases similar to this are found in all parts of the world. Ricketts[12] and King[13] independently announced in 1906 the transmission of spotted fever to guinea pigs by ticks. Ricketts noted the occurrence of large numbers of organisms in the ova of ticks, and showed that these organisms were agglutinated by immune serum from human beings and guinea pigs. He described the organism in blood films from guinea pigs and man. Wolbach[11] named the etiological agent *Dermacentroxenus rickettsi* and differentiated between this organism and nonpathogenic organisms in ticks. He was the first to demonstrate the intranuclear multiplication of the organism in tick tissues. The etiological relationship was further confirmed by cultivation in tissue culture. Spencer and Parker[14] demonstrated that the "virus" of this disease could exist in ticks in an inactive form but it seems probable, according to Pinkerton, that rickettsiae in noninfective ticks are the nonpathogenic rickettsiae which are often found in ticks and which resemble *D. rickettsi* morphologically. These nonpathogenic rickettsiae are never found within cell nuclei, however, and are believed to be distinct from *D. rickettsi.*

D. rickettsi are about the same size as *R. prowazeki.* Filtration through Berkefeld filters makes the material containing them noninfectious. The **staining characteristics** of *D. rickettsi* are similar to those of *R. prowazeki.* The Giemsa method gives excellent results. A modification of the Macchiavello method was found in Pinkerton's laboratory to be unsatisfactory for staining spotted fever rickettsiae. There are two modifications of the Macchiavello method that stain *D. rickettsi* very sharply and deeply in sections of the guinea pig testicle. By the following modification, the organisms stain deep red and are clearly distinguishable, even though the surrounding tissue is also partly red.

Staining Methods

Staining methods for Rickettsiae are described in full on page 1413.

A good additional routine is:

Fix tissues in Regaud's fluid S-45, cut thin paraffin sections and run through xylol and graded alcohols to distilled water in the usual way.

Stain in 1% aqueous methylene blue overnight.

Decolorize in 95% alcohol.

---

[11] J. Med. Research 41: 1, 1919.

[12] J. A. M. A. 47: 358, 1906.

[13] Pub. Health Rep. 21: 863, 1906.

[14] U. S. P. H. S., Hyg. Lab. Bull. No. 154, 1930.

Counterstain in 0.25% aqueous basic fuchsin for 30 minutes.
Decolorize rapidly (about 3 seconds) in 0.5% citric acid.
Differentiate rapidly in absolute alcohol.
Clear in xylol and mount in gum dammar.

The second modification stains the rickettsiae deep blue against a background which is partly red and partly blue:

Procedures are the same as above, through decolorizing in 0.5 per cent citric acid.
Wash lightly in distilled water.
Counterstain again in 1% aqueous methylene blue for 5 seconds.
Differentiate in 95% alcohol.
Dehydrate in absolute alcohol and clear in xylol. Mount in gum dammar.

The essential lesion of spotted fever is a specific endangiitis. Focal brain lesions have been found in spotted fever guinea pigs which do not die in the earlier stages of the disease. Monkeys, rabbits, and guinea pigs are susceptible to spotted fever; the pathologic picture in these animals is the same as in man. Dogs are susceptible to infection with fièvre boutonneuse.

The diseases recognized as belonging to the spotted fever group are as follows: 1. Rocky Mountain spotted fever; 2. Eastern spotted fever; 3. Fièvre boutonneuse; 4. São Paulo typhus; and 5. South African tick-bite fever.

Either Proteus OX19 or Proteus OX2 is agglutinated.

The results of complement fixation tests are excellent, but cross reactions with rickettsialpox are the rule.

Rickettsia Tsutsugamushi.*—This is a rickettsial disease due to the *Rickettsia tsutsugamushi.* It was transmitted by Ishiwara and Ogath[15] to the rabbit by intratesticular inoculation. *R. tsutsugamushi* is similar in its morphology to *R. prowazeki* and *D. rickettsi.* It is a short diplobacillus with bipolar staining. It is shorter and plumper than typhus and spotted fever rickettsiae. Ogata and Unno[16] showed short chains. It stains like the other rickettsiae but shows bipolar staining more prominently.

In cultivation work, it grows more freely in the cytoplasm of the interstitial cells of the rabbit testis and the endothelial cells overlying Descemet's membrane than the other organisms in this class. The lesion is essentially that of an endangiitis, with ascites in infected guinea pigs; rickettsiae are found in cells of the ascitic fluid. Rodents are the reservoir.

The Weil-Felix reaction is characterized by agglutination of *Proteus vulgaris* OXK in high serum titer. Complement fixation is not used because no antigen is available.

Rickettsia Wolhynica (Trench Fever).—The body louse was found to transmit trench fever in man during the world war of 1914-1918. It can be transmitted to human volunteers by rubbing the feces of infected lice into the scarified skin and also by allowing infected lice to feed on the volunteers. The evidence of the etiological relationship of this organism to trench fever has not been completely described. There has been an utter failure in inducing infection in experimental animals.

---

*Scrub typhus; Japanese river fever.

[15] Tokyo Ijishinshi, No. 2581: 1555, 1928.

[16] Mitt. med. Ges. Chiba 7: 1929.

R. wolhynica is more deeply stained in film preparations than the more characteristic rickettsiae. The organisms are also somewhat plumper, more definitely oval, and less pleomorphic than typhus rickettsiae.

Coxiella Burnetii (Diaporica). (Q Fever).—Burnet and Freeman[17] described a rickettsia-like organism in smears from the spleens of infected mice, in studying an epidemic among individuals working in abattoirs or on dairy farms in Australia. It was called *Rickettsia burnetii* by Derrick.[18] It was found to be pathogenic for guinea pigs. This organism was also called *Rickettsia diaporica.* The relationship of *C. burnetii* and *C. diaporica* to Q fever in Australia and in the United States has been established by guinea pig inoculation and serologic tests.

This organism is filtrable, hence the name "diaporica." Morphologically the rickettsiae of Q fever are similar to those of spotted fever and typhus, but appear somewhat larger because they stain more deeply. They grow in various media containing living cells commonly used for the growth of rickettsiae and filtrable viruses.

The essential pathologic findings in man are pulmonary edema and congestion. It is an atypical pneumonia. Similar pathologic changes were seen in the lungs of experimentally infected monkeys. Guinea pigs have been successfully infected by the inoculation of human blood or urine.

Proteus OX19, OX2, and OXK are not agglutinated by the serum of the patient, but complement fixation is of great value.

North Queensland tick fever gives a positive agglutination test with Proteus OX2. Complement fixing antibodies appear and are specific. The animal reservoir is unknown.

Rickettsialpox is a mite-borne tenement disease, carried by mites to man from mouse. It is caused by *Rickettsia akari.* Protei are not agglutinated by the serum of the patient, but complement fixing antibodies cross-reacting with Rocky Mountain spotted fever are present.

Weil-Felix Reaction

There is an agglutination reaction, known as the Weil-Felix reaction, performed on the serum of typhus patients, which is considered diagnostic of typhus. This reaction takes place between the patient's serum agglutinins and certain varieties of Proteus organisms, which though isolated from typhus cases are presumably not the cause of the disease. These organisms include the *Proteus X* strains of Weil and Felix. These organisms are nonmotile, produce indol, and acid and gas from glucose, maltose, and saccharose, but not from lactose or mannitol. They digest gelatin and blood serum somewhat more slowly than typical cultures of *Proteus vulgaris.* The reaction appears during the first week of the disease but becomes quite marked in the second week and during convalescence. In nonvaccinated individuals, a titer of 1:160 or higher is significant.

Technic.—

The *Proteus X* cultures are grown on agar slants, pH 7.4, then thinly inoculated on the dry surface of agar in Petri plates, and incubated for 24 hours at 37° C. From these plates smooth, nonspreading "O" type colonies are transferred to tubes of broth and slanted agar. If at the end of 24 hours' incubation the cultures are nonmotile, they are used in preparation of the antigen O. The living organisms are suspended in physiologic salt solution until a standard degree of turbidity is produced corresponding to tube No. 3 of the McFarland nephelometer.

---

[17] M. J. Australia 2: 299, 1937.

[18] M. J. Australia 1: 14, 1939.

A macroscopic agglutination test is now carried out.* Take 2 to 5 c.c. of the patient's blood by venous puncture and separate the serum from the clot.

Arrange 6 small test tubes in a rack.

In the first tube place 2.3 c.c. of 0.85% saline and 1 c.c. in all the remaining tubes.

Next, to tube No. 1 add 0.2 c.c. of serum.

Mix, transfer 1 c.c. to tube No. 2 and discard 0.5 c.c.

Mix the contents of tube No. 2 and transfer 1 c.c. to tube No. 3.

Continue this until the last tube, from which 1 c.c. is discarded.

TABLE 166

NAME OF DISEASE	LOCALITY	VECTOR	AGGLUTINATION WITH PROTEUS X TYPES			COMPLEMENT FIXATION TEST
			OX19	OX2	OXK	
Epidemic typhus	Old and New Worlds	Lice	xxx	x or –	–	Used
Endemic typhus	Old and New Worlds	Rat fleas and lice	xxx	x or –	–	Used
Brill's disease (recrudescence)	Europe, U.S.A.		x	–	–	Used
Tsutsugamushi (scrub typhus)	Far East	Mites	–	–	xxx	
Rocky Mountain spotted fever	U.S.A.	Ticks	xxx or –	– or xxx	–	Used; cross-reaction with rickettsialpox
Fièvre boutonneuse	Mediterranean	Ticks	x	x	–	?
South African tick-bite fever	South Africa	Ticks	x	x	x	?
North Queensland tick typhus	Australia	Ticks	–	xxx	–	Used
Q fever	Old and New Worlds	Varies	0	0	0	Used
Rickettsialpox	U.S.A.	Mites	0	0	0	Used; cross-reaction with Rocky Mountain spotted fever

xxx—Main agglutination. x—Group agglutination. ?—Not tested adequately.

To all tubes add 1 c.c. of antigen and shake well. The final dilutions of serum will now be 1:25, 1:50, 1:100, 1:400, and 1:800.

Incubate the tubes at 50° to 55° C. for 2 hours and place in the refrigerator overnight. Read only 2+ or stronger agglutinations.

Controls should be carried out using a known positive human or rabbit immune serum; also tests employing a known normal human serum.

The agglutination titer of sera from typhus cases may vary from 1 to 50 to 1 to 50,000 while the titer of normal sera is rarely higher than 1 to 25 or 1 to 50. Agglutination with low titers may be of diagnostic significance if found early in the disease, especially if they follow a negative reaction.

Rapid slide tests are described on page 1529.

---

*See p. 1529 for the febrile antigens—rapid macroscopic agglutination tests.

Gintcheff Slide Agglutination Test.—

The Gintcheff method uses dried blood collected on a slide. For Gintcheff's method, prepare a suspension of Proteus OX19 in 1.5% sodium citrate. Filter the suspension through a few layers of gauze and heat it for 30 minutes at 80° C. on a water bath.

To each 100 c.c. of the suspension, add 0.2 c.c. of Formalin and 0.5 c.c. of a saturated solution of malachite green *or* of a saturated alcoholic solution of fuchsin. Filter the mixture again.

Add one drop of the suspension to a drop of dried blood on a slide and mix. Formation of small flakes is equivalent to a 1:50 positive reaction in the tube test, while large flakes indicate a reaction corresponding to a positive reaction of a 1:400 dilution or higher in the tube method.

Cross Agglutination Reaction Between Brucella and Proteus.—Observations have been made with cross agglutination in patients suffering from tularemia or brucellosis, but such reactions had not been noted until Calder[1] called attention to this phenomenon between Brucella and Proteus. He found significantly high agglutinin titers for Proteus in chronically febrile patients who gave no clinical story or physical signs suggesting the possibility of typhus or Rocky Mountain spotted fever. A detailed study was made by the Brucellosis Laboratory of the Clayton Foundation for Research, at Houston, Texas, using six organisms as follows: *Brucella abortus; Brucella melitensis; Pasteurella tularensis; Proteus OX19,* from the National Institutes of Health; *Proteus OX19,* obtained from the laboratories of the Texas State Department of Health; and *Proteus HX19* strain, prepared by treating a motile strain with 0.4 per cent Formalin. The macroscopic method was used. Preparations were read against a strong light in a darkened room after two hours' incubation at 37° C., 22 hours in a refrigerator, and 24 hours at room temperature.

As a result of their work, it was found that agglutinins for *Pasteurella tularensis* were encountered very seldom, and when present, the titer was usually low. Chronically ill patients, therefore, are not likely to show tularensis agglutinins, which would lead to erroneous diagnoses. On the other hand, agglutinins for Proteus were frequently noted in these ill persons. The titers were at times high enough to be interpreted as positive Weil-Felix reactions. The explanation appears to be that there is an antigenic relationship between Brucella and Proteus, probably due to certain components shared by the respective somatic antigens.

The following warning, therefore, must be issued in doing laboratory work on chronically ill persons—a high Proteus agglutination must be very carefully studied before it is taken as an indication in a chronically ill patient as a truly positive Weil-Felix reaction. On the contrary, a very high titer showing Proteus agglutinins exceeding the Brucella agglutinins in brucellosis should arouse the suspicion that the patient is suffering from brucellosis and not from typhus or Rocky Mountain spotted fever.

Practically, these reactions should not be confusing if repeated tests are made, for, contrary to the ascending titers seen in typhus, the Proteus agglutinins do not rise in brucellosis with the passage of time.

Diagnosis by Complement Fixation Tests.—(See pages 1742 ff.)

---

[1] J. Bact. **41**: 593, 1941.

ANIMAL TESTS

For the diagnosis of typhus, the test is carried out by inoculating susceptible animals with whole blood or a fresh saline suspension of the macerated insect vector subcutaneously or intraperitoneally. Susceptible animals are guinea pigs, rabbits, and monkeys. At the end of a week and not later than two weeks, in guinea pigs, we note a fever which lasts from three to fourteen days. The virus is found in the blood but is more concentrated in the brain. It can be maintained in a virulent state by passage. Animals recover and are then immune to reinfection. The female shows only fever but the male guinea pig develops characteristic inflammatory and hemorrhagic lesions of the genitals. The virus of endemic typhus causes a marked swelling of the scrotum while that of epidemic typhus causes little or no visible change. Rickettsiae may be found in the tissues, especially in the scrapings from the tunica vaginalis.

Rabbits and monkeys are also susceptible to infection but are more resistant than guinea pigs. They do not show symptoms but give a positive Weil-Felix reaction whereas the blood serum of infected guinea pigs gives a negative reaction.

CULTURE METHOD

The chorio-allantoic membrane is an excellent medium for culturing Rickettsiae and may be used in place of many of the animal tests, if necessary. Egg inoculation is given on pages 1473 and 1745.

Rocky Mountain Spotted Fever.—This disease has been reported from western states, particularly Montana and Idaho. It was first noted in the Snake River Valley of Idaho, about 1893, and in the Bitter Root Valley of Montana.

Diagnosis of Rocky Mountain Spotted Fever by Animal Tests.—Inject 1 c.c. of patient's blood intraperitoneally into male guinea pigs. The animal develops fever. Lesions noted are characterized by erythema and swelling of the scrotum, with appearance of small red macules. Ulceration occurs. Testicles are enlarged and surrounding tissues are edematous. Spleen is enlarged. As noted above, most of the animals give a positive Weil-Felix reaction and a low titer. Monkeys are less susceptible. Complement fixing antibodies appear soon.

Maxcy[1] affirms the usefulness of the rabbit test in the diagnosis of Rocky Mountain spotted fever. Specific agglutination of *Proteus OX19* by the serum of rabbits two or three weeks after inoculation with Old World typhus was reported by Weil and Felix[2] in 1920. Foot[3] had previously shown that rabbits were likewise susceptible to infection with passage virus of the Rocky Mountain spotted fever. Munter[4] had no difficulty in demonstrating agglutinins for *Proteus X19* in the serum of rabbits inoculated with a passage strain of Rocky Mountain spotted fever virus. Maxcy, using strains received originally from A. Felix, repeatedly plated the cultures for purity of the ''O'' or nonmotile variant and absence of ''H,'' or motile, spreading colonies before the final growth on infusion agar in Blake bottles. According to Felix, the purity of the ''O'' phase is a more important consideration than the question of whether living or killed organisms are used as antigens. Rabbits inoculated with blood from Rocky Mountain spotted fever cases develop agglutination for the *Proteus X19*. The method used by Maxcy to carry out the test is to give 3 c.c. of blood intravenously and 3 c.c. intraperitoneally. These rabbits showed, between the 4th and the 9th day of the disease, distinct agglutination with *Proteus X19*.

The procedure, therefore, of proving the diagnosis of Rocky Mountain spotted fever is to inoculate rabbits directly with citrated blood and carry out agglutination tests.

RABIES

Rabies is a very common disease. It is known as rabies, lyssa, tollwut, hundswut, hydrophobia, rage, rabbia, canine madness. It is an acute, fatal, infectious disease, and is found principally in animals of the canine variety, such as dogs, wolves, foxes, hyenas, jackals. Its manifestations denote great irritation of the central nervous system, followed by definite symptoms of paralysis, after a variable period of incubation. There are very few pathologic anatomic findings visible to the naked eye in lower animals and human beings dying with this disease. The disease is commonly communicated from sick animals to man by biting, the saliva supposedly carrying the virus of this disease.

---

[1] J. Infect. Dis. 58: 288, 1936.
[2] Wien. klin. Wchnschr. 33: 423, 1920.
[3] J. Med. Research 39: 495, 1919.
[4] Ztschr. f. Hyg. u. Infektionskr. 109: 124, 1928.

Rabies is due to a virus. Attempts to cultivate the street virus of rabies have been successful as reported by Kanazawa,[1, 2] who used a medium consisting of rabbit embryo brain tissue suspended in Tyrode solution, without serum; by Webster and Clow[3, 4] in a medium consisting of mouse and chick embryo brain tissue suspended in serum Tyrode; and by Schultz and Williams,[5] who confirmed the latter's work. Direct in vitro cultivation of the street virus of rabies was not reported by these investigators. However, Plotz and Reagan[6] report in vitro cultivation of street virus.

The virus is maintained, however, either in animal brains or in developing chick embryos.

In 1903, Negri described characteristic bodies, small round corpuscles which were found in the ganglion cells of the sick animals. He believed these were protozoa and thought that he had found the cause of the disease. It has since been proved that these are not protozoa and therefore are not the causative factors of the disease, although they are present constantly in about 90 per cent of animals and human beings dying with rabies.

Microscopic diagnosis of rabies can therefore be made by finding Negri bodies in the large cells of the cornu ammonis of the brains of animals submitted to the laboratory for examination. The laboratory is sometimes consulted before the dog is actually captured and killed. Our policy, in case of a dog bite, is to observe the dog and look for symptoms of rabies rather than to kill him precipitantly and not find the Negri bodies; in other words, a policy of watchful waiting, of observation of the dog, and noting the presence or absence of suspicious symptoms. The history of the dog should be taken into account in ascertaining the probable diagnosis of rabies. History shows that dogs incubating rabies frequently change their habits. They leave home, wander about, eat foreign bodies, such as pieces of wood, sticks, pieces of iron. When the disease is fully developed, their behavior is very characteristic. They run along snapping and biting at everything that interferes with their progress. There soon develops muscle paralysis, followed by excessive salivation and convulsions. The bark becomes hoarse or disappears, the lower jaw hangs and the tongue may protrude. The hind legs become weak, ataxia develops and the legs no longer support the dog. The entire duration of sickness in the dog before death ensues is from four to seven days, occasionally

[6] Science **95**: 102, 1942.

longer. They are likely to bite man, live stock, trees, fences. This is what is known as "furious rabies." There is another type known as "paralytic rabies" in which the dogs do not bite but simply have the symptoms of difficulty in swallowing. Frequently the owner thinks his dog has a foreign body in his esophagus. Do not put the bare hand into the mouth of a dog with these symptoms in order to remove the supposed foreign body; there is a great possibility of infection from the saliva. If the animal must be killed, it is advisable to tell the person in charge of the investigation for rabies in a dog to be sure when killing the dog not to injure the brain. The dog should preferably be shot through the heart, or other part of the body, not through the head.

One must remember that diseases other than rabies may produce some of the symptoms of rabies infection in dogs, so that the clinical diagnosis in dogs is not always easy. Distemper may produce excessive salivation, convulsions, and leg weakness. "Blacktongue" has been at times confused with rabies. Many other conditions may induce irritability, convulsions, and muscle paralysis in dogs.

In general, the best policy to pursue with a dog suspected to be rabic is to confine him, keep him alive under the eye of an experienced veterinarian, and kill only when the characteristic symptoms seem to indicate beyond reasonable doubt that rabies exists.

Rabies Infection in Man.—It is often ushered in by tingling sensations and soreness, especially in the region of the bite. There follow loss of appetite, restlessness, irritability, and melancholic symptoms. Headache and emaciation follow. The stage of excitement starts abruptly, with general excitement and chorea-like symptoms. Intense spasms set in, with difficult and painful respiration. The onset of convulsions of the pharyngeal muscles gives the disease its name "hydrophobia" which is really not fear of water, but convulsive efforts when the patient attempts to drink or eat. The convulsions which have been seen by this author in patients with rabies were so severe that the patients could hardly be restrained from falling out of bed. Hallucinations of sight and hearing soon begin. Excessive sweating and salivation occur and swallowing becomes impossible. Paralyses begin, often in the muscles adjacent to the site of the bite. The pupils dilate, reflexes disappear, and death occurs, usually in from one to eight days after the first symptoms started.

There has been considerable discussion as to the incubation period of this disease in man: the author has a record of one case, a bite on the face in a boy of fourteen years. In this case, the diagnosis in the biting dog was made immediately after the attack on the boy took place; anti-rabic serum was started, the boy developed symptoms of rabies on the sixth day after the bite. These symptoms were ushered in by a change in the expressions of the eyes—unusual brightness and fixation of the eyes, followed by a rise in temperature, then convulsions and death within forty-eight hours. Diagnosis in the boy was confirmed by autopsy finding of the Negri bodies in the brain and production of rabies in a rabbit after ten days. The author has a record of one patient of an incubation period one and one-half years after receiving a bite. The literature speaks of two years as the longest period of incubation.

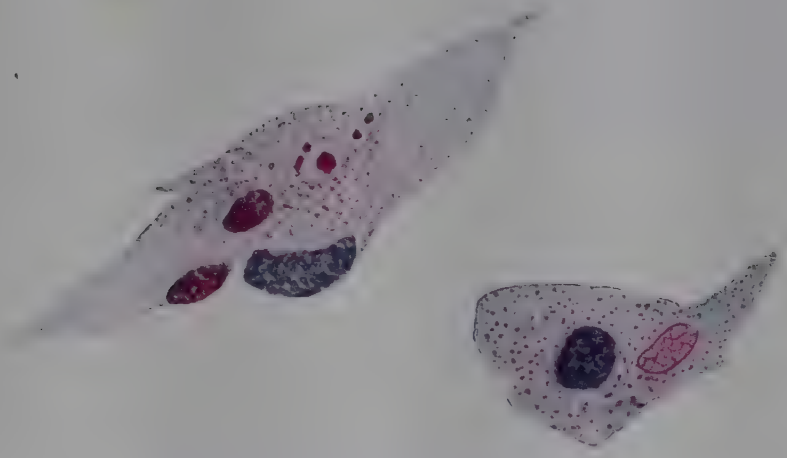

PLATE XLV.—NEGRI BODIES, VAN GIESON STAIN.

Technic of the Test for Negri Bodies

The dog's head is amputated and brought to the laboratory as soon as possible before decomposition sets in. In summer it is advisable to pack the head in ice during transportation. The operator should wear rubber gloves. The head is placed upon a board and the skull cap is removed by sawing. The brain is removed from the skull. An incision is made straight down on one side of the hemisphere into the lateral ventricle. At the posterior part of the floor of the lateral ventricle, an incision is made deep down into the cortex. Here is found a structure known as "Ammon's horn," where Negri bodies are most likely to be found.

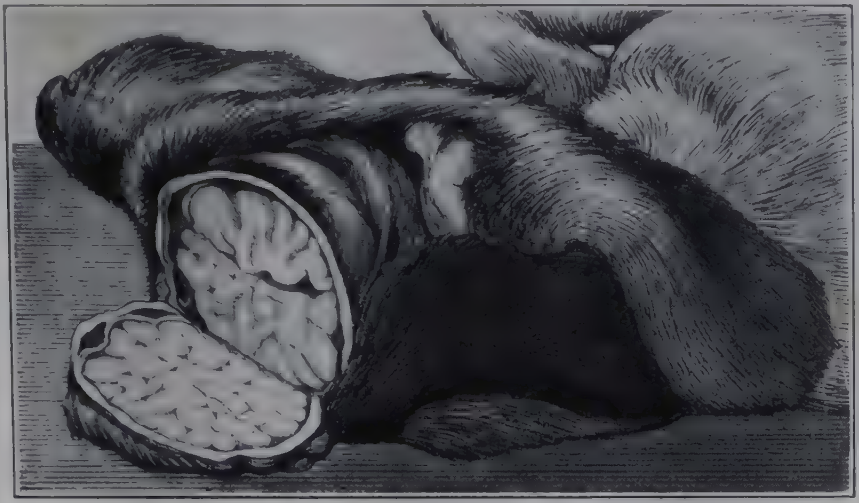

Fig. 406.—Section through dog's head for Negri bodies examination.

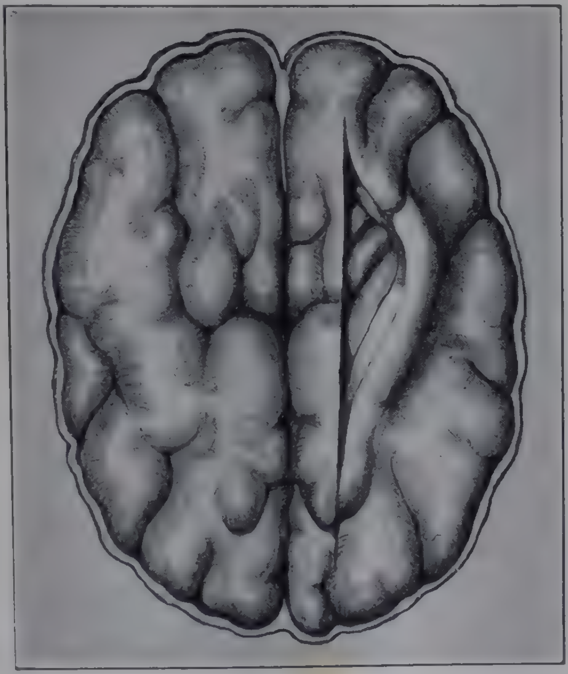

Fig. 407.—Dog's brain, showing method of locating Ammon's horn.

To make an impression preparation, cut out a 1 to 2 mm. cross section from the middle of Ammon's horn and place it on a piece of blotting paper.

Use a clean slide and make several impressions by pressing the slide down on the cut surface of the section.

While still wet, layer over with Seller's stain for 10 seconds.

Rinse with tap water, and allow to dry.

Examine with an oil immersion objective, or mount with a cover slip, using Canada balsam or gum damar.

Another method is to place a small piece of the brain, about a quarter of an inch square, in a Petri dish, using sterile forceps.

Remove a piece of tissue and place on a glass slide.

Superimpose another slide upon it and make smears by pulling the slides against each other in opposite directions. This gives two smears at the same time.

Similar smears should also be taken from the cerebellum and from various parts of the cerebral cortex.

Demonstration of Negri Bodies

Seller's Stain

Stock Solution:

(a) Saturated solution of basic fuchsin in methyl alcohol
(b) Saturated solution of methylene blue in methyl alcohol

Staining Solution:

Stock basic fuchsin	3.5 c.c.
Stock methylene blue	15.0 c.c.
Methyl alcohol	25.0 c.c.

The staining solution may be kept in a dropping bottle. If stored in a refrigerator when not in use, it may be used for several months.

Negri bodies appear mauve to pink-red; the basophilic staining inner bodies are well demonstrated. The cell cytoplasm, nuclei, and nucleoli stain blue. Interstitial tissue and fibrillae stain pink.

If the preparations are from human material, there is little chance of confusing the inclusion bodies of rabies with those which occur in other diseases. In dog brains, however, other inclusion bodies such as those found in canine distemper may be found. These inclusion bodies are pale red and more refractile than those due to rabies and occur more frequently in the thalamus and lentiform nuclei than in the Ammon's horn.

Atypical intracytoplasmic inclusion bodies are sometimes found in the brains of nonrabid mice; these are probably due to a natural virus disease of mice. Such inclusions stain pink to bright red, are refractile, uniformly round, and do not have any inner structure; they show a blue-staining margin.

Description of Negri Bodies

Negri bodies are sharply outlined, round, oval, or somewhat irregular structures of variable size, from 1 to 27 microns in diameter. In dogs the average diameter is from 4 to 10 microns. Negri divides them according to size as follows:

Smaller forms from 1 to 5 microns in diameter.
Medium forms from 10 to 15 microns in diameter.
Large forms, 22 to 23 microns in diameter.
Very large forms, 27 microns.

They consist of a hyaline-like cytoplasm, in which when properly stained, one or more chromatin bodies can usually be seen. They are situated chiefly within the cytoplasm of the large cells of the central nervous system, as already stated. In many cases they suggest red blood cells lying within nerve cells.

Animal Inoculation.—If Negri bodies are found, this is sufficient evidence for the diagnosis of rabies. If they are not found, it is necessary to inoculate animals. The favorite animals in the past have been guinea pigs and rabbits. Since the demonstration that the intracerebral injection of rabies virus into white mice produces a typical and constant infection, the white mouse has become increasingly popular as a test animal.[1] The chief advantages of the mouse are the low cost, making it possible to use several animals for one specimen; the relatively short incubation period, ordinarily six to thirteen days with street virus; and the consistency of production of inclusion bodies in the brains of mice infected by intracerebral injection.

---

[1] William A. Hagan, et al.: Ann. New York Acad. Sc. 48: 373, 378-381, 1947.

A small amount of the hypocampus is rubbed up, with sterile precautions, in a sterile mortar with sterile physiologic saline solution. This is picked up in a sterile 1 c.c. or 2 c.c. syringe, and 0.03 c.c. is injected into the animal, just behind the lateral corner of the eye, with a short bevel 24 gauge needle.

Incubation in guinea pigs is eight to twenty days. Incubation in rabbits is from fourteen to twenty-one days. The onset of the disease in each animal is marked by paralysis of the fore or hind quarters. Diagnosis can be confirmed by finding Negri bodies in the brain of the inoculated animal.

It is to be emphasized that the failure to find Negri bodies is not proof of the nonexistence of rabies. In all cases, the history of the animal, the circumstances of the bite, and, last of all, the inoculation into guinea pigs and rabbits of brain matter from the suspected dog must be carried out. In cases in which the bite has been inflicted and the dog has escaped and there is no way of telling from the examination of material of the dog whether he has or has not rabies, the safest course to pursue is to use the Pasteur antirabic virus as a preventive measure.

The Pasteur Treatment for Rabies

Johnson[1] advises the following **criteria for vaccine treatment.** He states that a number of factors must be considered before advising rabies vaccine treatment for persons bitten or scratched by domestic and wild animals. It should be ascertained whether there has been any rabies reported in the vicinity during the previous year and also whether the animal was apprehended or killed. If the animal was captured, it should be turned over to a veterinarian, who should be consulted as to whether or not there are clinical signs of rabies. Clinically normal animals should be quarantined for 14 days. If the animal subsequently shows clinical signs of rabies, the attending physician should be notified immediately. If the animal is killed or dies while in quarantine, the brain should be examined for Negri bodies and, if negative, animal inoculation should be made.

If the patient has been bitten by a stray dog which has not been apprehended or which was killed immediately, an attempt must be made to ascertain the animal's behavior before biting the patient. An attempt should be made to locate the animal.

Rabies vaccine treatment must be begun immediately when a person has been bitten or scratched under the following circumstances:

1. The animal was apprehended and presented clinical signs of rabies.
2. The animal was killed and the brain found positive for rabies by microscopic examination.
3. The animal was killed, the brain was negative, but the animal was suspected of being rabid.
4. The person was exposed by a stray animal which escaped and where rabies was known to be present in the community.

---

[1] Johnson, Harald N.: Rabies, New York, 1943, The Oxford University Press.

Vaccine treatment is recommended also for persons who have handled animals diagnosed as rabic by clinical or laboratory examinations, or when fresh abrasions of the skin have been contaminated by the saliva of the infected animal.

When an animal is captured after having bitten a person, the animal must not be killed, but should be confined under the supervision of a veterinarian. If the animal is rabid, it will usually die within 2 or 3 days. Since the inclusion bodies of rabies are often absent in the early stages of the disease, it is important that the animal not be killed immediately upon biting.

Even though the animal was apparently normal at the time of biting, treatment should be instituted if the animal later develops clinical signs of rabies while in quarantine. However, if the biting dog remains well for 10 days while held in quarantine, treatment may be discontinued.

When an animal is killed immediately after biting, and the brain is examined and found negative by microscopic examination, a confirmatory mouse inoculation test should be performed.

Johnson advises the following **local treatment** of persons bitten by or exposed to the saliva of rabid animals. It has been shown that infection can be produced readily in animals by rubbing the virus into the scarified skin. Wounds in areas heavily supplied with sensory organs, such as the face and hands, are especially dangerous. Wounds which penetrate the muscle tissue probably are even more serious.

Shaughnessy and Zichis[2] compared the effectiveness of 20 per cent green soap solution, nitric acid, and tincture of iodine for treatment of wounds in experimentally infected guinea pigs, and showed that the green soap solution is as effective as nitric acid cauterization where the treatment is carried out within 2 hours after exposure. Tincture of iodine is less effective.

Harris[3] recommends carbolic acid cauterization instead of nitric acid, as he has found it more effective. The first and most important step in treatment of wounds produced by supposedly rabid animals is cleansing with warm water and soap to remove the saliva and to encourage bleeding before cautery is applied. Deep lacerations can be effectively cleansed with a syringe.

All patients should receive local treatment with carbolic acid. The wound should be sponged dry and the carbolic acid applied with a capillary dropper or wooden applicator, taking care not to miss small or superficial abrasions. The margins of torn skin of larger wounds must receive particular attention. If the wounds are severe, cauterization may be performed under anesthesia. If the lacerations occur on the face, thorough cleansing should be carried out with green soap solution, followed by carbolic acid cauterization of superficial abrasions, puncture wounds, and the margins of the lacerated skin.

Harris' method of local treatment is carried out as follows: The wound should be mechanically cleansed, cauterized with pure carbolic acid, and immediately bathed with 95 per cent alcohol.

The next and most important step is to determine whether or not the biting animal is rabid, for if it is, vaccine treatment must be begun at once.

---

[2] Shaughnessy, H. J., and Zichis, J.: Proc. U. S. Livestock San. Assoc., pp. 1-4, 1941.
[3] Harris, D. L.: Personal communication.

Harris states that any biting animal should be suspected of being rabid until proved otherwise. If the animal cannot be confined and observed, it should be regarded as rabid.

No preparation of antirabies vaccine is invariably effective or entirely free from dangerous sequelae. In rare cases, the injection is followed by a severe and sometimes fatal paralysis. This is probably due to individual sensitiveness to rabbit's brain and cord and is probably not the result of an infection by the vaccine.

Recommendations for the Control of Rabies in the United States

These recommendations are well set forth by Hagan and associates.[1]

Rabies control should be coordinated through some national agency. This control work is strictly a veterinary problem. Hagan recommends that the U. S. Department of Agriculture, Bureau of Animal Industry, be given authority to coordinate and supervise rabies control work. This is not possible under existing Federal legislation. A bill has been introduced in Congress which would include the dog and other domestic carnivores with those domestic animals subject to the supervision of this branch of our government. If this bill is passed a nationwide rabies control program could be developed through each State Department of Agriculture, Live Stock Sanitary Division. At the present time, rabies control work is conducted on a municipal or county basis under the authority of the City or County Board of Health, and the work is maintained only as long as the emergency persists. Hagan states further that rabies control work on a state basis should be under the supervision of a full-time veterinarian. Rabies in animals should be made a reportable disease, new cases to be reported immediately to the veterinarian in charge of rabies control in the State, and weekly, through regular reporting channels, to the U. S. Department of Agriculture, Bureau of Animal Industry. Past experience has shown that the disease is apt to be of epizootic proportions in a given locality, before the State authorities responsible for rabies control are aware of the outbreak. The heads of all domestic and wild animals suspected of having rabies should be submitted for examination, regardless of whether or not there was human exposure to the disease. Rabies existing in a wild life species should be reported to the U. S. Fish and Wild Life Service, as well as to the State Wild Life Department, so that a cooperative control program may be developed.

Taxation and licensing of dogs is further recommended as the most effective means for insuring enforcement of rabies control regulations. The traditional rabies control program is one which requires strict quarantine for all dogs for a period of six months after the last reported case of rabies. Field experience has shown that vaccination of all owned dogs, carried on in conjunction with collecting and impounding of unvaccinated dogs found at large, has brought about the elimination of rabies. This method of rabies control has been used effectively in several foreign countries, as well as in many communities in the United States. Compulsory vaccination of dogs for rabies, on a State-wide basis, has been difficult to enforce. In Alabama, the enforcement of vaccination of dogs for rabies, combined with collection of unvaccinated dogs found on the street, was effective in limiting the disease.

---

[1] Ann. New York Acad. Sc. 48: 373, 378-381, 1947.

Strict quarantine for all dogs should be enforced for a period of at least thirty days, as soon as rabies appears in a community. Then dog owners should be required to have their pets vaccinated or keep them confined until the area is officially certified free of rabies. Vaccinated dogs, properly tagged, may be allowed at large thirty days after vaccination. A course of three weekly injections of vaccine will produce a more certain immunity to rabies. Dogs known to have been exposed to rabies must be destroyed, or kept confined for six months.

Hagan emphasizes that unvaccinated dogs and stray dogs should be picked up promptly throughout the control program. This should be continued for at least ninety days following the last reported case of rabies.

The statistics on rabies for the United States show that domestic cats are infected quite frequently. The bite of a rabid cat is probably more dangerous than that of a dog. Cat owners should have their pets vaccinated by the three-injection method. Stray cats should be impounded and destroyed. If rabies becomes established among wild animals, it is necessary to carry out a program of reduction of the number of the affected species until the disease disappears.

DEMONSTRATION OF INFLUENZA VIRUS IN THROAT WASHINGS

The detection of influenza virus in throat washings is an important method, during epidemics, of determining the causative virus as rapidly as possible. Various methods have been described; for instance, isolation of influenza in ferrets and mice,[1] in hamsters,[2] and in chick embryos by amniotic[3] or allantoic[4] inoculation. Egg inoculation, with subsequent Hirst test, is used in actual practice. Refer to Egg Inoculation.

Technic.—

Inoculate 6 to 24 chick embryos 11 or 12 days of age by the amniotic route with each throat washing filtered through Berkefeld N filters. With most specimens the window method of Burnet[3] is used, but with some the stab method described by Hirst[5] may also be employed. Carry out three to five amniotic passages at intervals of two to five days with each throat washing before the result is considered negative. Virus may be detected in the amniotic or allantoic fluids by agglutination of chicken erythrocytes[6] and may be identified by inhibition tests with known types A and B antisera.

Allantoic inoculations are made with unfiltered throat washings centrifuged for 20 minutes at 4,000 r.p.m. in an angle head and also with duplicate specimens treated with Zephiran*[7] at a dilution of 1:20,000 for 20 to 30 minutes. Detect and identify the virus by the method used for the amniotic passages. Withdraw allantoic fluids from the third to the sixth day after inoculation daily by a needle and syringe from the living embryos and test for agglutinins so that they may be harvested or passed if positive.

---

*Zephiran, manufactured by Alba Pharmaceutical Co., Inc., is a mixture of high molecular alkyl dimethyl benzyl ammonium chlorides.

ETIOLOGICAL AGENT OF INFECTIOUS HEPATITIS

Numerous reports have appeared in the literature describing the occurrence of jaundice in man following the administration of human blood products and indicating that the icterogenic agent or agents of such homologous serum jaundice[1-4] and post-vaccinal jaundice[5-10] are filtrable through a Seitz filter and can withstand heating to 56 to 60° C. for 30-60 minutes. More recently, certain planned experiments,[11, 12, 13] on the transmission of these diseases to human volunteers have corroborated these facts. A most important report on the properties of the icterogenic agent of the naturally occurring disease, infectious hepatitis, appeared in 1945.[14] The agent of this disease is a virus.

As in homologous serum jaundice and post-vaccinal jaundice the icterogenic agent of infectious hepatitis is filtrable and withstands heating to 56° C. for 30 minutes. It also demonstrated that this agent can be transmitted in serial passage in human volunteers.

There is plenty of evidence that during World War II transfusions were the commonest cause of jaundice among military forces.[15] A large amount of plasma was collected during World War II by the American Red Cross for use of the Services. Necessarily, in this large amount of plasma, undoubtedly some bloods were taken from recovered cases of hepatitis. Even when diluted with the pool with which this plasma was placed, there was sufficient substance present to cause trouble. A tremendous amount of this plasma was left after the war and is being distributed to the hospitals. The problem of whether or not this plasma will induce infectious hepatitis is serious enough to be considered. The danger is proportional to the number of donors who supply plasma. It has been proved that the virus of this disease may be present in the blood for as long as 60 days prior to the onset of jaundice.[16] In view of this fact, blood banks must adopt some procedure for the observation of donors over a period of time both prior and subsequent to their actual use. This will unquestionably reduce introduction of contaminated bloods into the pool. The use of human immune gamma globulin has been suggested as an agent to be added to pooled plasma prior to its use. It might be administered prophylactically early in the incubation period to all persons who have received plasma.[15]

It is generally believed that, from a laboratory standpoint, the differentiation of viral hepatitis from obstructive jaundice can be made by two tests.

The cephalin flocculation test is generally increased in viral hepatitis and the alkaline phosphatase test tends to remain normal in this condition.

Patients in the hospitals are exposed to hepatitis through the use of nonsterile or poorly cleansed syringes, needles, or surgical instruments, and through the injection of blood or blood products, such as plasma, which may contain the virus of hepatitis. This type of hepatitis is distinct from epidemic hepatitis. The incidence of serum hepatitis following the use of pooled plasma is high. The risk is greater whenever a large number of donors are used in the pool. The danger of hepatitis following the use of blood alone is rather slight. Acceptable figures indicate that serum hepatitis develops in 2.5 to 7.3 per cent of the recipients of pooled plasma, while less than 1 per cent develop this disease following use of blood transfusions alone. Plasma has been irradiated with ultraviolet light in an attempt to inactivate the virus of hepatitis.

Sborov, Giges, and Mann[1] reported on the incidence of hepatitis in a large number of recipients of pooled plasma in three army hospitals. They found in a study of 587 wounded soldiers that 21.9 per cent of those who received both plasma and blood developed hepatitis. Their study also indicated that, following the use of plasma irradiated with ultraviolet light, the incidence of hepatitis was no different from that following the use of nonirradiated plasma. The mean incubation period of hepatitis was about 90 days, thus indicating that the hepatitis indeed represented the serum type.

Pooled human plasma in a stockpile for use by civilian physicians in hospitals carries with it the risk of hepatitis. Furthermore, even those batches of pooled plasma which are irradiated with ultraviolet light are just as likely to cause hepatitis as the nonirradiated variety.

LYMPHOGRANULOMA VENEREUM*

Lymphogranuloma venereum has also been known as "climatic bubo," the sixth venereal disease, Nicolas-Favrè disease, subacute inguinal lymphogranulomatosis, lymphogranuloma inguinale, and by many other names. It is a generalized disease acquired, like syphilis, usually by sexual contact. It is principally genitorectal, with preference for lymphatic and nervous tissues, with possible invasion of other organs.

It is caused by a virus which is filtrable through Chamberlain 13 and Berkefeld V filters. Dimensions vary from a fraction of a micron to 4 to 6 microns, exceptionally even larger forms being found.

It has not been cultivated on routine laboratory media but has been transmitted to animals.

Rake, McKee, and Shaffer[2] noted similarities and differences between infectious agents of the "lymphogranuloma-psittacosis" group, which includes agents of lymphogranuloma venereum, trachoma, inclusion conjunctivitis or blennorrhea, psittacosis, and human atypical pneumonia (virus pneumonia), acute meningopneumonitis, and rat pneumonitis.

*After Soto Rozas in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, St. Louis, 1948, The C. V. Mosby Co.

[1] Arch. Int. Med., Nov., 1953.

[2] Proc. Soc. Exper. Biol. & Med. 43: 332, 1940.

The agent is susceptible to the action of sulfa drugs. It can be preserved in mouse brain tissue or in chick embryo in the frozen state. It resists desiccation, pure glycerin, and freezing under vacuum, but does not resist ultraviolet light, 0.1 per cent Formalin, 2 per cent urea, 50 per cent glycerin, or ether.

The Frei test has been used successfully in making this diagnosis.

The Frei Reaction

This is a method of making the diagnosis of this disease by the use of an antigen prepared from the pus withdrawn by aspiration from the bubo. It was published by Frei[1] in 1925. The value and specificity of the test have been demonstrated by Frei in subsequent papers[2] in 1927 and 1932, and have been confirmed by Frei and Hoffmann[3] in 1927, and by a number of other workers.

Frei's directions for the preparation of this antigen are as follows: The person from whom the antigen is to be made should be proved free from tuberculosis and venereal diseases by clinical examination and negative tests for syphilis, gonorrhea, and soft chancre. The pus must be withdrawn from a gland that has undergone softening but not fistulation. Aspirate by means of syringe and thick needle, under sterile precautions, obtaining as far as possible, blood-free pus. This pus is mixed with physiological saline in the proportion of 1 part of pus to 5 parts of saline in a sterile tube, and immediately put up in 0.5 to 1 c.c. doses in hard-glass ampules. It is heated to 60° C. for two hours over a water-bath, and the following day at 60° C. for one hour. This material is tested for sterility by culture under aerobic and anaerobic conditions at room and incubator temperatures. This antigen should give a negative reaction in the skin of normal individuals. The antigen should be preserved at a low temperature and unexposed to light. If an ampule is opened, the remaining contents should be thrown away or resterilized.

Method of carrying out the test: Disinfect the skin with alcohol. Use the skin of the outer forearm. Inject intracutaneously 0.1 c.c. antigen. A corresponding area on the other side of the body should be injected with the same amount of normal saline. It is well to inject two normal controls with the same antigen and the same saline in the same way and at the same time. Read the result after forty-eight hours, and not before. A positive reaction consists in the production of an infiltrated inflammatory dome-shaped area one-half cm. in diameter at least, and often larger, which can be felt as well as seen. It is often noted that there is a small area of necrosis in the center surrounded by a red zone.

Antigens usually remain active for several months, sometimes for a year, but not always.

The Vesicular Test for Lymphogranuloma Venereum (Inguinale)

Owing to the difficulty of obtaining material at times for the making of the original Frei antigen, Ottolina[4] has suggested the use of concentrated spinal fluid from a known case, using this material for skin inoculation. This is based upon the fact that in experimental infections of this disease, the cerebromedullar axis is prevailingly affected. Spinal fluid, therefore, constitutes a human antigen, easy to obtain, aseptic, and with a small amount of albumin.

The method described by Ottolina is to perform a spinal puncture under aseptic conditions and carry out a vacuum concentration of the fluid. By reducing 10 c.c. of fluid to 1.5 c.c., a colloidal-like solution is obtained which is opalescent and foams upon agitation.

[1] Klin. Wchnschr. 4: 2148, 1925.

[2] Klin. Wchnschr. 6: 2042, 1927; Klin. Wchnschr. 11: 512, 1932; Dermat. Wchnschr. 95: 1576, 1932.

[3] Arch. f. Dermat. u. Syph. 153: 179, 1927.

[4] Am. J. Trop. Med. 21: 597, 1941.

If this concentrated fluid is injected intradermally a vesicle appears twenty-four hours later at the point of injection; this phenomenon has been called the "vesicular test." The vesicle may be ovoid, circular, or triangular but there is a definite trend toward the hemispheric form. The ovoid type measures 4 mm. in length, 2 mm. in width, and 1 mm. in height while the more rounded forms approach approximately 3 mm. by 2 mm. by 1. The color of the skin covering the blister is light or dark brown, sometimes dark gray. The blistered skin always has a darker shade than the surrounding skin.

Twenty-four hours after the injection the blister preserves the same morphology, the fluid within showing a light tension. Forty-eight hours later a certain umbilication may be noted, the fluid tension has relaxed, and the blister skin is more colored than on the first day. Three days later there is a distinct flaccidity in the blister and desiccation begins at that time and ends in between four and five days. Five or six days after its appearance the blister is only a pigmented spot about 2 mm. in diameter. The vesicular fluid has a light brown color and microscopically shows a few polynuclear neutrophilic and mononuclear leukocytes. This fluid is sterile.

Technic is to concentrate fluid employed from 10 c.c. to 2 c.c. and inject intradermally 0.3 c.c.

It is interesting to note, according to Ottolina's researches, that this test, when applied to the positive patient from whom it was obtained, produced a typical positive reaction. In other words, it is an autoreaction, which emphasizes its diagnostic value.

Mouse Brain Antigen for the Frei Reaction

Grace and Suskind

Hellerström[1] has shown that antigens made from the brains of monkeys infected through subdural injection give the same specific Frei reaction when used on human beings as when the human antigen is used. Working along this line, Grace and Suskind[2] developed a mouse brain antigen which is more highly potent than that made directly from the same human material used in the preparation of the brain antigen. This antigen is a 10% emulsion of infected mouse brain; for each test 0.1 c.c. is injected intradermally, using a 1 c.c. tuberculin type of syringe with a 27 gauge needle.* If positive, the raised papular reaction is noted in from forty-eight to seventy-two hours. If negative, no reaction occurs; if one uses an injection of a similar emulsion of normal mouse brain as a control, no reaction appears.

Chick Embryo Antigen for the Frei Reaction

The three sources of antigen for the Frei test just described are: (a) pus from the inguinal bubo of the patient, (b) macerated material from diseased glands, and (c) emulsions of the brains of mice intracerebrally infected with virus. Since antigens prepared from human pus are not readily available, and since considerable doubt has been expressed as to the reliability of the mouse brain antigen, a successful method of producing antigen has been evolved by propagating the virus of lymphogranuloma venereum on the chorio-allantois of developing chicks. This has been successfully carried out by Rake, McKee, and Shaffer[3] working in the Squibb Institute of Medical Research. These workers developed a method for obtaining a highly potent and purified antigen for this test. The virus was inoculated into the yolk-sac of 5- or 6-day-old fertile eggs, as demonstrated by Fig. 408.†

By suitable methods of purification a virus was obtained which, when undiluted, was about one million times more potent than the lymphogranuloma virus obtained from mouse brain. Not only did the yolk-sac method yield a more potent virus than the other methods but, also, by a process of differential centrifugation, a practically pure suspension of the virus could be obtained. In other words, the extraneous inert material from the yolk-sac can be almost completely eliminated.

---

*The Lederle Laboratories have put this on the market in syringes ready for use. They furnish it in 1 c.c. syringes for one dose and in 10 c.c. syringes for ten doses. There is an expiration date on these packages.

†Furnished by permission of E. R. Squibb & Sons.

[1] Acta dermat. venereol., supp. 1, pp. 5-244, 1929.

[2] Proc. Soc. Exper. Biol. & Med. 32: 71, 1934.

[3] Proc. Soc. Exper. Biol. & Med. 43: 332, 1940.

In a very interesting trial of this material, Sulkin, Fletcher, Huber, and Reh* reported forty-two patients with active lymphogranulomatous infection or with a history of past infection, who were tested with the various antigens. They made a series of intradermal injections on the arm, the proximal injection being made with human Frei antigen, two middle injections with egg and mouse brain antigens and two distal injections with the corresponding controls. Reactions were read within forty-eight to ninety-six hours. Of the forty-two patients tested, forty gave a positive, one a doubtful and one a negative reaction to yolk sac antigen; thirty-four gave a positive, five a doubtful, and three a negative reaction to mouse brain antigen; and thirty-eight gave positive, one a doubtful, and three negative reaction to human pus antigen. Thirty-three persons had positive reactions with all three antigens.

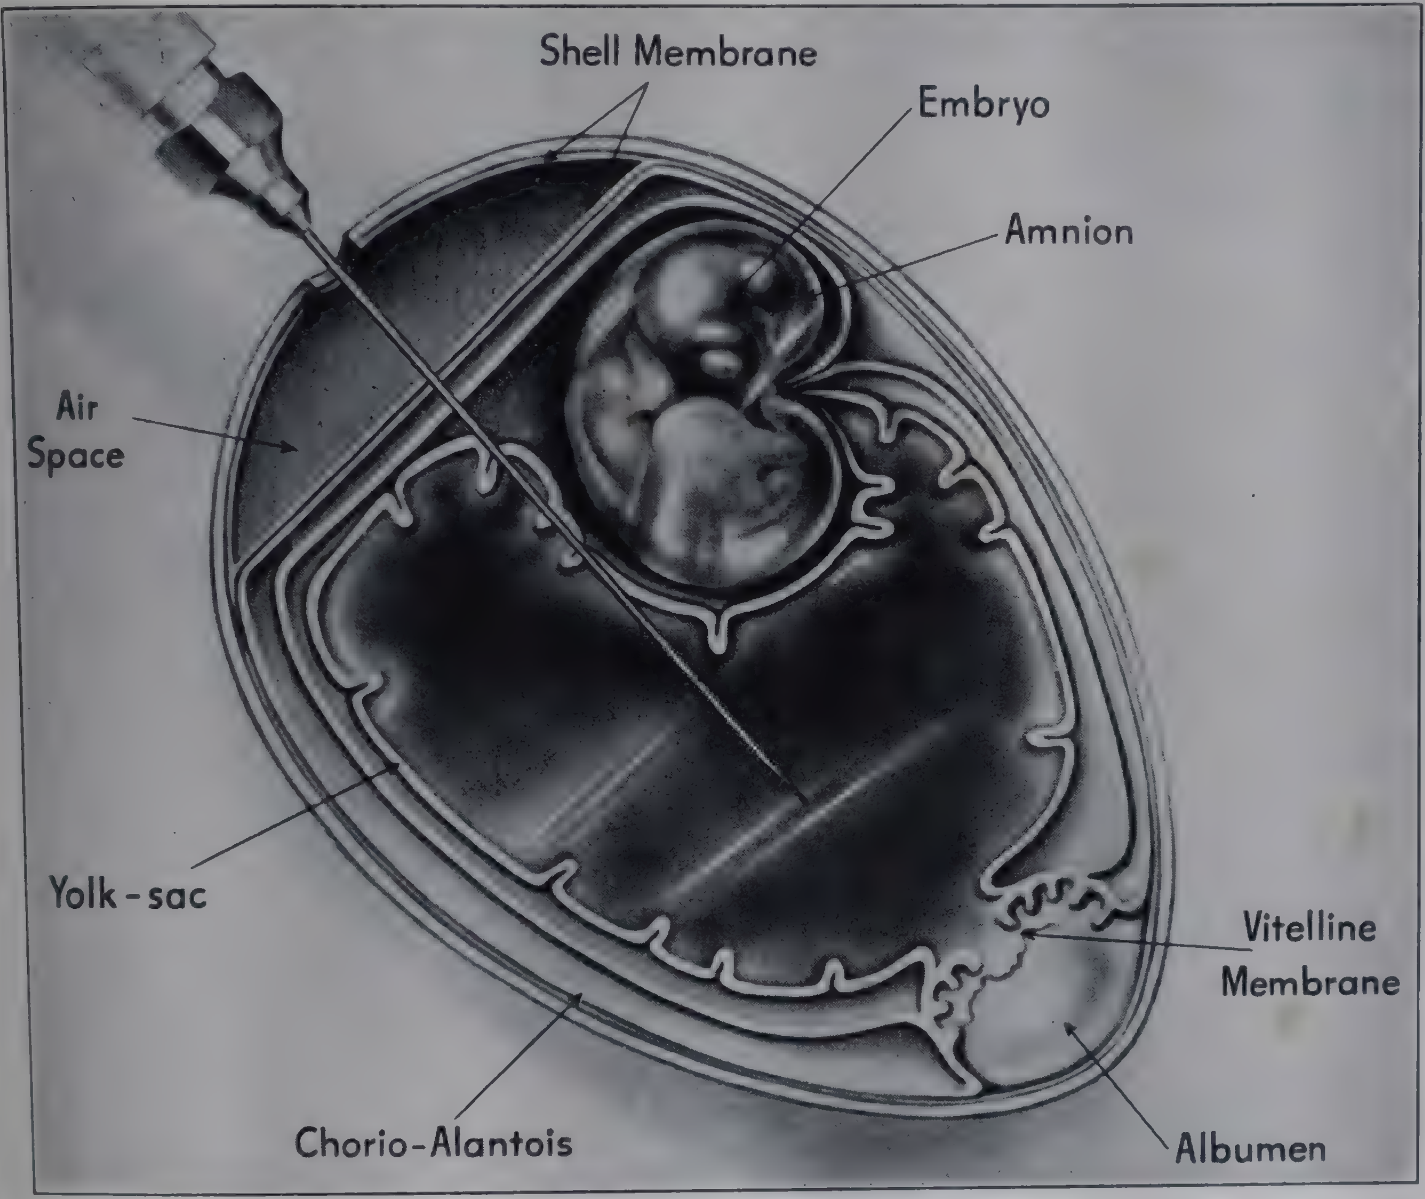

Fig. 468.—Method of injecting the yolk-sac of a developing chick. (Courtesy E. R. Squibb & Sons.)

As these writers point out, any foreign substance when injected intradermally into a human subject will produce an inflammatory response at the site of inoculation and the severity of the reaction will be influenced by any hypersensitivity to the material in the person inoculated. These facts, of course, must be considered in determining the cutaneous response to any Frei antigen. The conclusions of these workers, however, were that the yolk sac antigen is superior to mouse brain antigen for performance of the Frei cutaneous

---

*J. A. M. A. **116**: 2663, 1941.

test for lymphogranuloma venereum and that comparatively few nonspecific reactions are produced with the egg control material as compared with the mouse brain control. This antigen is made by Squibb and Lederle, respectively.

Technic of the Test.—Inject 0.1 c.c. of Frei antigen of chick embryo origin intradermally into the flexor surface of the arm. Read reaction within 48 or 72 hours. In order to eliminate false positives due to chick protein sensitivity, a control is supplied by the manufacturer for each test. This consists of normal chick embryo protein prepared in a manner similar to that of the antigen. A positive test is seen by the appearance of a reddish papule 6 mm. or more in diameter, surrounded by a fainter erythematous area of varying size. This papule must be measured with a millimeter scale. The extent and intensity of the erythematous area around the papule is of no diagnostic significance. Strongly positive reactions may have a papule surmounted by a vesicle, or pustule which may break down and form a crust. The reaction will gradually regress, ending as a faintly pigmented area with or without a scar.

The intradermal Frei test is positive only at the peak of the allergic period, when specific antibodies have been formed in the infected organism. This usually becomes positive about 2 weeks after inoculation, sometimes later. It may be negative during the menstrual period and in the not-so-rare cases of florid syphilis if the two diseases coexist.

Interpretation of results should be made from the fourth day. The reaction appears in 24 to 48 hours, reaching a maximum in 3 days, after which it gradually decreases in intensity. A positive reaction consists of a papule, vesicle, or pustule with a diameter larger than 6 mm. It is more intense in inguinal than in rectal cases. The reaction persists for several weeks. Saline control injection should always be made. Nonspecific reactions have a diameter of less than 6 mm. and decrease after three days.

Most of the American workers agree that the chick embryo antigen, Lygranum, is superior to all others for use in the Frei test.

The sole disadvantage of this test is its delayed appearance. Ravaut, Levaditi, and Maisler[1] proposed a hemo-reaction for early diagnosis. Their antigen is injected intravenously, producing a rise of temperature to 102° to 104° F. in 12 to 18 hours which remains for 24 to 48 hours and is accompanied by general malaise, chills, headache, insomnia, weakness, arterial hypotension, and leukopenia. The test has the disadvantage that it can be used only once. It is positive in 97 per cent of the cases.

The complement fixation test may give false positive results, especially in diseases caused by viruses belonging to the same group.

The presence of Miyagawa corpuscles in infected tissues as seen in secretions is considered diagnostic of the disease. These corpuscles can be demonstrated with certain stains: eosin and methylene blue, Macchiavello, Giemsa, Noble.

The blood picture shows leukocytosis, oligocytosis, neutrophilia, lymphopenia, monocytopenia.

The Intradermal Chancroid Test

In connection with the foregoing remarks on lymphogranuloma venereum, it must be remembered that every case of venereal disease requires exhaustive laboratory tests to prove the true diagnosis. It has been found that many cases of chancroid infection have been thought to be lymphogranuloma venereum, but a negative Frei test has caused some doubt concerning this diagnosis. Greenblatt and Sanderson[1] have called attention to a very valuable method of including or excluding chancroid infection in a diagnostic survey of these venereal cases. They have originated an intradermal test for chancroid infection using an antigen made from a saline suspension of the Ducrey bacillus. Their method for growing the Ducrey bacillus is as follows:

---

[1] Bull. Soc. franç dermat. et syph. 7: 1262, 1932.

Greenblatt and Sanderson Method of Cultivating Hemophilus Ducreyi

To tubes of beef infusion agar in slants is added 1 c.c. of defibrinated human blood. The blood is inoculated with 0.1 c.c. from an actively growing culture and placed under partial oxygen tension. To obtain this environment, the cotton plug is cut off short and pushed slightly into the tube; the upper portion of the tube is heated, but not too much, in a Bunsen flame, and the tube is sealed by inserting a tightly fitting rubber stopper. The culture is incubated for from two to three days at 37° C. During this period good growth takes place in the fluid blood, and a lesser growth appears on the surface of the slant. After the incubation, the blood, as well as the surface growth, if any, is removed with a sterile pipette and added to approximately 25 c.c. of sterile distilled water in a sterile centrifuge tube of sufficient volume, and the contents are sedimented by high speed centrifugation. The supernatant fluid is removed aseptically and discarded, and the process is repeated. Two such treatments suffice to remove most of the hemoglobin. The sediment of bacilli and red cell debris are suspended in sterile physiologic solution of sodium chloride, 10 c.c. per slant being placed in sterile vials, and heated for thirty minutes at 60° C. A 1:10,000 solution of Merthiolate is used as a preservative. One-tenth cubic centimeter is employed for intracutaneous tests, and the reactions are observed in forty-eight hours.

With this bacillary antigen of Ducrey's bacillus, it is possible to make the diagnosis in venereal cases completely and accurately. It must be remembered that some patients with lymphogranuloma venereum, with a positive Frei test, are also suffering with a chancroid infection, in which case the intradermal chancroid reaction will be present. A positive chancroid test is only presumptive evidence and does not necessarily mean that the lesion under consideration is chancroid. A similar conclusion should be borne in mind in the interpretation of a reactive Wassermann as well as of a positive Frei test in every case of genital lesion unless other confirmatory laboratory evidences are present. A negative intradermal test with bacillary antigen is diagnostic so far as it rules out infection by the bacillus of Ducrey. A positive intradermal chancroid test commits one to the diagnosis of chancroid infection only when the Frei test, the Wassermann test, and microscopic examinations for malignant disease and granuloma inguinale give negative results. This reaction remains positive for life and this fact should be borne in mind in dealing with the above considerations.

GRANULOMA INGUINALE*

Granuloma inguinale is a granulomatous process which usually occupies the inguinal region. It is a mildly contagious, chronic, and progressive autoinoculable disease involving skin and corium and occasionally the lymphatics. Its venereal origin has never been absolutely proved.

---

*After Greenblatt in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, St. Louis, 1951, The C. V. Mosby Co.

[1] Arch. Dermat. & Syph. 36: 486, 1937.

The etiological agent is the Donovan body or *Donovania granulomatis*. The disease has been reproduced in human beings by inoculation of aspirated pus from pseudobuboes of granuloma inguinale which contained no other organisms than Donovan bodies. Donovan bodies are strictly tissue parasites of man, but have been successfully cultivated in the yolk sac of developing chick embryos, and less luxuriantly in certain yolk-free media. Inoculation into human volunteers has not been followed by typical reproduction of the disease.

Essential features of the histologic picture are (1) the massiveness of the cellular reaction in which the luxuriant granulation tissue is surcharged with plasma cells; (2) the relative and conspicuous paucity of lymphocytes; (3) the diffuse sprinkling of polymorphonuclear leukocytes, with focal collections in the superficies and papillae; (4) the pronounced marginal epithelial proliferation simulating early epitheliomatous changes; (5) the pathognomonic large mononuclear cells scattered in various numbers throughout the granulation tissue.

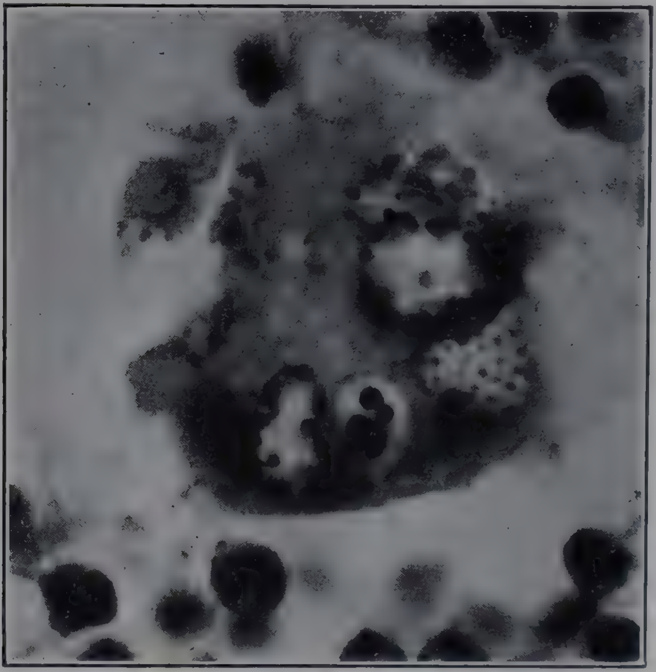

Fig. 409.—Negro male. Granulating lesions of glans penis. Biopsy. Diagnosis: Granuloma inguinale. A pathognomonic cell containing the encysted Donovan bodies. Stained with hematoxylin and eosin (×2,280). (Courtesy Pund, E. R., and Greenblatt, R. B.: Arch. Path., February, 1937.)

The pathognomonic cell is specific for granuloma inguinale. The relatively large size of the cells, the diameter of which varies from 25 to 90 microns, and the many intracytoplasmic cysts filled with deeply stained bodies are its cardinal features according to Greenblatt.[1]

Diagnosis.—

Make spreads by obtaining a minute piece of granulation tissue from the surface of the wound if it appears to be clean, or from the deeper part of the lesion if it appears to be markedly infected.

Remove the exudate covering the infected lesions.

Obtain a small piece of granulation tissue with a sharp instrument such as a small bone curette.

---

[1] Pund and Greenblatt: Arch. Path. 23: 244, 1937.

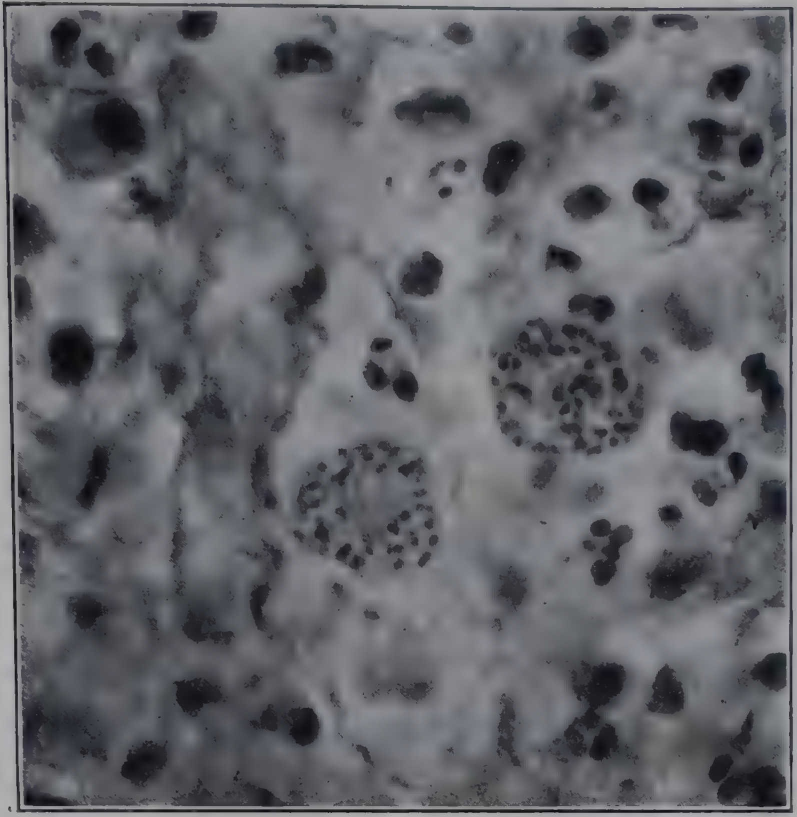

Fig. 410.—Pathognomonic cell of granuloma inguinale containing the encysted Donovan bodies. Stained by Dieterle's silver method. (Courtesy E. R. Pund and R. B. Greenblatt, Personal communication.)

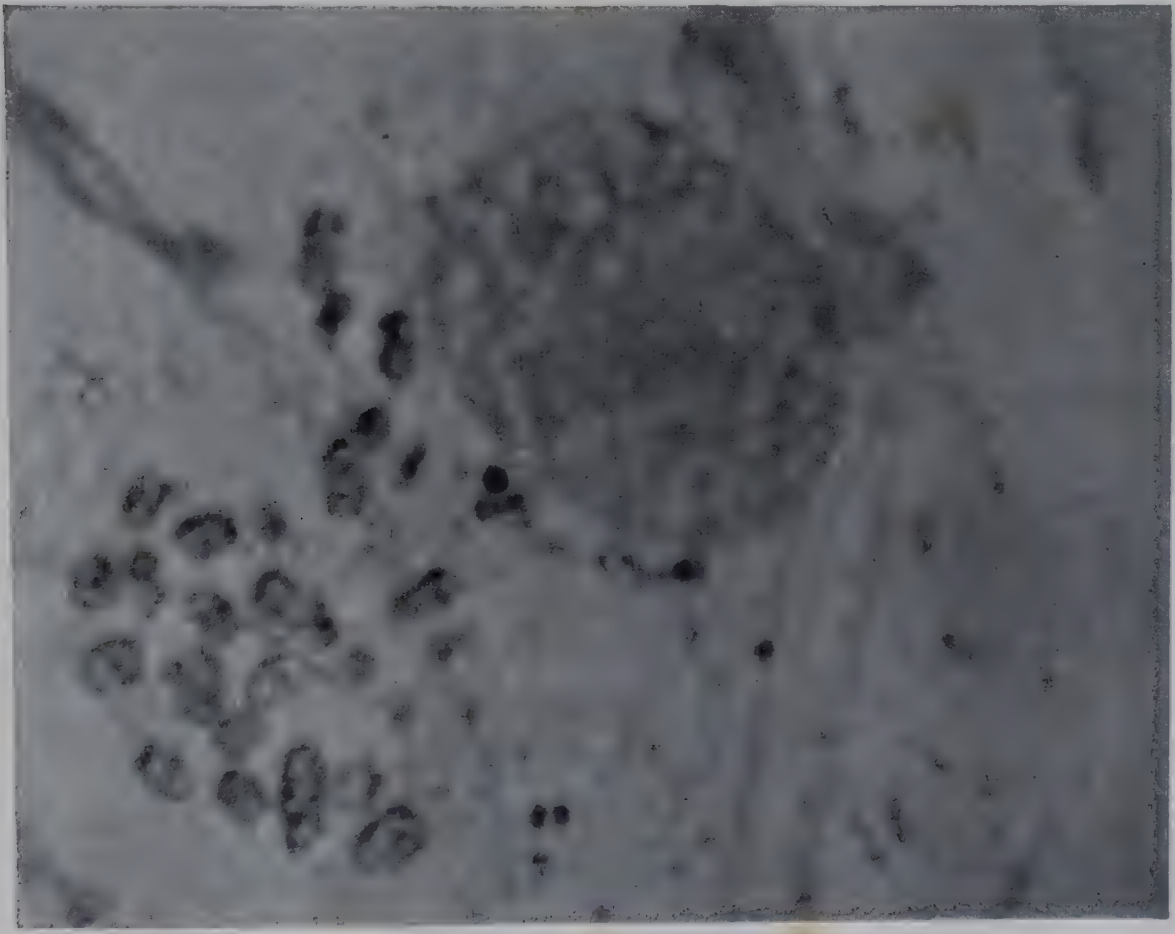

Fig. 411.—Donovan bodies from spreads of lesion (greatly magnified). (From Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Smear the tissue along several glass slides or crush it between two slides and then spread along the slide.

Dry and stain with either Wright or Giemsa stain.* If Giemsa stain is used, the slides must be fixed first in methyl alcohol.

If spreads fail to corroborate the clinical diagnosis, biopsy material may be stained with hematoxylin and eosin or by a silver technic. If the Dieterle method is used,[1] the cell outline, nucleus, and cyst walls stain pale yellow, while the Donovan bodies appear as dark brown or brown rectangular or elongated ovoid forms with intense bipolar staining. Because of their contour and polar characteristics, they resemble a closed safety pin.

YELLOW FEVER†

Yellow fever is an acute infectious disease caused by a specific virus and transmitted by certain species of mosquitoes. It has probably existed in America and Africa since time immemorial. It is believed that the Amazon Valley constitutes a permanent focus of yellow fever, principally maintained in jungle animals. From this enormous endemic region, epidemics originate from time to time and invade the more densely populated areas.

No yellow fever exists in Asia, although the vector, *Aëdes aegypti,* is found there in abundance.

The virus is found in man in the blood, up to the third or fourth day of the disease. It later disappears from the circulation, giving place to neutralizing antibodies. During the period in which it is found in the blood, the virus may infect certain species of mosquitoes which feed thereon.

The virus does not multiply in culture media unless living cells are present.

Yellow fever virus measures approximately 20 millimicrons, being one of the smallest viruses. It remains active for long periods if kept at very low temperatures (–78° C.). Desiccated and kept in sealed glass containers, it remains active several months at 8° C., and almost indefinitely at temperatures below 0° C.

It can cause a disease similar to that in man when injected into rhesus monkeys. It produces a fatal encephalitis when introduced into the central nervous system of white mice. It can be maintained serially by inoculating developing chick embryos a few days old.

Isolation of the Virus.—Take blood from the patient during the first three days of the fever.

Inject 0.03 c.c. intracerebrally into a series of 6 to 12 white mice. If the virus is present, the animals become sick and die usually after a week. It is advisable to make passages with the material from one of the sick mice to another group before trying to make an immunologic identification of the agent.

Neutralizing Test.—

(1) **Identification of the Virus.**—

Prepare suspension in physiologic saline from the brains of mice which have become sick as a result of infection with the virus after several mouse passages.

Make serial dilutions of the suspension, and add a constant quantity of known immune serum to each. Set up a control with normal serum.

Inject each mixture intracerebrally into a group of 6 or 12 mice.

If the immune serum protects the animals in one or more dilutions, the virus is that of yellow fever, provided that mice which receive normal serum and the virus die.

---

*See pages 615 and 620.

†Penna, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, St. Louis, 1951, The C. V. Mosby Co.

[1] Arch. Neurol. & Psychiat. **18**: 23, 1927.

(2) **Determination of Specific Antibodies in Serum.**—

Add the unknown serum to a filtered suspension of triturated brains from mice which have become sick after the inoculation of neurotrophic yellow fever virus. Use desiccated material.

Calculate the dilution of the suspension to contain a quantity of virus that can be neutralized by an equal volume of a standard immune serum, and which is sufficient to kill all the animals when mixed with the same volume of normal serum.

Inject 0.03 c.c. of the mixtures of unknown sera and the virus intracerebrally into each of 6 mice.

After a few days, encephalitis can be noted in the animals if the sera do not contain neutralizing antibodies, whereas all mice which receive sera containing such antibodies will remain well.

This test is performed with serum collected during the first days of the illness and again during convalescence. The first sample is usually negative and the second positive.

Viscerotomy.—

In fatal cases, histopathologic examination of the liver should be made, preferably using a "viscerotome."* Specimens are preserved in 10 per cent Formalin.

Complement Fixation.—

Perlowagora and Hughes[1] in 1946 prepared a purified antigen and were able to perform complement fixation tests for yellow fever successfully. Since complement-fixing antibodies disappear from the blood after a relatively short period of time, and neutralizing antibodies persist, it is possible to draw conclusions regarding the probable date of infection by carrying out both tests simultaneously.

Treatment.—

No specific treatment is known against yellow fever. The most practical way of controlling the disease consists in combating the mosquito vector. Vaccination attempts have been unsuccessful.

DENGUE

Dengue is a benign, acute, infectious, noncontagious disease of the tropics, with paroxysmal fever, severe pain in the joints and muscles, multiform and irregular rashes, tendency to relapse, and low mortality. It is also called "break-bone fever," "sun fever," "solar fever," "broken-wing fever," "three-day fever," "bouquet or bucket fever," "eruptive rheumatic fever," "dingee," and "denguis."

It is caused by a virus which passes through most filters and is found in high concentration in the blood during the period of fever. Cultures in the chick embryo have caused lesions on the chorio-allantoic membrane. The virus appears in cultures as globoid bodies 0.1 to 0.3 micron in diameter and arranged singly, in pairs, and in short chains.

The virus retains its virulence in the serum of patients at room temperatures for 1 to 2 months. It resists temperatures as low as −20° C. for at least

---

*Penna, loc. cit.

[1] J. Immunol. 55: 103, 1946.

48 hours, and also x-rays and ultraviolet rays. In desiccated blood, it has been known to remain active for at least 285 days. It is destroyed by heat at 50° C. for one-half hour.

Direct transmission of infected blood to normal individuals causes a typical disease, experimental dengue. Mosquitoes become infected when they feed on patients during the first three days of the illness. The virus can be found in the cerebrospinal fluid. Nasopharyngeal exudate and urine have always been negative.

It is transmitted by mosquito vectors.

Immunity is possible, but variable and of short duration.

The red count remains within normal limits, with very slight anisocytosis and poikilocytosis. Leukopenia is constant, the count fluctuating between 1,000 and 4,000 per cu. mm. on the fifth day. There is a relative monocytosis, as high as 14 per cent. There is a left nuclear shift with metamyelocytes and stabs, beginning on the third day. No pathologic forms have been noted. The count returns to normal soon after the beginning of convalescence. An increase in small lymphocytes has been noted by some authors, with a gradual increase of large lymphocytes, and a slight increase of eosinophiles.

Often there are black vomit, hematuria, jaundice, and active delirium.

Degenerative changes occur in the leukocytes.

TRACHOMA BODIES AND OTHER INCLUSION BODIES

Trachoma is a disease of the eye which was well known among the ancient Egyptians, Romans, and Greeks. It has come down to us through the ages and is still a very common disease, not only in modern Egypt but in many places in the United States. It is interesting to recall that, so prevalent was this disease in Egypt, most of the 30,000 grenadiers who swept into Egypt with Napoleon contracted trachoma.

Many attempts have been made to find the etiological agent. It remained for v. Prowazek and Halberstädter, who, during a student journey to Java in 1907, found in the conjunctival sac of trachomatous patients cells which under Giemsa staining showed homogeneous irregular *inclusion bodies* near the nuclei of epithelial cells. These bodies were round or oval, sometimes assuming a mulberry formation. They stained red, often filling up the cytoplasm of the cell in the form of small islands. In smears free bodies were seen. The material in which these bodies were found could be successfully used to inoculate eyes of animals. It is generally considered that these trachoma bodies are protozoan in nature.

Technic.—The technic for demonstration of trachoma bodies is as follows: Clean glassware must be used. After being thoroughly washed, it is finally cleaned in absolute alcohol. The conjunctiva is wiped clear of pus with gauze, not cotton, and then by scraping with a dull knife over the mucosa, enough material is obtained to cover the slide. The purpose is to remove as many pus cells as possible and to obtain epithelial cells from the tissue. The specimen is fixed one to two minutes with methyl alcohol and then stained with dilute Giemsa stain for one to two hours. Permanent specimens are made by covering the slide with cedar oil and then superimposing a cover glass. It is not advisable to use Canada balsam which is likely to decolorize the specimen.

These trachoma bodies may also be demonstrated in sections using Heidenhain iron hematoxylin for staining.

Rice's Method of Demonstration of Inclusion Bodies in Trachomatous Material

This method was suggested by Dr. C. E. Rice,* Medical Officer in Charge, Trachoma Prevention, United States Public Health Service, Rolla, Missouri.

Smears from trachomatous lids are fixed in 95% alcohol. Place several drops of Lugol's solution on slide and drop a thin cover slip over the solution. It can be found under low power and observed under high power. When preparation begins to dry, the cover slip can be flooded off with water, the slide washed slightly in tap water and the smear can again be flooded with Lugol's solution and a cover slip applied. This can be repeated an indefinite number of times.

The inclusions appear as amber-colored bodies, while the cell itself is slightly yellowish. The nucleus can be made out. The amber colored bodies are the so-called von Prowazek-Halberstaedter inclusions found in the epithelial cells in trachoma.

The actively secreting so-called acute trachoma[1] may be divided into three types as follows:

(1) *Chronic trachoma plus superimposed infection.* Contaminating bacteria are found in smear and culture. Inclusions and free bodies rare.

(2) *Subacute trachoma plus superimposed infection.* Secondary bacterial agents found in smear and culture. Inclusions and free bodies often numerous.

(3) *Subacute trachoma, unassociated with pathogenic bacteria.* Inclusions and free bodies numerous.

In chronic trachoma the inclusions and free bodies are found with such difficulty that search for them is not recommended. The fact that large mononuclear cells predominate in expressed follicular materials aids in the differential diagnosis from follicular conjunctivitis in which the lymphocytes predominate.

The Inclusion Bodies.—The cytoplasmic inclusion bodies of trachoma and inclusion conjunctivitis are basophilic and heterogeneous, differing from the inclusions of most other virus diseases which are acidophilic and homogeneous. That this difference is more apparent than real is suggested by the findings of Goodpasture and Woodruff,[2] and Goodpasture, Woodruff, and Buddingh[3] which indicate that such typical virus inclusions as those of vaccinia and fowlpox are composed of masses of elementary virus particles embedded in acidophilic matrices. The elementary bodies of these two diseases, as well as those of psittacosis,[4] closely resemble in size and staining reaction the elementary bodies of trachoma and inclusion conjunctivitis. The discovery that psittacosis virus has a life cycle resembling that of inclusion conjunctivitis virus further emphasizes the essential similarity of the cytoplasmic virus inclusions.

The inclusions of trachoma and inclusion conjunctivitis have in the past been confused with nonspecific bodies such as extruded nuclei,[5] phagocyted nuclear fragments, and phagocyted bacteria.[6] Such confusion is unnecessary if one has had an opportunity to study early cases of inclusion blennorrhea in which the various stages in the development of the inclusions from the initial body form to the elementary body form[7] are easily found. For convenience of reference the inclusions may be spoken of as early (initial body), intermediate (mixed), and late (elementary body).

---

*Personal communication.

[1] Thygeson, P.: Arch. Path. 12: 307, 1934.

[4] Bedson, S. P., and Bland, J. O. W.: Brit. J. Exper. Path. 8: 461, 1932.

[5] Gifford, S. R., and Lazar, N. K.: Arch. Ophth. 4: 468, 1930.

[6] Williams, A.: J. Infect. Dis. 14: 261, 1914.

Free elementary and initial bodies are frequently useful in diagnosis, particularly in acute trachoma and in inclusion blennorrhea in which they often appear in large numbers. The initial bodies stain blue and bipolarly with Giemsa stain and are cocco-bacillary in shape. The elementary bodies are small granules about 0.25 μ in diameter, which stain reddish blue with Giemsa stain. They may be identified from their uniform size, frequent diplococcal form, and the fact that they are alcohol-fast, while nonspecific granules, such as neutrophilic granules, decolorize readily.

Inclusion Blennorrhea

This affection is also, like trachoma, very common. It is an intrapartum affection of newborn children contracted from mothers infected with this disease. It has been well studied by Lindner. Five or six days after birth, clinical symptoms appear in the form of redness and swelling in the region of the conjunctiva with a purulent secretion.

The bodies resemble trachoma bodies in every particular. Thygeson, of Columbia University, has described the elementary body as follows: it is similar in size and staining reaction to elementary bodies of such virus diseases as vaccinia, fowl-pox, and psittacosis. They are minute, sharply defined granules of uniform size, often in pairs, staining reddish blue with Giemsa stain. The average diameter is about 0.25 micron. The so-called initial body is similar in size and staining characteristics to the trachoma body and to the large form of psittacosis virus. It is cocco-bacillary in shape, staining blue and bipolarly with Giemsa stain.

Essential characteristics of elementary and initial bodies: gram-negative; stain poorly with aniline dyes; alcohol-fast. Not cultivable on artificial media.

The initial body is the early phase of the virus, the elementary body the late phase. The elementary body is the infective stage. Its life cycle is as follows: (1) Penetrates epithelial cell. (2) Grows to initial body size. (3) Multiplies, the individual elements gradually becoming smaller and smaller until (4) Elementary body stage is reached. (5) Cell ruptures and liberates elementary bodies.

Multiplication of Virus During Incubation Period.—Three complete life cycles from elementary body to elementary body were demonstrated during six-day incubation period of an experimental infection. The life cycle, therefore, is probably 48 hours.

Filtrability of Virus.—The virus filters readily only during the acute stage when free elementary bodies are abundant. In chronic stages elementary bodies are in insufficient numbers to saturate absorptive properties of the filter and thus are all retained in the filter.

Inclusion blennorrhea is a birth canal infection. This has been proved by the demonstration of inclusion bodies and free virus in vaginal scrapings from mothers of infected infants and also by infection of monkey conjunctiva with vaginal secretions.

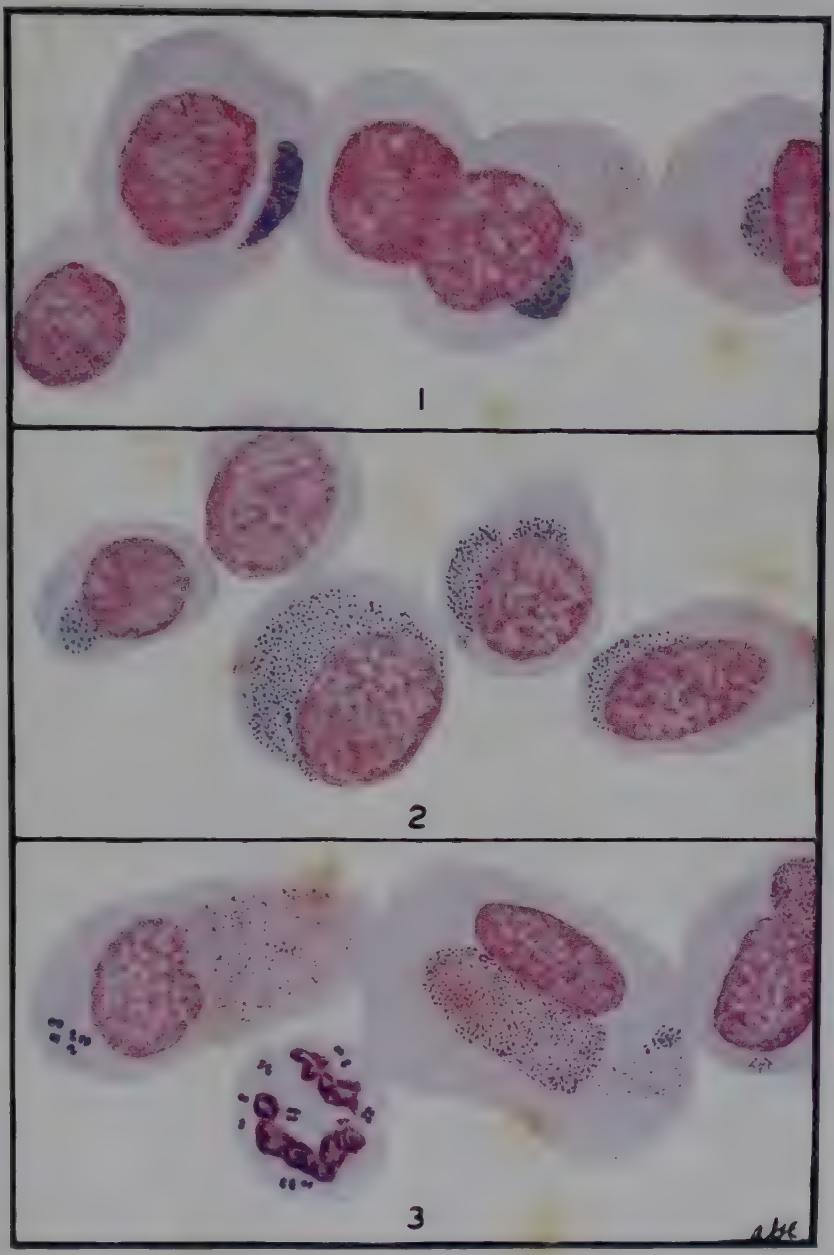

Plate XLVI.—Giemsa-Stained Preparations of Various Types of Inclusions.

(1) Trachoma; (2) Inclusion Blennorrhea of the Newborn; (3) von Prowazek-Halberstädter Bodies and Gonococci.

Technic.—Scrape epithelia from conjunctiva of baby by anesthetizing with drop of cocaine. Fix in methyl alcohol for ten minutes. Stain overnight in the incubator with Giemsa stain at 37° C. Dilute Giemsa stain 1 drop to each c.c. of neutral distilled water before using. Decolorize in 95% alcohol in two solutions for a total of five seconds. Dry in the air and examine.

Inclusion Bodies of Swimming-Pool Conjunctivitis

Swimming-pool conjunctivitis was described by Fehr in 1900.[1] It has frequently been described since then and has occurred in epidemics from bathing in swimming pools. The diagnosis clinically rests upon an acute beginning and the remarkable discrepancy between the slight subjective symptoms and the marked objective changes—such as marked swelling of the conjunctiva, overfilling of the follicles, etc. Since the advent of swimming pools into our community life, it is well to be on the lookout for this disease. The virus is evidently a body very similar to the trachoma and the inclusion blennorrhea bodies described by Lindner. This ''swimming pool'' inclusion body was first described in 1913 by Huntemuller and Pederstein.[2] They called attention to the similarity of this body to the Halberstädter body. Thygeson is of the opinion that the term ''inclusion conjunctivitis'' should include the two nonbacterial conjunctival diseases, inclusion blennorrhea and swimming-pool conjunctivitis, which are caused by a single virus. The name ''swimming-pool conjunctivitis'' should be discarded in favor of ''adult inclusion conjunctivitis'' since the swimming pool no longer plays a major part in the spread of the disease. The majority of cases now seen are the result of direct transfer from inclusion disease of the genitourinary tract.

The demonstration of the inclusion bodies of swimming-pool conjunctivitis is carried out just as described above for inclusion blennorrhea.

This disease usually appears as a follicular conjunctivitis, subacute at onset. Occasionally, however, it is seen as a papillary conjunctivitis in which follicles are either absent or masked by the papillary hypertrophy. The latter type is the more severe. Inclusions are often abundant in the early stages although never in such numbers as in the disease of the newborn. In the former type the inclusions are few in number and are commonly found only during the first few weeks of the disease. Free elementary and initial bodies are sometimes present even when inclusions are not demonstrable.

It is this type of follicular conjunctivitis which is most often confused with trachoma. The examination of expressed follicular contents after staining with Giemsa is a useful diagnostic procedure. In trachoma the large mononuclear cells predominate, while in all forms of follicular conjunctivitis the small mononuclear cells are the most numerous. In the trachoma follicle the central portion, made up of large mononuclear cells, has undergone gelatinous degeneration and expresses easily. The follicles in follicular conjunctivitis, on the other hand, are hard and have to be torn out in toto. The small mononuclear cells making up the peripheral portions of the follicles then appear in greatest number.

[2] Deutsche med. Wchnschr., p. 63, 1913.

Results Obtainable with Combined Film and Culture Technic.—Some indication of the results to be expected from the technic described is given by the following figures derived from the study of 314 consecutive cases of conjunctivitis at the ophthalmologic clinic of the University Hospital, Iowa City:

	Etiological Agent Determined in
Acute conjunctivitis	91% of cases
Subacute conjunctivitis	85% of cases
Chronic conjunctivitis	46% of cases

SUMMARY OF THE LABORATORY DIAGNOSIS OF VIRAL DISEASES

The procedures followed in the laboratory diagnosis of diseases caused by viruses are analogous to those used in bacterial infections. Conclusive evidence consists in the demonstration and identification of the virus. This may be accomplished in some of the virus diseases (psittacosis, yellow fever, influenza, and rabies) by using susceptible laboratory animals or chick embryos instead of the ordinary culture media used for the isolation of bacteria. Unfortunately, many factors complicate the use of animals in virus study: (1) costliness of animals often prohibits their use (monkeys in poliomyelitis); (2) in some cases animals must be strictly isolated to prevent contact infections (Russian spring-summer encephalitis); and (3) latent viruses of ordinary laboratory animals frequently confuse diagnosis.

Once the virus is recovered, identification is accomplished by determination of the animals for which it is pathogenic, routes by which it can be injected, tissues it infects, pathologic lesions produced, and through the use of the classical immunologic reactions, viz., neutralization, complement fixation, agglutination or precipitation reactions. The neutralization or so-called "protection test" was the first immunologic phenomenon to be used in connection with virus diseases (Babes and Cerchez,[1] Tizzone and Schwartz[2]). The complement fixation test came into use in 1906 when Jobling[3] showed that the serum from individuals convalescent from vaccinal infection would fix complement after being mixed with vaccine virus. A few years later Paschen[4] showed that elementary bodies of vaccinia and smallpox were specifically agglutinated by serum from individuals convalescing from these infections.

Microscopic study of virus-containing tissues is of value in identification and in establishing the relationship of the virus to the human disease under investigation. Certain viruses producing apparently identical lesions, however, may be distinguished only by their species specificity or their immunologic reactions. Inclusion bodies are not in all cases distinct enough from the morphologic standpoint to serve as characteristic indicators of the presence of virus. Furthermore, these bodies have not been demonstrated in a number of virus diseases; they have been found often in pathologic material in which the presence of a virus could only be suspected; and they have been produced in tissues in which the presence of a virus could be excluded with reasonable certainty (Olitsky and Harford[5]). When a virus can be demonstrated by passage as indicated above, the presence of inclusion bodies may serve as corroborative evidence.

Neutralization Tests.—Neutralization tests are generally used for detecting the presence of virus-neutralizing antibodies for diagnostic or epidemiologic purposes. The serum to be tested is mixed with the virus in suitable proportions and then inoculated into susceptible animals. In some of these tests the amount of virus used is kept constant and different dilutions of serum are added, while in others the amount of serum is kept constant and the virus diluted. In general, the basis upon which such neutralization tests are interpreted depends upon the susceptibility of the animal used. Usually, when the virus is highly pathogenic, the results are interpreted according to the proportion of animals which survive. With some viruses it has been possible to utilize skin reactions for titrating the antibody content of immune serum, thus permitting one to carry out several experiments simultaneously on a given animal. This procedure was used by Gordon[6] in his studies with vaccinia virus and by Van Rooyen and Rhodes[7] with rabbit myxoma and Shope's fibroma viruses. More recently the chorio-allantoic membrane of the developing chick embryo has been used for virus neutralization tests by Burnet[8] and by Blattner and Cooke.[9]

Olitsky and Harford[10] have shown that demonstration of protective antibodies is more effective when serum-virus mixtures are given by some routes of inoculation than by others. This fact must be considered in carrying out practical diagnostic tests.

Frequently a specimen of serum can be obtained only during convalescence. In such cases, the validity of the diagnosis depends on the frequency with which sera from apparently normal individuals in a given community give positive tests. In attempting a diagnosis of St. Louis encephalitis or lymphocytic choriomeningitis by single specimens of serum taken during convalescence it must be remembered that the sera of many normal persons of the same community also give positive results (Wooley and associates[11]). During epidemic periods, because of subclinical exposure, a large percentage of normal persons may develop antibodies against the virus responsible for the outbreak. Accordingly, based on the study of serum specimens from the general population and from cases of influenza occurring during the 1940-1941 outbreak in St. Louis, the level of complement fixing antibodies near a titer of 1 to 16 in terms of the original dilution of the patient's serum was found to be significant of epidemic influenza (Sulkin and associates[12]). In certain virus diseases specific antibodies develop quite rapidly (St. Louis encephalitis and equine encephalomyelitis), while in others, antibodies may not become apparent for several weeks or even months. The technic of neutralization tests is given on page 1752.

In Vitro Tests.—The early literature contained many conflicting reports concerning the application of complement fixation tests to the study of virus diseases. In subsequent years, however, various improvements have been introduced which have increased the practicability and resulted in the more extensive use of this test. Merrill[13] has indicated that theoretically in vitro immunologic reactions should be demonstrable, provided a sufficient quantity of virus is contained in the tissue used as antigen. However, if the concentration of virus in the tissues is low, a delicately balanced system must be used as suggested by Bedson.[14] Sufficient time must be allowed for the union of antigen and antibody. Accordingly, Bedson and Bland[15] permitted complement fixation to occur over a period of hours at low temperature, employing the procedure previously used for increasing the delicacy of the Wassermann test.

COMPLEMENT FIXATION TESTS FOR RICKETTSIAL AND VIRAL DISEASES

Complement fixing antibodies begin to appear in the blood of the patients usually in the middle of the second week of the illness. Titers of 1:10 or higher are indicative. The test should be repeated at about 10-day intervals, whether the reaction has been negative or not. Neurotropic viruses will seldom give titers higher than 1:30.

Antigen.—

The principal difficulty in applying the complement fixation technic to viral and rickettsial diseases has been the preparation of suitable antigens. DeBoer and Cox,[16] and later Van der Scheer, Bohnel, and Cox,[17] have developed a method of preparing antigens in which nonspecific reactions are reduced and by which the rickettsial antigens may be purified and concentrated. Further studies led to commercial production of usable antigens, of which those of Lederle Laboratories are recommended.[18] The following list gives information concerning these antigens and the tissue utilized in preparing them.

Antigen	Tissue Source
Equine encephalomyelitis (Eastern) (EEE)	Whole chick embryo
Equine encephalomyelitis (Western) (WEE)	Whole chick embryo
Japanese B encephalitis (Jap B)	Mouse brain
St. Louis encephalitis (SL)	Mouse brain
Lymphocytic choriomeningitis (LCM)	Guinea pig lung
Mumps	Chick embryo—chorio-allantoic fluid
Influenza (all available strains)	Chick embryo—chorio-allantoic fluid
Psittacosis (PSI)	Chick embryo—chorio-allantoic fluid and membrane
Q fever (all available strains)	Purified rickettsial suspension
Rickettsialpox (RP)	Chick embryo—yolk sac
Rocky Mountain spotted fever (RMSF)	Chick embryo—yolk sac
Typhus (both strains)	Chick embryo—yolk sac

Sheep Cells.—

Collect sheep blood in a bottle containing a few glass beads and shake thoroughly. Filter through several layers of sterile gauze and store in a refrigerator.

---

[13] J. Immunol. **30**: 169, 1936.

[14] Brit. J. Exper. Path. **9**: 235, 1928.

[15] Brit. J. Exper. Path. **10**: 393, 1929.

[16] J. Immunol. **55**: 193, 1947.

[17] J. Immunol **56**: 365, 1947.

[18] Antigens for these tests are obtainable from the Lederle Laboratories Division of the American Cyanamid Company, 30 Rockefeller Plaza, New York 20, N. Y., and are recommended for routine use.

This suspension is suitable for use for 5 to 6 days. Sheep cells defibrinated and stored in this manner have been found more satisfactory for use with the present antigens than citrated cells or blood stored in various preservatives.

Remove adequate portions as required and wash in the usual manner (page 2048) with saline, until the supernatant fluid is colorless.

Suspend the cells in the proportion of 2 c.c. of packed cells to a total of 100 c.c., using 0.85% saline as the diluent.

The washed cells, if stored in a refrigerator at 6° to 8° C., may be used for two successive days.

Titration of Hemolysin.—

Prepare serial dilutions of antisheep hemolysin, as in the Kolmer test (page 2051).

Prepare 1:30 dilution of complement as in the Kolmer test (pages 2049, 2051).

Carry out the titration as follows:

TUBE NUMBER	HEMOLYSIN		1:30 COMPLEMENT C.C.	SALINE C.C.	2% SHEEP CELLS C.C.
	DILUTION	C.C.			
1	1:1,000	0.25	0.25	0.75	0.25
2	1:2,000	0.25	0.25	0.75	0.25
3	1:3,000	0.25	0.25	0.75	0.25
4	1:4,000	0.25	0.25	0.75	0.25
5	1:5,000	0.25	0.25	0.75	0.25
6	1:6,000	0.25	0.25	0.75	0.25
7	1:8,000	0.25	0.25	0.75	0.25
8	1:10,000	0.25	0.25	0.75	0.25
9	1:12,000	0.25	0.25	0.75	0.25
10	1:16,000	0.25	0.25	0.75	0.25

Incubate at 37° C. in a water bath for 1 hour.

Read. The highest dilution of hemolysin which causes complete hemolysis at the end of an hour is *one* unit. Use *two units* in all subsequent titrations and in the test.

Example: If tube 4 shows complete hemolysis and tube 5 shows only partial or slight hemolysis, one unit of hemolysin is 0.25 c.c. of a 1:4,000 dilution. Two units would be 0.25 c.c. of a 1:2,000 dilution. It is not advisable to use the sheep cells if the titer is lower than 0.25 c.c. of a 1:1,000 dilution; new cells must be prepared.

Preparation and Titration of Complement.—

Dilute the complement 1:30 with saline, as for the Kolmer test, pages 2049, 2051.

TUBE	1	2	3	4	5	6	7	8	9	10
Complement (1:30) c.c.	0.100	0.125	0.150	0.175	0.200	0.225	0.250	0.275	0.300	0.325
Saline c.c.	0.650	0.625	0.600	0.575	0.550	0.525	0.500	0.475	0.450	0.425
Antigen 2 units c.c.	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25
Incubate in a water bath at 37° C. for 1 hour.										
Hemolysin 2 units c.c.	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25
2% sheep cells c.c.	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25
Incubate in a water bath at 37° C. for 1 hour.										

Read. The smallest quantity of 1:30 dilution of complement which shows complete hemolysis is *one exact unit.* Use *two exact units,* contained in 0.5 c.c., for all antigen titrations and for the test.

If the complement is prepared in the laboratory from fresh guinea pig blood, the overnight-icebox incubation should be used instead of the first incubation in a water bath, and any serum rejected if it shows less complement activity than average in the presence of 2 units of a given antigen.

Use the following table to determine the required complement dilution so that 0.5 c.c. contains exactly 2 units.

ONE EXACT UNIT OF COMPLEMENT	TWO EXACT UNITS OF COMPLEMENT
0.100 c.c. of 1:30 dilution	0.5 c.c. of 1:75 dilution
0.125 c.c. of 1:30 dilution	0.5 c.c. of 1:60 dilution
0.150 c.c. of 1:30 dilution	0.5 c.c. of 1.50 dilution
0.175 c.c. of 1:30 dilution	0.5 c.c. of 1:42.8 dilution
0.200 c.c. of 1:30 dilution	0.5 c.c. of 1:37.5 dilution
0.225 c.c. of 1:30 dilution	0.5 c.c. of 1:33.3 dilution
0.250 c.c. of 1:30 dilution	0.5 c.c. of 1:30 dilution
0.275 c.c. of 1:30 dilution	0.5 c.c. of 1:27.5 dilution
0.300 c.c. of 1:30 dilution	0.5 c.c. of 1:25 dilution
0.325 c.c. of 1:30 dilution	0.5 c.c. of 1:15 dilution

The Diagnostic Complement Fixation Test.—

To make serial dilutions of the patient's serum, make a 1:4 dilution in saline by adding 0.3 c.c. of the freshly inactivated serum to 0.9 c.c. of saline.

Rack up 6 tubes for the test, 3 for the serum controls, and 3 for other controls.

Place 0.25 c.c. of saline in tubes 2 through 6, and in tubes 8 and 9.

Place 0.25 c.c. of the 1:4 dilution of patient's serum in tube 1 and in tube 2 of the test (first six tubes) and in tubes 7 and 8 of the controls.

Mix the contents of tube 2 and transfer 0.25 c.c. to tube 3, mix and transfer 0.25 c.c. to tube 4, and continue through tube 6. Discard the extra 0.25 c.c. of diluted serum.

Mix the contents of tube 7, transfer 0.25 c.c. to tube 8, mix, and transfer 0.25 c.c. to tube 9. Mix and discard 0.25 c.c. of diluted serum.

Tubes 1 through 9 now each contain 0.25 c.c. of various dilutions of serum as follows:

Tube	1	2	3	4	5	6	7	8	9
Dilutions	1:4	1:8	1:16	1:32	1:64	1:128	1:4	1:8	1:16

Prepare the diagnostic complement fixation test indicated in Table 167, adding the reagents in the order listed.

TABLE 167.—DIAGNOSTIC COMPLEMENT FIXATION TEST FOR RICKETTSIAL AND VIRAL DISEASES

	TEST						SERUM CONTROLS			OTHER CONTROLS		
	1	2	3	4	5	6	7	8	9	10	11	12
Serum dilutions	1:4	1:8	1:16	1:32	1:64	1:128	1:4	1:8	1:16	a	b	c
c.c.	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	–	–	–
Antigen 2 units c.c.	0.25	0.25	0.25	0.25	0.25	0.25	–	–	–	0.25	–	–
Complement 2 units c.c.	0.50	0.50	0.50	0.50	0.50	0.50	0.50	0.50	0.50	0.50	0.50	0.50
Saline c.c.	–	–	–	–	–	–	0.25	0.25	0.25	0.25	0.50	0.75
Incubate overnight at +6° to +8° C.												
Hemolysin 2 units c.c.	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	–
2% Sheep cells c.c.	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25
Incubate at 37° C. for 15 minutes in a water bath												

Read.

One set of serum controls is run for each serum sample, and one set, in duplicate, of other controls for all sera.

Tube *a* is the antigen control, and should show complete hemolysis.

Tube *b* is the complement control and should show complete hemolysis.

Tube *c* is the sheep cells control and should show complete absence of hemolysis.

The highest dilution of the patient's serum exhibiting 3 or 4 plus reaction—between 75 and 100% inhibition of hemolysis—represents the serum titer.

Whereas various nonspecific and zone reactions may seemingly occur if the tests are read as soon as the antigen and serum control tubes show complete hemolysis, "true" reactions will persist longer.

Allow the tubes to stand at room temperature for 1 hour following the first reading, and read again. "True" reactions should persist for this additional length of time.

A known positive serum must be included as a control for each antigen utilized in the diagnostic test. It is advisable to use the same positive serum each time a particular antigen is used. Thus, a definite rise or fall in titer exhibited by the control serum will be indicative of a faulty test run.

If a question arises as to whether a positive reaction is due to the organ content of an antigen rather than to the etiological agent, a control for specificity must be included. Refer to the table, page 1742, showing the tissue source of each antigen, and select an antigen which will serve as a control for another. For example, equine encephalomyelitis, Eastern, may serve as a control for equine encephalomyelitis, Western; mumps, psittacosis, and influenza can control each other; rickettsialpox, or Rocky Mountain spotted fever, can control either of the typhus strains. Japanese B encephalitis and St. Louis encephalitis must be compared with normal mouse brain antigen.

The Use of the Chick Embryo as an Aid in Diagnosis.—The fertile egg is now widely used and has been found to be applicable to the study of a variety of virus problems. One of the first publications on the use of chick embryos for studying bacterial infections was that of Levaditi[19] in 1906. According to this investigator, however, chick embryos were used the previous year by Borrel. Subsequently they were used by a number of investigators including Rous and Murphy,[20] Juan and Staub,[21] Gay and Thompson,[22] and others, but the method was generally introduced into bacteriology by Goodpasture and his associates[23] in their study of fowl pox virus.

The chick embryo is now widely used for the isolation, cultivation, and titration of viruses; for titration of antiviral sera; as a source of antigen for immunologic procedures; for the preparation of vaccines for human use; and for studying the development of lesions. The reader is referred to the articles by Goodpasture and his associates,[23] Burnet,[24] Stevenson and Butler,[25] and Bengtson and Dyer.[26] Convenient histologic methods of examining infected chorio-allantoic membranes have been described by Goodpasture and his coworkers,[27] Himmelweit,[28] and more recently Burnet and Faris.[29] Cooke and Blattner[30] have described a method of staining virus foci on chick membranes. The staining procedure, using trypan blue, facilitates the recognition and enumeration of lesions on the developing chick membrane. See pp. 1473 ff.

Egg Culture Methods.—Egg culture methods are described in detail on pages 1473 ff. Method of injecting into the yolk sac is shown on page 1729.

Preservation of Viruses.—It has long been known that viruses which are unstable and rapidly become inactivated at room temperatures retain their infectivity for longer periods at lower temperatures. The most widely used method of preservation is 50 per cent glycerin.* This method is simple, but does not maintain the infectivity of some viruses over long periods.

A technic for the preservation of various bacteria, filtrable viruses, and other biologic preparations by desiccation from the frozen state was developed through the studies of Shackel,[31] Swift,[32] Sawyer and associates,[33] Elser and associates,[34] and more recently by Flosdorf and Mudd.[35] The latter investigators have described procedures and apparatus for preservation of viruses and other biological materials by drying while in the frozen state. This system, known as the "lyophile process," has been used effectively by Wooley.[36] Flosdorf and Mudd[35] later described the so-called "cryochem process," a further refinement of the original method. This procedure has since been used for the preservation of numerous types of infectious materials, and has been found to be highly effective for most viruses.

Carbon dioxide in solid form has been used to maintain virus-containing materials at very low temperatures with conspicuous success. The specimen tubes are surrounded by a mixture of alcohol and carbon dioxide snow. The tubes containing the material are rotated, so that the contents freeze uniformly. Then a vacuum is attached and the tubes sealed. They may be stored in a freezer without vacuum desiccation.

Common Errors in Laboratory Procedure.—The diagnosis of virus diseases is subject to numerous difficulties, both in the handling of specimens and in procedure of the various tests. These pitfalls may arise from complications inherent in the virus itself or in the nature of the test being used. The worker must therefore have a clear understanding of the mechanism of any test undertaken. In the following discussion, some of the more common errors in laboratory diagnosis will be pointed out.

One frequent error occurs when a latent virus appears during animal passage and is mistaken for that causing the human disease. Several spontaneous infections in apparently healthy mice from various highly inbred laboratory stocks have complicated experimental study of viruses.

Authorities differ as to the amount of incubation of serum-virus mixtures necessary in the performance of neutralization tests. Although some workers advocate definite incubation periods, good results have been obtained where only sufficient time to make necessary manipulations was allowed. Incubation may cause some inactivation of the virus so that it is important that control animals inoculated with normal serum-virus mixtures be carefully observed. It is desirable to inoculate the immune serum-virus mixtures first so that any protection observed cannot be attributed to standing during inoculation of control animals.

---

*It is not necessary to use Schering-Kahlbaum brand of glycerin, but it is desirable to use a pure good grade.

[36] Pub. Health Rep. **54**: 1077, 1939.

The diluent used for suspending the virus-containing tissues is an important factor and is almost always stated. In general, 1 to 10 per cent solutions of normal horse or rabbit serum in saline are satisfactory, but it must be made certain that the serum does not contain specific antibodies against the virus used. Infusion broth is also valuable, but in some instances has been found to be inferior to serum. Beef infusion broth containing 20 per cent horse serum has been found satisfactory in studies with influenza virus.

Although specific complement fixing antibodies have been demonstrated in many virus diseases, these reactions are so delicate that the execution of the tests, their adequate control, and interpretation of results demand utmost care and attention. One of the chief obstacles remains that of nonspecific complement fixation caused by tissue proteins from which viruses are inseparable. For example, the appearance of certain immunologic effects, such as the Forssman phenomenon, may interfere with the interpretation of the results of serologic reactions. The animal species from which antigen is derived and animal species from which antibody is obtained must be considered. Fairbrother and Hoyle[37] found from their control experiments that the complement fixation which occurred between anti-influenzal ferret serum and influenzal mouse lung was nonspecific in character as the same effect was obtained with normal mouse lung as antigen. Therefore, suitable antigen and serum controls must be included before the results of these tests can be interpreted. In addition, unless the same pooled complement is used throughout a series of tests, comparisons cannot be made, as the deviability of different specimens of complement is likely to vary considerably.[38] Refer to page 1745.

Many workers in the fields of biology and medicine believe that if results need statistical evaluation they are of such inconclusive nature that they should not be considered valid. On the other hand, we are of the opinion that results which look significant may well be given the test of statistical analysis since occasionally they may not prove to be as conclusive as they appear. Mainland[39] discusses the use of statistical methods in such situations. Furthermore, in the primary isolation of a virus, it is desirable to use a large number of animals. This obviously increases the possibility of obtaining positive results, and if all animals show signs of infection, activation of a latent virus is less likely to have occurred. Again, in making serum protection tests, the use of a large enough number of animals makes the conclusions less open to criticism. Schaeffer and Muckenfuss[40] have shown how the difficulty in using large numbers of monkeys in experimental poliomyelitis has made results in many cases invalid.

Within recent years a number of new procedures have appeared in the literature which give promise of simplifying laboratory technic with regard to the diagnosis of virus diseases. Hirst[41] discovered that the allantoic fluid of chick embryos infected with either influenza "A" or "B" virus was capable of agglutinating red blood cells. This phenomenon was utilized to detect influenza virus in throat washings and to measure antibodies in serum. Hirst's studies clearly indicate that the amount of agglutination-inhibiting substances in influenzal antiserum parallels the neutralizing antibody titer more closely than the complement fixing titer. It now appears that this simple in vitro test will be sensitive and specific enough to replace the more cumbersome mouse protection test. The same phenomenon was observed independently by McClelland and Hare[42] who confirmed the observations of Hirst. Nagler[43] has described a similar phenomenon with vaccinia virus. Mumps and certain viral encephalitis viruses give a similar phenomenon.

PREPARATIONS OF SPECIMENS IN THE DIAGNOSIS OF VIRAL DISEASES

If serum, spinal fluid, or other material is mailed to another laboratory, it should be sent in a frozen state. Put it in a sterile ampule or small tube, immerse the glass in a mixture of dry ice and ethyl alcohol. Rotate the vessel to assure proper freezing. Then seal the ampule or the tube, and forward it, packed in dry ice, in a double container.

Several samples of blood and spinal fluid should be collected, at weekly intervals, beginning with the first day when suspicion of a viral disease arises.

Egg inoculations may be carried out if facilities for proper histologic examinations exist. Animal tests are meaningless in diseases other than rabies and variola if proper control strains and sera are not available.

Table 169 shows the most frequently recommended procedures used in the diagnosis of viral diseases.

Virology is a relatively new science. Many methods used in virologic laboratories are not suitable as yet for smaller units. As a general rule, histologic work and complement fixation tests can be performed in nonspecialized laboratories, provided that reliable antigens are available. The method prescribed for use with the particular antigen must be followed to the letter, even more carefully than in work with syphilitic sera. If, for instance, the temperature stated in the outline is 37° C., that does not mean 36.5° or 37.5°, but exactly 37° C. Maintenance of the stock cultures and preparation of the sera for neutralization tests demand so much time, effort, and specialized knowledge that it is usually best to forward such sera for such reactions to a large laboratory which is especially equipped for the work and has properly trained personnel. Most state health laboratories and many university laboratories will have such facilities and will be glad to assist if requested to do so.

Variola	Blood Local lesion	x	Chorio-allantoic membrane		x	Rabbit eye
Herpes	Blood, spinal fluid Local lesion	x	Chorio-allantoic membrane	x	x	
Primary atypical pneumonia						Cold hemagglutination, strep. MG agglutination
Influenza	Blood Nasal washings		Amniotic cavity		x	Hemagglutination inhibition
Mumps	Blood, spinal fluid				x	Hemagglutination inhibition
Equine, Japanese B, St. Louis, and Russian encephalitis	Blood, spinal fluid			x	x	Mouse, intracerebral
Lymphocytic choriomeningitis	Blood, spinal fluid			x	x	Mouse, intracerebral, guinea pig
Dengue, Colorado tick fever, yellow fever	Blood			x		Mouse, intracerebral
Poliomyelitis	Blood Stools			?	?	Monkey
Coxsackie virus	Blood Stools, nasal washings			x	?	Suckling mouse, intraperitoneal
Common cold	Nasal and throat washings					Cell agglutination

Neutralization Tests[1]

Following recovery from a viral or rickettsial disease, blood sera of man and animals generally contain immune substances capable of neutralizing the infectious agent. These protective antibodies, which are highly specific, are demonstrated by adding the serum to infectious material and then inoculating the susceptible host with the mixture. This serves as an indicator of the presence or absence of active agent in the mixture.

The information obtained is useful in diagnosis as well as in estimation of the response of the host to certain vaccines, and the test can be used to identify newly isolated strains of virus.

There is no standard neutralization test. Each method represents a compromise in the selection of various factors which influence the final result: choice of indicator host, route of inoculation, source of virus, type of antiserum, use of constant dilutions of serum with serial dilutions of virus or vice versa, time and temperature of incubation of virus-antiserum mixture, and age of inoculated animals.

The following is an example of a neutralization test in which death or survival of the animal serves to indicate presence or absence of active virus. This is the method recommended by the Neurotropic Virus Disease Commission in 1942 for the diagnosis of epidemic viral encephalitides of North America.

(a) Virus.—

Remove 10 or more brains from mice showing nervous signs.

Grind with sand or Alundum.

Add 10 c.c. of inactivated (56° C. for ½ hour) undiluted rabbit serum for each gram of brain tissue.

Centrifuge at 2,000 r.p.m. for 10 minutes.

Withdraw the supernatant fluid. This is regarded as the 1:10 dilution of the virus.

Titrate part of it immediately. Distribute the rest in 1 c.c. amounts (2 c.c. quantities may be used) in ampules.

Seal the ampules and freeze quickly in a mixture of solid CO_2 and 95% alcohol, and store in a solid CO_2 refrigerator. One or more ampules are thawed and used in each test, the unused portion of the virus being discarded.

(b) Preparation of Virus Dilutions, and Control and Serum-Virus Mixtures.—

Use the 1:10 dilution from the frozen ampule.

Prepare 1:50, 1:500, 1:5,000, etc., up to 1:500,000,000 or 5,000,000,000 dilutions, using 10% rabbit serum in saline as the diluent, and a separate pipette for each dilution.

Add 0.2 c.c. of the selected dilutions to labeled tubes containing 0.2 c.c. of the undiluted unknown serum and also to 0.2 c.c. of a tested negative, undiluted rabbit serum for the control mixtures.

(c) Selection of Critical Dilutions.—

If the preliminary titration has indicated that the LD_{50} titer of the virus to be used is in the range of the 10^{-8} dilution, after incubation at 37° C. for 2 hours, the control dilutions to be tested will be 10^{-6}, 10^{-7}, 10^{-8}, and 10^{-9}, and the serum dilutions 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}. Similarly:

(1) with preliminary LD_{50} titer of virus in the range of 10^{-7}, control dilutions are 10^{-5}, 10^{-6}, 10^{-7}, and 10^{-8}, while serum dilutions are 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6};

(2) with preliminary LD_{50} titer of virus in the range of 10^{-9}, control dilutions are 10^{-7}, 10^{-8}, 10^{-9}, 10^{-10}, and serum dilutions are 10^{-5}, 10^{-6}, 10^{-7}, and 10^{-8}.

---

[1] Smadel, Joseph E.: Serologic Reactions in Viral and Rickettsial Infections, in Thomas M. Rivers Viral and Rickettsial Infections of Man, ed. 2, 1952, J. B. Lippincott Co. This section is abstracted from the original article by permission of the author, the publisher, and by the National Foundation for Infantile Paralysis, Inc.

These dilutions are selected in order to be within the range of 100% mortality at one end and 100% survival at the other in the control titration, bearing in mind the variations in titer that may be expected with virus suspensions preserved in the frozen state.

If the test is to be used for diagnosis with a virus that maintains its titer well, one may dispense with the lowest dilution in the serum mixtures and use 3 instead of 4 serum-virus dilutions. If the virus preparations have diminished in titer by 1.5 to 2.0 log dilutions during storage, they should be replaced by new materials.

(d) Incubations, Numbers of Mice, and Period of Observation.—

Use 5 mice for each dilution. If it is necessary to limit the number of mice, 4 may be used for each dilution.

Using 0.25 c.c. tuberculin syringes, inject 0.03 c.c. of each dilution intracerebrally into the mice.

The controls and serum-virus mixtures must be incubated in a water bath at 37° C. for 2 hours and then placed in an ice bath until ready to use.

Inject the highest dilutions first (10^{-10}, 10^{-9}, etc.). The control mixtures should be injected last.

Observe the mice for at least 10 days in the case of Western and Eastern equine encephalomyelitis and for at least 14 days in the case of St. Louis encephalitis virus. Report deaths when they occur. All deaths within 24 hours after inoulation must be regarded as due to traumatic or nonviral causes, and in the case of St. Louis encephalitis virus, all deaths during the first 3 days must be regarded as nonspecific.

Example

TABLE 170

	FINAL DILUTION OF VIRUS						LD$_{50}$ TITER LOG OF DILUTION	NEUTRALIZATION INDEX	RESULT
MIXTURE	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}	10^{-9}			
Control	---	---	5/5	4/5	3/5	0/5	8.0		
Serum A	5/5	5/5	5/5	3/5	---	---	7.0+	<10	Negative
Serum B	5/5	5/5	3/5	2/5	---	---	6.5	32	Equivocal
Serum C	5/5	4/5	3/5	0/5	---	---	6.0	100	Positive

Fraction 3/5 indicates that 5 mice were inoculated and in 3 death occurred as a result of the virus infection.

TABLE 171.—PROCEDURE USED IN CALCULATING LD$_{50}$ TITER*

CONTROL

			ACCUMULATION TOTALS			
	DIED	SURVIVED	DIED	SURVIVED	DEATHS	% MORTALITY
10^{-6}—5/5	5	0	12	0	12/12	100.0
10^{-7}—4/5	4	1	7	1	7/8	87.5
10^{-8}—3/5	↑ 3	2 ↓	3	3	3/6	50.0
10^{-9}—0/5	0	5	0	8	0/8	0

Therefore LD$_{50}$ titer, log of dilution = 8.0.

Arrows indicate direction of addition for accumulation totals.

*The Reed-Muench formula will be used even in the absence of a zero mortality end point or of 2 dilutions below the 50 per cent or more mortality range, with the clear understanding that the results are not absolutely accurate. This is the best available procedure for a standard method of expressing the results under circumstances which make it impractical to increase the number of dilutions to cover the strict requirements of the Reed-Muench formula.

SERUM B

			ACCUMULATION TOTALS			
	DIED	SURVIVED	DIED	SURVIVED	DEATHS	% MORTALITY
10^{-4}—5/5	5	0	15	0	15/15	100.0
10^{-5}—5/5	5	0	10	0	10/10	100.0
10^{-6}—3/5	3	2	5	2	5/7	71.4
10^{-7}—2/5	2	3	2	5	2/7	28.6

$$\frac{\text{\% mortality above 50\%} - 50\%}{\text{\% mortality above 50\%} - \text{\%mortality below 50\%}} = \text{factor or proportionate distance or}$$

$$\frac{71.4\% - 50\%}{71.4\% - 28.6\%} = 0.5$$

When tenfold dilutions are used, LD_{50} titer = log of dilution above 50% + factor or in this case = 6.0 + 0.5 = 6.5.

Calculation of Neutralization Index for Serum B

Control titer log of dilution = 8.0
minus
Serum B titer log of dilution = 6.5
Neutralization index log = 1.5
Antilog of 1.5 = 31.6 or 32; therefore neutralization index = 32.

The Commission regarded a neutralization index of 1 to 9 as negative, of 10 to 49 as equivocal, and of 50 or more as positive.

Finding a neutralizing antibody against a virus in a single specimen of serum usually cannot be regarded as proof that the recent illness was caused by the virus in question. Neutralizing antibodies which appear following many infections persist for long periods of time. The picture is further complicated by the occurrence of neutralizing substances in sera of persons who have suffered unrecognized disease in the form of inapparent or atypical infection, or who have been vaccinated with active or inactive virus. Therefore, the presence of a specific neutralizing antibody can be regarded as evidence of previous experience with the agent but no date can be given for the episode.

For this reason, two samples of serum must be taken for testing: the first is taken early in the disease when antibodies are absent or at a low level, and the second at an appropriate time during convalescence.

Hemagglutinin Inhibition Test

The agglutination of erythrocytes by microbial agents, called "Hirst's phenomenon," is a valuable aid in investigating and in diagnosing a number of viral diseases. The test given here as an example is that used for influenza.

Materials Needed.—

0.85% sodium chloride in freshly distilled water, the **Saline solution.**

Type O human red blood cells, either fresh or preserved in Alsever's solution.

Standard dried type A (PR8), type A′ (FM1), and type B (Lee) antigen.

Standard dried chicken antisera against each of the viruses mentioned above.

Kahn tubes, 12 by 75 mm., with evenly rounded bottoms.

Racks for Kahn tubes, flat-bottom type without depressions.

1 c.c. serologic **pipettes,** graduated in 0.01 c.c., and **5 c.c. pipettes,** graduated in 0.1 c.c.

Glassware must be chemically clean. Traces of acid or alkali interfere with the test. Kahn tubes which do not have evenly rounded bottoms should be discarded. For influenza work, reserve specially selected and clean tubes.

Standard Antigens.—

Antigens are prepared according to the method of Hilleman, Buescher, and Smadel.[*]

Inoculate 9- or 10-day embryonated eggs from chickens free of *Salmonella pullorum* and Newcastle disease, by way of the allantoic cavity, with 0.4 c.c. amounts of a dilution of the appropriate seed virus, usually 10^{-4} to 10^{-5}, which has been found in preliminary titrations to produce chorio-allantoic fluids with hemagglutinin titers of 1:320 or greater.

---

[*] See footnote, page 1752.

Incubate the eggs at 35° C. for 44 to 48 hours.

Candle the eggs and select those in which the embryos are still alive.

Chill these overnight in a refrigerator at 4° C.

Harvest the allantoic fluids aseptically and pool.

Test for sterility.

Add Merthiolate to a final concentration of 1:10,000.

Distribute these pooled fluids, or antigens, in 5 c.c. amounts in appropriate containers, and lyophilize in a chamber or manifold drier so that a final moisture content of less than 1% is assured.

When properly sealed to exclude moisture, such antigens are stable during storage for at least three years at refrigerator temperature.

Control Antisera.—

Control antisera are prepared in chickens.

Select roosters weighing 6 to 8 pounds.

Inject both intravenously and intraperitoneally with 5 c.c. amounts of the appropriate freshly harvested allantoic fluids having hemagglutinin titers of 1:320 or greater.

After 10 days, bleed the roosters to the point of exsanguination by cardiac puncture.

Allow the blood to clot.

Cut the clots into small pieces.

Store overnight at 4° C., and 4 or 5 hours at room temperature the following day to facilitate contraction of the clot.

Centrifuge and remove the serum.

Inactivate at 56° C. for one-half hour.

Dispense in 0.5 c.c. amounts in ampules for drying by the chamber or manifold method.

Satisfactory sera are those which (1) have inhibitory titers of 1:800 or greater when tested with the homologous antigen and of not more than 1:100 when tested with the two heterologous antigens; and (2) are obtained from roosters which possess no viral inhibitor prior to immunization.

Properly dried and sealed antisera are stable for at least several years.

Titration of Antigens.—

Before use, rehydrate the standard antigen aseptically with 5 c.c. of distilled water.

Remove a sample of this stock material for the day's work, and store the remainder in a stoppered bottle at 4° C. or preferably at –20° C.

Dilute the sample with 10 parts of physiologic saline.

Allow to stand for 1 hour at room temperature, to facilitate elution of virus from the small amount of particulate matter in the preparation.

Using Kahn tubes, mix 0.5 c.c. volumes of serial twofold dilutions of antigen (1:20 to 1:5,120) in physiologic saline with 0.5 c.c. volumes of a 0.5% suspension of human group O red cells.

Shake thoroughly.

Read the pattern of the sedimented cells after 60 to 70 minutes at room temperature. The tubes must not be disturbed during this period.

The last tube showing hemagglutination is the end point of the titration.

The diagnostic test for influenza antibodies employs 4 units of virus in 0.25 c.c. In the above titration, the agent is contained in 0.5 c.c.

Therefore, the concentration required for the serum test is 8 times that represented as the end point of the virus titer.

Thus, if the last tube showing agglutination contained 0.5 c.c. of a 1:320 dilution, then 8 times this concentration, or a 1:40 dilution, that is, 1:2 of the day's stock or 1:40 of rehydrated antigen, would contain 4 units in a 0.25 c.c. volume.

Erythrocyte Suspension.—

Use human blood, group O, either fresh or preserved not longer than 1 month in Alsever's solution.

Wash three times in saline solution.

For the final centrifugation, place the suspension in a 15 c.c. graduated tube.

Centrifuge at 1,500 r.p.m. for 10 minutes in a centrifuge having a horizontal head with a radius of 5½ inches from axis to trunnion slot.

Withdraw the supernatant fluid without disturbing the packed cells.

Read the volume of cells.

Add enough saline solution to make a 0.5% suspension.

The suspension is usable only on the day of preparation.

Diagnostic Agglutination-Inhibition Test.—

Two serum specimens from each patient must be tested simultaneously with all three types of antigen. The first of these, or the acute phase, is obtained within 2 or 3 days after onset of illness; the second or convalescent serum 10 to 14 days after onset of illness.

Inactivate 0.3 c.c. amounts of the sera to be tested, at 56° C. for 30 minutes.

Dilute each serum 1:8 by adding 2.1 c.c. of saline solution to each.

Use three rows of 10 Kahn tubes in a rack for each serum.

Place in tubes 2 to 10 in the front row 0.75 c.c. of saline.

Leave tube 1 in the front row and all the tubes in the middle and back rows empty.

Place in the first tube of each row 0.25 c.c. of inactivated 1:8 dilution of serum.

Place 0.75 c.c. of the same dilution of serum (1:8) in tube 2 of the front row.

Mix tube 2, front row, and transfer 0.25 c.c. amounts to tubes 2 of the middle and back rows.

Transfer 0.75 c.c. from tube 2, front row, to tube 3, front row.

Mix contents of tube 3, and place 0.25 c.c. amounts in the tubes 3 of the middle and back rows, and 0.75 c.c. in tube 4 of the front row.

Continue in this manner throughout the 10 tubes.

There are now 3 identical series of twofold dilutions, with each tube containing 0.25 c.c. of the serum in dilutions ranging from 1:8 to 1:4096.

Add 0.25 c.c. of properly diluted PR8 test antigen (4 units) to each tube in the first row.

Add 0.25 c.c. of FM1 antigen to each tube in the second row.

Add 0.25 c.c. of Lee antigen to each tube in the third row.

Shake thoroughly.

Add 0.5 c.c. of 0.5% erythrocyte suspension to the serum-antigen mixtures, in each tube.

Shake thoroughly.

Leave the racks undisturbed at room temperature for 60 minutes. Read.

The titer of the serum is the highest dilution which inhibits hemagglutination.

Example: If inhibition is observed in tubes 1 to 7 of the front row, and 1 through 3 in the middle and back rows, the titer would be 1:512 with PR8 and 1:32 with FM1 and Lee antigens.

Controls.—

Standard Antisera:

Antisera from roosters immunized against the PR8, FM1, and Lee strains of influenza virus are used for controls, and are included in each day's tests.

Add 5 c.c. of sterile distilled water containing 1:10,000 crystalline Merthiolate to a specimen of lyophilized inactivated serum, making a 1:10 dilution of the original serum.

Store this stock solution at 4° C. in a sterile, tightly stoppered container.

Remove 0.3 c.c. of the stock for the day's work.

Mix with 2.7 c.c. of saline solution, making a 1:100 dilution.

Perform agglutination-inhibition tests with the standard antisera in the same manner as for unknown sera, except that tubes No. 1 contain 1:100 dilution instead of 1:8.

These controls serve to confirm the identity of the antigen used, and assist in correlating the results obtained in tests performed on different days.

Although the titer of a given serum is inversely affected by changes in the concentration of virus used in the test, the titer of a positive control serum is more regularly reproducible than that of an antigen preparation since it is changed little by minor differences, a unit or more, in the amount of antigen employed. The end point for a given standard antigen should not vary more than a single twofold dilution from that obtained in previous tests.

Retitration of Test Antigen:

A portion of the diluted stock antigen containing an estimated 4 agglutinating units in 0.25 c.c. and used in the agglutination-inhibition test must be retitrated to determine its potency. This is done in the same manner as the initial antigen titration after rehydration except that tube No. 1 receives 0.5 c.c. of the diluted stock. Complete agglutination should occur in the first 4 tubes of the titration.

Interpretation.—

Report results in terms of the titers of each of the paired sera obtained with each antigen.

A fourfold or greater increase in titer with any one of the antigens during convalescence is considered of diagnostic significance.

A rise in titer to both type A and type B virus should be suspected as due to recent vaccination, and a thorough investigation of this possibility should be made.

Concurrent infection in a single individual with both type A and type B influenza virus is a rare occurrence.

Cold Hemagglutination Test in Diagnosis of Primary Atypical Pneumonia

That the cells of an individual may be agglutinated by his own serum has been observed for many years. It was also noted that clumping of these cells was more marked when the blood was chilled; moreover, that this phenomenon seldom occurred at body temperature. In 1943, Peterson, Ham, and Finland first noted that this agglutination reaction was found in cases of primary atypical pneumonia. Numerous contributions have been made since that time, among them that of Humphrey.[1] In this series 93 per cent had positive reactions. In a series of 80 controls, representing patients with upper respiratory and pulmonary diseases, there was no strong reaction. The first positive reactions were noted within 4 to 8 days after the onset, but in some instances the reaction might be delayed until the early part of the third week. The maximum titer usually occurred between the sixteenth and twenty-third days of illness, and became weak or negative between the thirty-fifth and forty-fifth days. There is very little relationship between the titer and the fever, although some parallelism exists between the test, the sedimentation rate, and the x-ray findings.

The advantages of the test lie in the fact that a definite diagnosis can often be made by its use. In certain instances the test may prove to be a means whereby a simple and economic procedure may supplant the more costly chest x-ray films. A disadvantage lies in the fact that the test is not consistently positive in the first week of the illness but it must be remembered that most of the agglutination reactions for other diseases are positive no earlier.

---

[1] U. S. Nav. M. Bull. 43: 1117, 1944.

Technic.—The method described by Humphrey may be accepted as a standardized procedure.

Place 6 drops of blood in a centrifuge tube containing 10 c.c. of 2.5 per cent sodium citrate solution. Mix by inverting the tube. To insure uniformity use a 21-gauge needle with the bevel held downward while the 6 drops from the syringe are delivered.

Place 4 to 6 c.c. of noncitrated blood in a small test tube and permit to clot. If the serum does not separate readily from the clot, centrifuge the specimen.

Centrifuge the cells for 15 minutes at 2,000 r.p.m., pour off the supernatant citrate, and resuspend the packed cells in 2 c.c. of 0.85% saline solution.

Place 0.75 c.c. of physiologic saline solution in a small test tube and add 0.25 c.c. of the serum to make a 1:4 dilution. Add to this 0.1 c.c. of the cell suspension.

Place this small test tube in a rack which is immersed in water and ice, and then place the rack and its container in an ice chest or refrigerator. Under ordinary circumstances the temperature will remain between 1° and 4° C. for hours, but it should be checked by a thermometer immersed in the ice and water mixture.

Allow the tube to remain in the refrigerator overnight and then read. If agglutination is present it will disappear in a few minutes, or at the most within an hour, at room temperature. When the mixture is replaced in the ice bath, it will reagglutinate within a few hours. This reversibility is characteristic and should be employed in doubtful cases.

To Determine Titer.—Make further dilutions by setting up a series of 10 test tubes, placing 1.5 c.c. of 0.85% saline solution in the first tube, and 1 c.c. in each of the remaining nine.

Pipette 0.5 c.c. of the serum into the first tube of the series, transfer 1 c.c., after mixing, to the second, and so on down the line of tubes, discarding the last c.c. from the tenth tube. Dilutions of serum are 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, 1:512, 1:1024, 1:2048.

Add 0.1 c.c. of the patient's own cell suspension to each tube, and place the tube in the ice bath overnight.

Reading the Agglutination Reaction.—Usually the result is definitely positive or negative, but a standard method of agitation should be employed. The tube should be inverted slowly four times, or flicked with the finger a definite number of times before reading. Placing the racks in the Kahn shaker, set at the usual speed, requires approximately 15 seconds, but this refinement is not considered necessary after some practice has been gained in reading.

If the reaction is 3 plus or 4 plus, the heavy clumps float in a clear fluid and quickly settle to the bottom. If the red cells form a solid clump or disk, it is definitely a 4 plus reaction. If the clumps are fine and granular on agitation, but the background is still a clear solution, it should be considered a 2 plus reaction; if the background is faintly pink or pearly it is a 1 plus reaction. Negative reactions show the pink iridescence indicative of individual cell dispersion. If this pearly or nacreous sheen is present in any degree, even in the presence of clumps, it should be considered a negative reaction.

Cultivation of Viruses on the Chorio-Allantois of the Developing Chick

This is discussed fully on pages 1473 and 1745.

THE BACTERIOPHAGE

The Isolation and Cultivation of the Bacteriophage

Explanation of Terms Used.—

A bacteriophage, according to d'Herelle, is an ultramicroscopic living corpuscle which derives its nourishment entirely from the bodies of living bacteria. In its parasitic action against the bacteria, the bacteriophage actually dissolves the bacteria on which it is living. The bacteriophage supposedly multiplies in the bodies of bacteria, just as bacteria multiply in culture media.

The bacteriophage is small enough to pass through the pores of a bacterial filter, such as the Berkefeld filter.

The process of this multiplication at the expense of the bacterial bodies is called **bacteriophagy**. The bacterium acted upon is said to be undergoing the process of bacteriophagy.

Bacteria are said to exert a **resistance** to bacteriophagy in the same manner as an animal body resists bacterial invasion of its tissues.

Virulence of bacteriophages against bacteria may be increased or diminished, just as virulence of bacteria may be changed. By passing bacteriophages successively through bacteria of increased resistance, the degree of virulence of the bacteriophage (produced by these successive passages) increases. Similarly, by placing the bacteriophages under adverse environmental conditions, the virulence may be attenuated.

The bacteriophage corpuscles are found normally in the intestinal tract, and are capable of being isolated from fecal matter. They are also found in secretions and excretions from other parts of the body.

The effect of bacteriophagy on a liquid medium is to render the cloudy medium clear. The effect on solid mediums is similar; that is, ''plaques,'' or bare areas, on the agar may be seen interspersed between the solid bacterial growth. These plaques represent ''colonies'' of bacteriophage corpuscles. After reaching maturity, the plaques do not increase in size.

Isolation of the Bacteriophage*

The isolation of the bacteriophage may be undertaken under one or another of the following circumstances:

1. The bacteriophage may be sought in a sterile fluid, for example, in normal blood, or in an organic fluid collected aseptically. With such no treatment is necessary.

2. The material to be examined may be a clear, but not sterile, liquid. With this, filtration will eliminate the bacteria while the bacteriophage passes through into the filtrate.

3. The material may show a homogeneous turbidity; such as a bacterial culture. Here, direct filtration results in an early occlusion of the pores of the filter candle. Thus, it is desirable to resort to a preliminary filtration. The following method of treatment is most satisfactory.

Provide a funnel with a folded filter paper sufficiently large to receive at one time the entire volume to be filtered.

Fill the funnel with water to which has been added a small amount of infusorial earth.

When the water has passed through, the paper is left coated with a thin layer of the infusorial earth, thus rendering the paper less permeable.

Through this, the material to be examined is filtered, prior to filtration through the candle.

4. The material may be a fluid holding in suspension organic particles, or it may be matter more or less solid in nature. This is the type of substance most frequently examined; such as, fecal material, more or less fluid, pasty, or solid; or excreta admixed to a greater or lesser degree with earth, organic debris, etc. In such case it is necessary to disintegrate as completely as possible the material to be examined. To effect such disintegration the simplest procedure consists in carefully suspending the material in bouillon, about 5 gm. to 50 c.c. of the medium, and incubating this suspension at 37° C. for from 12 to 18 hours. The bacterial fermentations which ensue, because of the divers organisms introduced into the medium, lead to a sufficient disintegration. Upon removal from the incubator the material may be treated, as indicated above, by filtration through infusorial earth and a candle.

If the material under examination contains the bacteriophage and has been subjected to filtration, the bacteriophage will be found in the filtrate.

---

*Condensed from d'Herelle: The Bacteriophage and Its Behavior, translated by George H. Smith: Williams and Wilkins, Baltimore, Md., 1926, pages 37 ff.

Method of Isolation of Bacteriophages

Bacteriophages pass through Berkefeld or Seitz filters and, therefore, may be obtained by filtration of the material from which they are obtained.

They also resist heat at 60° C. If, therefore, there are no spore-bearers present, bacteriophages may be isolated by heating the material from which they are to be derived at 60° C. long enough to kill the vegetative forms of the bacteria.

Assume that the bacteriophage to be isolated is the one which is active against the typhoid bacillus. Obtain the feces from a convalescent typhoid case.

Suspend the feces in broth M-1, about 5 gm. to 50 c.c. medium.

Incubate at 37° C. for 12 to 18 hours.

Filter through infusorial earth, then a bacterial filter.

The bacteriophage, if present, will be found in the filtrate.

Technic of Cultivation

A. **In a Liquid Medium**: Make a heavy inoculation of the selected bacteria in a tube containing 10 c.c. sterile nutrient broth M-2. The broth becomes turbid.

Incubate about 4 hours at 37° C.

Add to this suspension of living bacteria the desired quantity of bacteriophage. The bacteriophage is either derived in the manner described above, or may be purchased from various supply houses. When an active race of bacteriophage is used, 0.05 c.c., or 1 drop, is sufficient quantity for the inoculation. If the strain is new, or unknown, use 1 c.c. of the filtrate from the Berkefeld preparation.

Replace the mixture of bacterial suspension and bacteriophage in the incubator.

Observe the results at the end of each hour, until the medium has become clear. At this point, bacteriophagy is complete. Often bacteriophagy is complete at the end of three hours' incubation.

Quite frequently, after bacteriophagy has apparently taken place to such an extent that all bacteria in the suspension seem to have been dissolved, further incubation leads to the development of secondary cultures. If bacteriophagy is absolutely complete, the tube in which the phenomenon occurred will remain clear indefinitely. In order to prevent the development of secondary cultures, which may obscure the observation of bacteriophagy, as soon as bacteriophagy has taken place (seen by the clearing of the medium), filter the culture through a Berkefeld filter. Transplant the filtrate to cultures of the same species of bacteria as used in the original culture. **Serial passages** of bacteriophage races may be made through suspensions of bacteria in nutrient broth M-2 from an agar culture, as follows:

Inoculate this turbid suspension with the bacteriophage to be cultivated.

Place in an incubator at 37° C. until the suspension becomes clear.

Make another suspension of bacteria in nutrient broth, following the instructions in the preceding paragraph.

Pick up a loopful of the clarified broth (which has just been taken from the incubator), and place in the tube of suspended bacteria.

Place this tube in the incubator at 37° C. until it clears. Repeat this process as often as desired.

The bacteria in each successive suspension should be completely dissolved. If there is possibility that any bacteria remain in the suspension undissolved, filter through a Berkefeld filter. In transferring bacteriophage suspensions, unusual care must be taken to eliminate possibility of air contamination.

In preparing suspensions of bacteriophage corpuscles for therapeutic use, the cultures must be filtered through a Berkéfeld or Seitz filter. It is advisable to filter twice to insure sterility.

B. **In a Solid Medium**: Make a heavy inoculation of 10 c.c. of sterile nutrient broth with bacteria taken from an agar culture. The suspension should be made in such way that it is markedly turbid.

Add a drop of bacteriophage suspension. (If a particularly active bacteriophage suspension is used, it must be diluted many hundreds of times before inoculating the broth. Saline is used as the diluent.)

Mix thoroughly.

Remove a drop of this mixture of suspended bacteria and bacteriophage corpuscles with a sterile dropper with a rubber bulb attached, or a sterile pipette.

Place on the surface of an agar plate. The agar in the plate should not be in too thin a layer, since the products of bacteriophage growth must be absorbed through the culture medium to enable the corpuscles to grow to their fullest extent.

Allow the drop to spread over the surface of the agar plate so that all portions of the plate are covered by the drop.

Incubate at 37° C. overnight.

The bacteriophage present will be seen in isolated glassy-appearing clear areas, or "plaques," over the surface of the agar plate, which is covered, except in the areas of the plaques, by the bacterial growth. If too heavy a suspension of bacteriophage corpuscles has been used in making the inoculation, the entire surface of the agar will present the glassy clear appearance of the isolated bacteriophage patches. In other words, it will present the appearance of a sterile uninoculated plate of agar.

By touching one of the plaques, and inoculating a suspension of bacteria with the bacteriophage corpuscles thus picked up (although the loop will appear as though there is nothing present on it), the bacteriophage may be successively transplanted over an unlimited period of time.

If the layer of bacterial growth is very thick, the plaques made by the growth of the bacteriophage will be correspondingly small.

Another method of inoculating solid media is to make a surface inoculation of the medium with bacteria so that the entire plate has been touched with the inoculating material. Dip a sterile rod into a suspension of bacteriophage corpuscles in broth, and streak with this rod across the surface of the plate.

Incubate the plate at 37° C. overnight.

The bacteriophage will grow in a solid plaque, or clear area, over the portion of agar touched by the rod. In other words, there will be a solid bacterial growth on the plate except in the areas touched by the rod. These areas will appear as if they are sterile.

A Procedure for the Preparation of Autogenous Bacteriophage for Therapy

(SUGGESTED BY NORMAN R. GOLDSMITH, LANCASTER, PENNSYLVANIA)

1. Loops directly from the infected area or material are streaked on an agar plate so as to obtain isolated colonies. A tube of broth is also inoculated. If the organism has been in pure culture, this tube will suffice; if not, a pure culture will be obtained from the plate. If there is more than one type colony, a separate bacteriophage must be prepared for each one, or as many as possible, since it is rare to find a single phage race potent against two organisms from the same source. A working diagnosis of the organism is determined from a Gram-stained smear, the appropriate races of stock bacteriophage being then selected.

2. A tube of pure culture is then allowed to incubate until it is markedly cloudy, but not over twenty-four hours. It is important to remember that the phenomenon of bacteriophage lysis occurs only with young, actively growing organisms.

3. An odd number of test tubes containing about 5 c.c. of medium each is then set up. To each two tubes, a single race of the stock bacteriophage is added, a different race to each pair of tubes, the quantity of phage being about five drops. All work is done with oven-sterilized, cotton-plugged pipettes. Phage lysis is such a variable matter that extreme accuracy, such as the use of absolutely uniform pipettes so as to obtain exactly equal-sized drops, is not a necessity. An approximation of the proportions given here should produce satisfactory results. The tendency is to use too great a quantity of phage. This often results in an impaired permanency of lysis.

4. One drop of the pure culture of bacteria is then added to each of the tubes containing phage; and to the remaining odd tube which serves, first, as a control of bacterial growth uninfluenced by phage, and, second, as the source of the pure culture for the next generation.

5. The tubes are then incubated until the above control tube is very definitely cloudy. A comparison with the tubes containing phage is then made. Certain pairs of tubes will be found to be less turbid than the control. The degree of lessened turbidity will vary greatly from almost complete clarity to a turbidity indistinguishable from the control. The tubes which are less turbid than the control are those in which some degree of phage action is taking place.

6. If no tubes appear to be less turbid, either the strain of bacteria is resistant to all the races of bacteriophage tested against it, or the degree of lysis is too small to be noticed by the ordinary eye. Ability at detecting extremely slight degrees of turbidity variation is achieved after considerable experience. A method of determining whether phage is present, which at times is effective, is to streak on agar a loop from the phage-inoculated tube beside one from the control tube. A dissimilarity between the two streaks, with a moth-eaten appearance on the streak from the phage-inoculated tube, is indicative of the presence of bacteriophage plaques. A more potent phage, sufficient to produce macroscopic clearing, may then be produced by the serial filtration method to be described. It must be remembered that certain strains of bacteria are absolutely resistant to any races of bacteriophage known today, and a certain percentage of failures is unavoidable.

7. The serial filtration method increases the specificity and potency of a given bacteriophage for a given organism. (There are a number of types of filter on the market; the most satisfactory in our hands has been the Chamberland-Pasteur, the technic being similar to that described in d'Herelle's ''The Bacteriophage and Its Behavior,'' 1926, p. 22. Many laboratories use the Berkefeld or others with excellent results.)

From each pair of partially lysed tubes, one is taken and filtered. The remaining tube is kept for observation of lysis permanency. The tubes are filtered through the same filter, thus producing a pooled filtrate of the most virulent races of phage for that particular organism.

8. Three tubes are now set up. To two of these, five drops of the filtrate are added. One drop of the previous control tube, provided it is not too old, is now added to each of the tubes containing the filtrate and to the remaining tube which in its turn becomes the untreated bacterial control. The remainder of the filtrate is put in a sterile tube and serves as an automatic check of phage sterility or as a reserve in the event of some unforeseen difficulty or failure.

9. The tubes are now incubated together. This time, the contrast between the phage-treated tubes and the control should be greater, and lysis should last for a longer period. Again, one of the lysed tubes is filtered, and the other kept for permanency observation. There is no arbitrary time rule when to filter the tubes. The period varies with each organism. In general, twenty-four hours is too long when first developing a phage, and filtrations should be made between four and eight hours after planting, else a secondary growth will appear in the tubes temporarily cleared, and the process will have to be repeated.

10. Another set-up of three tubes is made. The filtrate from step 9 is added in 5-drop amounts to two tubes; one drop of the previous control is added to them and to the remaining tube, which, in its turn, is to serve as bacterial control; the remainder of the filtrate is stored and tested for sterility. Tubes are then incubated.

11. This process of repeated filtrations is continued until a filtrate is obtained which produces a lysis persisting for twenty-four hours or more. This may necessitate as many as 10 separate filtrations, but three to six is the average. (Obviously, in emergency work this ideal cannot be obtained, but when time permits, better therapeutic results will be obtained with a highly potent phage rather than a weak one.)

12. A large volume can now be prepared. Add 2 c.c. of the last filtrate to 100 c.c. of media in an Erlenmeyer or Florence flask. Then add about 21 drops of the previous bacterial control. Tubes are also prepared for a new bacterial control and for a retest of lysing permanency using similar proportions. At times, a cleared flask will again become cloudy. Do not discard this immediately unless it contains an obvious contamination. Often it will clear again, and a filtrate of this second clearing usually yields an extremely potent phage. If the flask does not reclear, it should be discarded and another flask planted.

13. The contents of the flask, if clear, are filtered and the filtrate is transferred with a sterile 10 c.c. pipette into sterile tubes in 10 c.c. amounts. This is for local therapy. Other 10 c.c. quantities are put into rubber-stoppered vaccine bottles for intradermal, subutaneous, or intravenous use, or shipment. The tubes and ampules are incubated in their entirety for twenty-four hours. Any which are not absolutely crystal clear are discarded.

14. Simultaneously, the titer of the bacteriophage may be determined. Then tubes containing exactly 4.5 c.c. of media are set up. To the first of these, exactly 0.5 c.c. of the previous filtrate is added and mixed. This gives a 1:10 dilution. Half a c.c. of this is transferred to the next tube, and so on, the dilution in the tenth tube being 1:10,000,000,000. To each of the tubes, and a control tube, one drop of the previous control is added. Observations as to what dilution lysis is present and permanent are made. An agar slant of the organism is made in order to keep the specific strain in the event of more autogenous phage being required.

15. The tubes which have been kept as a test of lysing permanency, if still clear, are now pooled and filtered together. This usually gives an extremely efficient phage. It is added to our stock of phage races and is used in testing new strains of bacteria.

Criteria for supplying bacteriophage: If the tubes are sterile, if cultures keep clear for 24 hours, and if the titer against the organism is at least $1:1 \times 10^{-7}$.

CHAPTER XI

MEDICAL MYCOLOGY

CHESTER W. EMMONS, PH.D.*

The lowest class of the plant kingdom, the Thallophyta, includes the Algae, which possess chlorophyll and therefore are autotrophic, and the Fungi, which lack chlorophyll and therefore are saprophytic or are parasitic on other plants or on animals. The Fungi include Schizomycetes (bacteria), Myxomycetes (slime fungi), and Eumycetes (true fungi).

The true fungi present a great variety of forms, including simple, unicellular, spherical, or elliptical cells which reproduce by budding (as in the yeasts), multicellular but microscopic organisms consisting of tubular, septate filaments which bear spores in various ways upon specialized hyphae or in complex fruiting structures (as in the molds), and those fungi which produce large, conspicuous reproductive structures (the mushrooms, toadstools, bracket fungi, etc.).

Numbering some 200,000 species, the true fungi are classified among Phycomycetes, Ascomycetes, Basidiomycetes, and Hyphomycetes. The Hyphomycetes are also called "fungi imperfecti" because they have only a vegetative or asexual type of reproduction without a known antecedent nuclear fusion. When study of the life history or chance observation reveals a more definitive type of reproduction in a member of this group, it is transferred to one of the three other groups. Most of the fungi pathogenic for man remain in this group, the life histories of which are incomplete or are incompletely known. Martin[1] has written a useful outline on classification of the fungi and the student may refer to Bessey's[2] authoritative text for a more detailed exposition of the principles of general mycology. An excellent handbook in medical mycology has been prepared by Conant and associates.[3]

The following **glossary** may be useful. A complete and authoritative glossary is to be found in Ainsworth and Bisby's *Dictionary of the Fungi.*[4]

Hypha.—A tubular, branching filament divided by cross walls (septa) into cylindrical cells. In some fungi septa are very infrequent.

Mycelium.—The mass of branching, frequently anastomosing hyphae which make up a colony of a fungus.

Conidium.—A spore borne externally, either terminally or laterally, on a hypha which may be morphologically specialized (a conidiophore). Conidia may be borne singly, in clusters, or in chains, they may be unicellular or multicellular, and they vary greatly in size, shape, and color.

Macroconidium.—The larger of two types of conidia produced by a given fungus (e.g., the "fuseaux" of the dermatophytes).

---

[4] Ainsworth, G. C., and Bisby, G. R.: A Dictionary of the Fungi, Kew, 1950, The Commonwealth Mycological Institute.

Endospore.—A spore abstricted within a tubular mother cell.

Sporangiospore.—A spore borne by "progressive cleavage" within a mother cell, the sporangium.

Arthrospore.—A spore formed by septation of a hypha. These may remain cylindrical or may round up into barrel-shaped or even elliptical cells.

Chlamydospore.—A thick-walled, intercalary or terminal resting spore.

Blastospore.—A term sometimes applied to the budding cells of a yeast, which are actually not spores but vegetative cells.

Conidiophore.—A specialized hypha which bears conidia.

Ascospore.—A spore formed by "free cell formation" within a mother cell (ascus), following a nuclear fusion and a subsequent reduction division. Typically there are 8 ascospores per ascus.

Basidiospore.—A spore borne externally on a basidium, following a nuclear fusion and subsequent reduction division. Typically there are 4 basidiospores per basidium.

Zygospore.—A spore formed by the fusion of two specialized hyphal tips with subsequent nuclear fusions.

Characteristics of Mycoses

Mycoses may be classified as superficial or systemic, although this is not a rigid scientific classification and many of the systemic mycoses commonly have skin manifestations.

The superficial mycoses include the dermatophytoses (ringworm, tinea, athlete's foot), a group of infections involving the skin and its appendages and caused by a group of related fungi. Thrush is another predominantly superficial mycosis involving the mucous membranes but it sometimes becomes systemic. Some mycoses invade the subcutaneous tissues (chromoblastomycosis) while others are truly systemic and invade any tissue of the body (coccidioidomycosis, blastomycosis, histoplasmosis). To varying degrees most of the pathogenic fungi are dimorphic, growing in one form in tissue or body fluids and with very different and usually richer morphology in culture. Therefore direct microscopic examination of exudates or sections and of cultures is essential in the identification of a fungus.

Saprophytism; Laboratory Infections

Recent research studies have emphasized the saprophytic sources of infection in the mycoses. An understanding of this is pertinent to the laboratory study of the pathogenic fungi. Contagion plays a minor or negligible role in the systemic mycoses and the infecting fungus is usually acquired from a saprophytic source in the environment of the patient rather than from another person. It follows that when a fungus is grown in the laboratory it reverts to its natural saprophytic state, produces large numbers of infectious spores, and becomes a potential hazard unless it is handled with caution. Laboratory infections with Coccidioides are especially frequent. Fortunately most of these have been benign, but clinical severity of a laboratory infection appears to be related to intensity of exposure. It therefore is important that the mycologist in a diagnostic laboratory observe certain precautions. Manipulations of cultures should be carried on so far as possible under a hood. Cultures should be maintained on agar slants rather than on Petri dishes, but if cultures must be made in Petri dishes the fungi should be transferred while colonies are young. The opening of an old plate culture endangers laboratory personnel if a pathogen is present and unnecessarily contaminates the laboratory if miscellaneous harmless molds are present.

HISTOPATHOLOGIC METHODS

Fungi are poorly differentiated in tissues by the routine histopathologic stains, and when present in small numbers may be overlooked. Staining schedules utilizing the Schiff reagent clearly demonstrate fungi, although mucin and other nonfungal elements in some tissues also stain. The Bauer[1] and Hotchkiss-McMannus technics are useful applications of this method to the study of mycotic lesions. Kligman and Mescon[2] have recommended the following schedule for the staining of fungi.

Schedule for Staining of Fungi.—

1. Fix.
2. Dehydrate.
3. Deparaffinize sections and dehydrate through absolute alcohol.
4. Wash in distilled water.
5. Immerse in 1% periodic acid for 5 minutes.
6. Wash in running tap water for 15 minutes.
7. Stain in Schiff reagent for 10 to 15 minutes.
8. Transfer directly to two changes of the following solution for 5 minutes:

10% potassium metabisulphite	5 c.c.
1 N hydrochloric acid	5 c.c.
Distilled water	100 c.c.

9. Wash in running tap water for 10 minutes.
10. Counterstain with light green.
11. Dehydrate, clear, and mount.

Schiff Reagent.—

Dissolve 0.5 gm. of basic fuchsin by pouring over it 100 c.c. of boiling distilled water.

Cool to 50° C.

Filter and add 10 c.c. of 1 N hydrochloric acid and 0.5 gm. of anhydrous potassium metabisulphite to the filtrate.

Allow the solution to stand in the dark overnight. The solution should become colorless or pale straw color.

If not completely decolorized, add 0.25 to 0.50 gm. of charcoal, shake thoroughly, and filter immediately.

This solution will keep for several weeks in a tightly stoppered bottle.

The above schedule may be modified by the use of hematoxylin as a counterstain.

COLLECTION OF SPECIMENS

A few general principles governing collection of specimens will be emphasized by consideration at this point, although many of them will be repeated later in connection with discussion of specific mycoses. Except in the case of dermatophytosis, where a limited degree of drying is not detrimental and may, on the contrary, be beneficial by destroying some of the bacteria, it is important to insist upon fresh specimens. In the case of pulmonary disease, a freshly collected sputum specimen, preferably an early morning specimen, is essential. In a 24-hour specimen, growth of bacteria may occur in dense colonies, giving rise to a false diagnosis of actinomycosis. The bacterial growth may kill delicate fungi by antibiotic activity or at best interfere with the isolation of a fungus, although the addition of penicillin and streptomycin may overcome this handicap to a considerable extent. On the other hand, certain fungi such as *Candida albicans, Mucor,* and *Cephalosporium* grow readily and rapidly in sputum at room temperature, and the early appearance of many colonies on the culture slant will then lead to an erroneous estimation of their importance in the flora of the sputum and may obscure the primary etiology by overgrowing the actual pathogen. Prompt handling of other body fluids, pus, surgical material, and autopsy tissues is also desirable.

[2] Kligman, A. M., and Mescon, H.: J. Bact. 60: 415, 1950.

PREPARATION OF CULTURES

Modified Sabouraud's agar (2 per cent glucose, 1 per cent neopeptone, 2 per cent agar, pH 6.5) is a satisfactory culture medium for most pathogens except *Actinomyces bovis.* For culture of sputum, ulcers, or draining pus, where bacterial contamination interferes with isolation of the fungus, penicillin and streptomycin should be added to the culture medium (after autoclaving) at a level of 40 to 60 units of each antibiotic per c.c. of agar. This culture medium must be stored in a refrigerator to retard inactivation of the antibiotics. The addition of Actidione (0.5 mg. per c.c.) to a medium is effective in retarding the growth of some saprophytic molds, while it permits the growth of such a pathogen as Coccidioides. Cultures may be incubated at room temperature, but incubation at 30° C. will enable earlier reading of the culture. Most of the fungi causing mycoses will grow at 37.5° C. in the laboratory, but primary isolation at this temperature is uncertain. Growth of most pathogens will be apparent after a few days but cultures should not be discarded as negative until they have been held at least one month.

EXAMINATION OF CULTURES

The experienced mycologist may be able to recognize a specific fungus by its characteristic appearance in a plate culture. In fact the rate of growth, surface configuration, texture, and color are major identifying characteristics among some species of dermatophytes. However, the primary basis for the identification of a mold is its microscopic morphology, particularly the size, shape, septation, and color of spores, and the manner in which spores are borne. It is essential, therefore, that a culture be examined when sporulation is most characteristic and the optimum time will vary, with the species, from 3 days to 3 weeks. It is generally useful to make the first examination when sporulation has just begun.

Drying and staining methods used in the study of bacteria are not useful.

The mycelium should be teased apart in a drop of mounting fluid and for this purpose two sharp, stiff, nichrome needles are essential. With one needle a bit of mycelium is picked up, touched to a drop of 95 per cent alcohol on the slide, and transferred immediately to an adjacent drop of 10 per cent sodium hydroxide.

With the two needles it is then gently spread in the drop.

The function of the alcohol is to wet the mycelium and eliminate air bubbles. Many mycologists prefer to use lactophenol and cotton blue as a mounting medium.

Lactophenol and Cotton Blue.—

Phenol crystals	20 gm.
Lactic acid	20 c.c.
Glycerol	40 c.c.
Distilled water	20 c.c.

Dissolve by heating over hot water. Add 0.5 gm. cotton blue.

ANIMAL INOCULATIONS

The inoculation of mice or guinea pigs for isolation of a fungus has a limited usefulness. It is effective in histoplasmosis, sporotrichosis, cryptococcosis, and coccidioidomycosis, and may be useful if the pathologic material is contaminated by saprophytic molds which are not inhibited by antibiotics added to the medium. Inoculation directly into the guinea pig testis sometimes produces an earlier infection than by other routes. In the case of histoplasmosis, the white mouse is a very susceptible animal and intraperitoneal injection of pus, ground tissue, or sputum is an effective method of isolating Histoplasma from contaminated material. Since sputum may contain pneumococci which cause early death of mice, penicillin (500 units per c.c. of sputum) should be mixed with the sputum before injection. Sacrifice the mouse 3 to 5 weeks after inoculation and make cultures from liver, spleen, omentum, and any abscesses or other lesions found.

The mouse is useful in the differentiation of virulent strains of *Cryptococcus neoformans* from morphologically similar nonpathogenic fungi. If 0.03 c.c. of a saline suspension containing 10,000 cells of a virulent strain is injected intracerebrally the mouse dies in 4 to 10 days and the encapsulated cells of *C. neoformans* are easily seen when a bit of brain tissue is crushed under a cover slip and examined microscopically. Mice similarly inoculated with avirulent strains or with yeasts survive, and cultures made from the brain after one month are usually sterile.

DERMATOPHYTOSIS

(Ringworm, Tinea, Athlete's Foot)

Dermatophytosis is caused by the invasion of the skin, hair, or nails by one of several closely related keratolytic fungi known collectively as dermatophytes. Lesions may be characterized by barely perceptible scaling of glabrous skin or palmar surfaces, extensive scaling with infiltration at the advancing border, vesiculation, or dense boggy areas, depending upon the species of fungus involved and the reaction of the host. Lesions involving the scalp may present alopecia, areas showing many broken hair stubs, or infiltrated areas (kerion). Infections of the nails (onychomycosis) may be characterized by thickened nails or chalky degeneration of nail tissue sometimes resulting in almost complete destruction of the nail.

In all types of dermatophytosis microscopic confirmation of the presence of a fungus and its isolation in culture are essential in the differential diagnosis. Clinical differentiation from dermatitis is often impossible.

Collection of Material

In lesions of the skin, thorough cleansing of the lesions with 70 per cent alcohol is desirable. This removes much of the superficial dead tissue in which the fungus cannot be demonstrated readily, it eliminates many contaminating bacteria and saprophytic mold spores, and it may remove ointments which make microscopic examination difficult. Specimens should be taken by stripping back the epidermis at the advancing edge of the lesion with forceps. If vesicles are present the roof of a vesicle may be clipped off with scissors, although many vesicular lesions represent an allergic reaction and are sterile. Nails should be scraped deeply to obtain freshly invaded tissue. In lesions of the scalp broken hair stubs should be collected. The selection of infected hairs can be facilitated by the use of a filtered ultraviolet lamp (Wood light) under which infected hairs fluoresce. Epidermal scales, nails, and ointments also fluoresce with varying degrees of brilliance and may confuse the inexperienced.

Specimens taken as suggested above are suitable for either direct microscopic examination or culture.

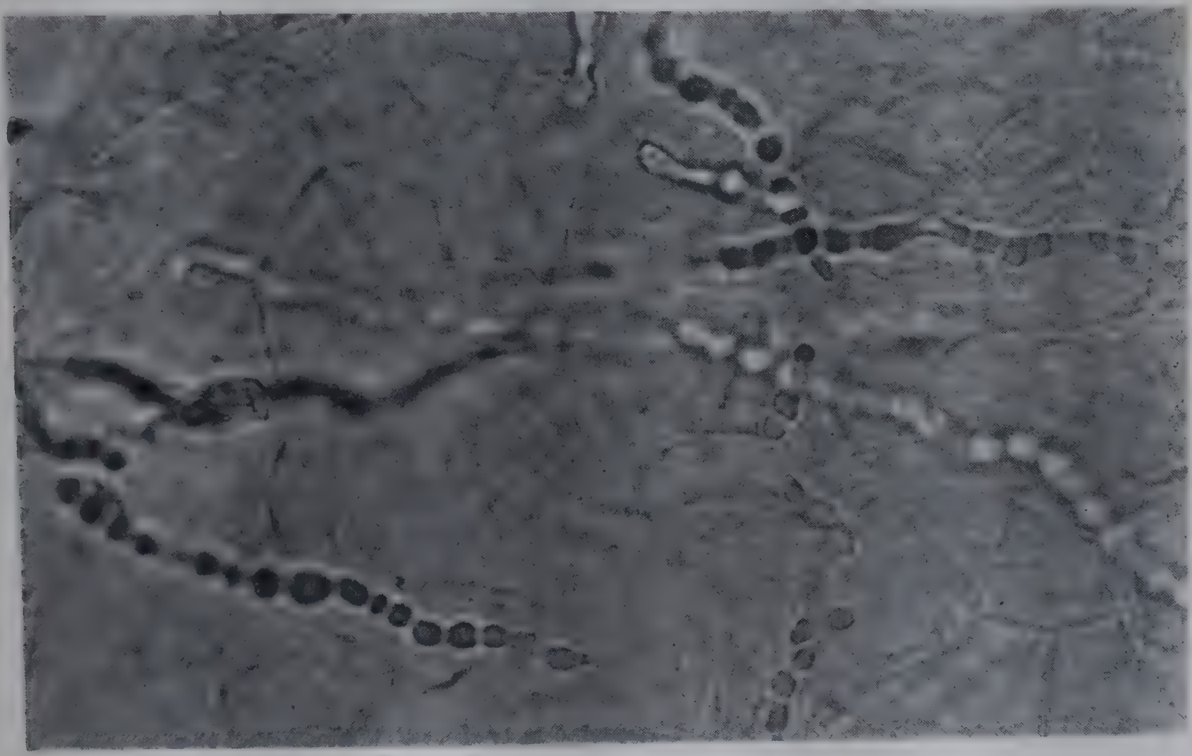

Fig. 412.—Hyphae of Trichophyton in epidermis. (×500.)

Microscopic Examination

Place the specimen (small pieces of epidermal scales, finely divided nail or hairs) on a microscope slide in a drop of 10 per cent sodium hydroxide, put a cover glass in place, heat the slide for a few seconds over a low flame until the specimen softens (but without boiling), and then examine under the microscope.

In epidermal scales and nails the fungus is seen as branching hyphae running through and between epidermal cells (Fig. 412). It is necessary to differentiate borders of epidermal cells, "mosaic fungus," and fibers. The "mosaic fungus" (Fig. 413) is an artefact consisting of cholesterol deposited in a mosaic pattern between epidermal cells.

Cotton fibers can be differentiated from dermatophyte hyphae by their flatness and varying width, wool fibers by their pattern of overlapping cells, and nylon and silk by the absence of cross walls and branching.

In hairs the hair shaft is usually invaded and, depending upon the species of fungus, there may or may not be a sheath of arthrospores outside the hair shaft.

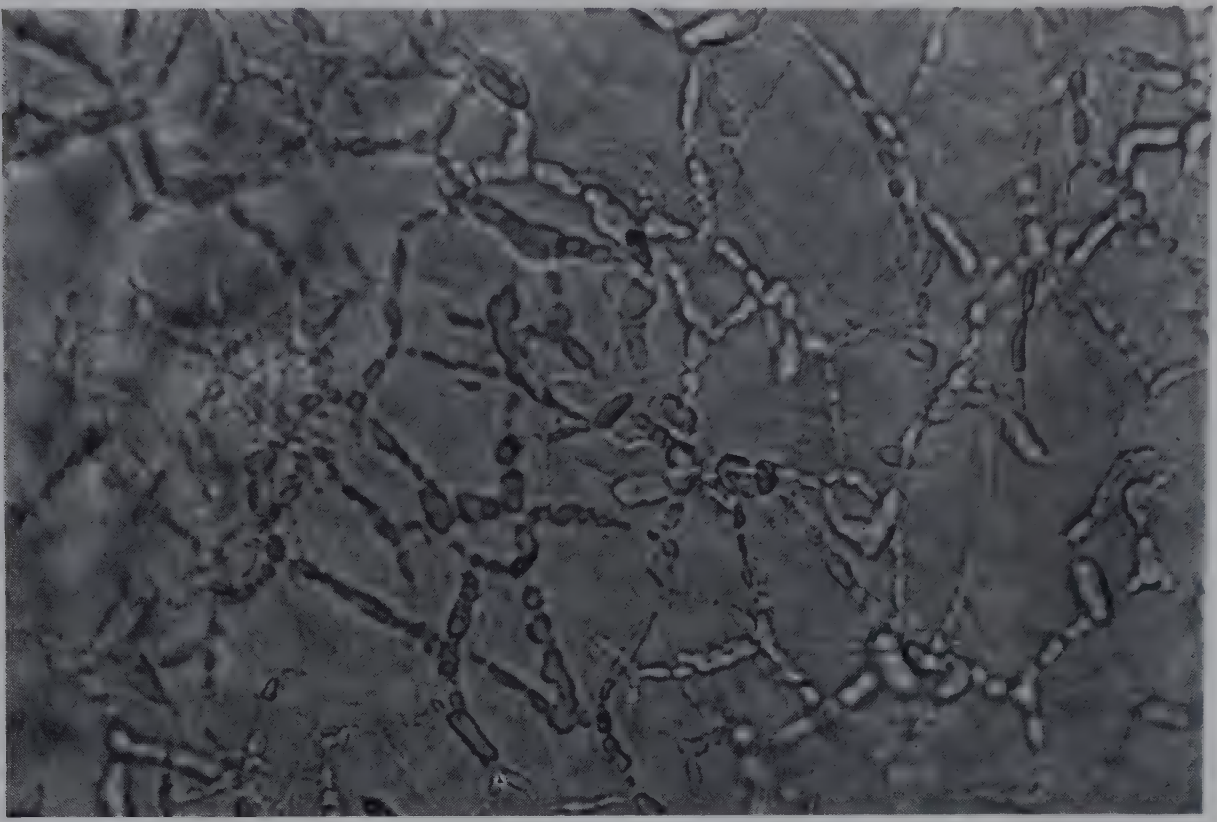

Fig. 413.—"Mosaic" consisting of cholesterol, an artefact to be differentiated from fungus hyphae. (×500.)

Cultures

Specimens may be planted on Sabouraud's agar, fortified with penicillin and streptomycin as indicated above. If it is inconvenient to use antibiotics in the medium, contaminating bacteria can be effectively eliminated from small epidermal and nail specimens by immersion in 70 per cent alcohol in a Petri dish. The bactericidal action of 70 per cent alcohol is greater than its fungicidal action. Begin transferring specimens to agar slants after 2 minutes' exposure to the alcohol, and take the final specimens before 8 minutes have elapsed. Cultures should be incubated at 30° C. or room temperature. Many dermatophytes grow promptly and can be identified in 7 to 10 days, but cultures should be held for one month before being discarded as negative.

Classification of Dermatophytes

Medical literature contains several hundred binomials for the dermatophytes. Most of these names are the result of taxonomic revisions or the creation of a new specific name on the basis of a slight variation in some characteristic. Modern usage based on mycologic criteria has reduced the number of genera to three: Trichophyton, Microsporum, and Epidermophyton.[1] The salient features of these three genera are illustrated in Fig. 414. There are perhaps 15 or 20 valid species.

---

[1] Emmons, C. W.: Arch. Dermat. & Syph. 30: 337, 1934.

TRICHOPHYTON Malmsten 1843

Trichophyton is the largest of the three genera in number of species and in frequency with which it attacks man. In lesions of the epidermis, Trichophyton produces branching hyphae which break up into arthrospores by septation and there are no characteristics which differentiate it from the other two genera. In the scalp, some species of Trichophyton which attack the hair produce also a sheath of spores surrounding the hair shaft. These spores are arranged in a linear pattern easily differentiated from the mosaic pattern seen in Microsporum infection (Fig. 415).

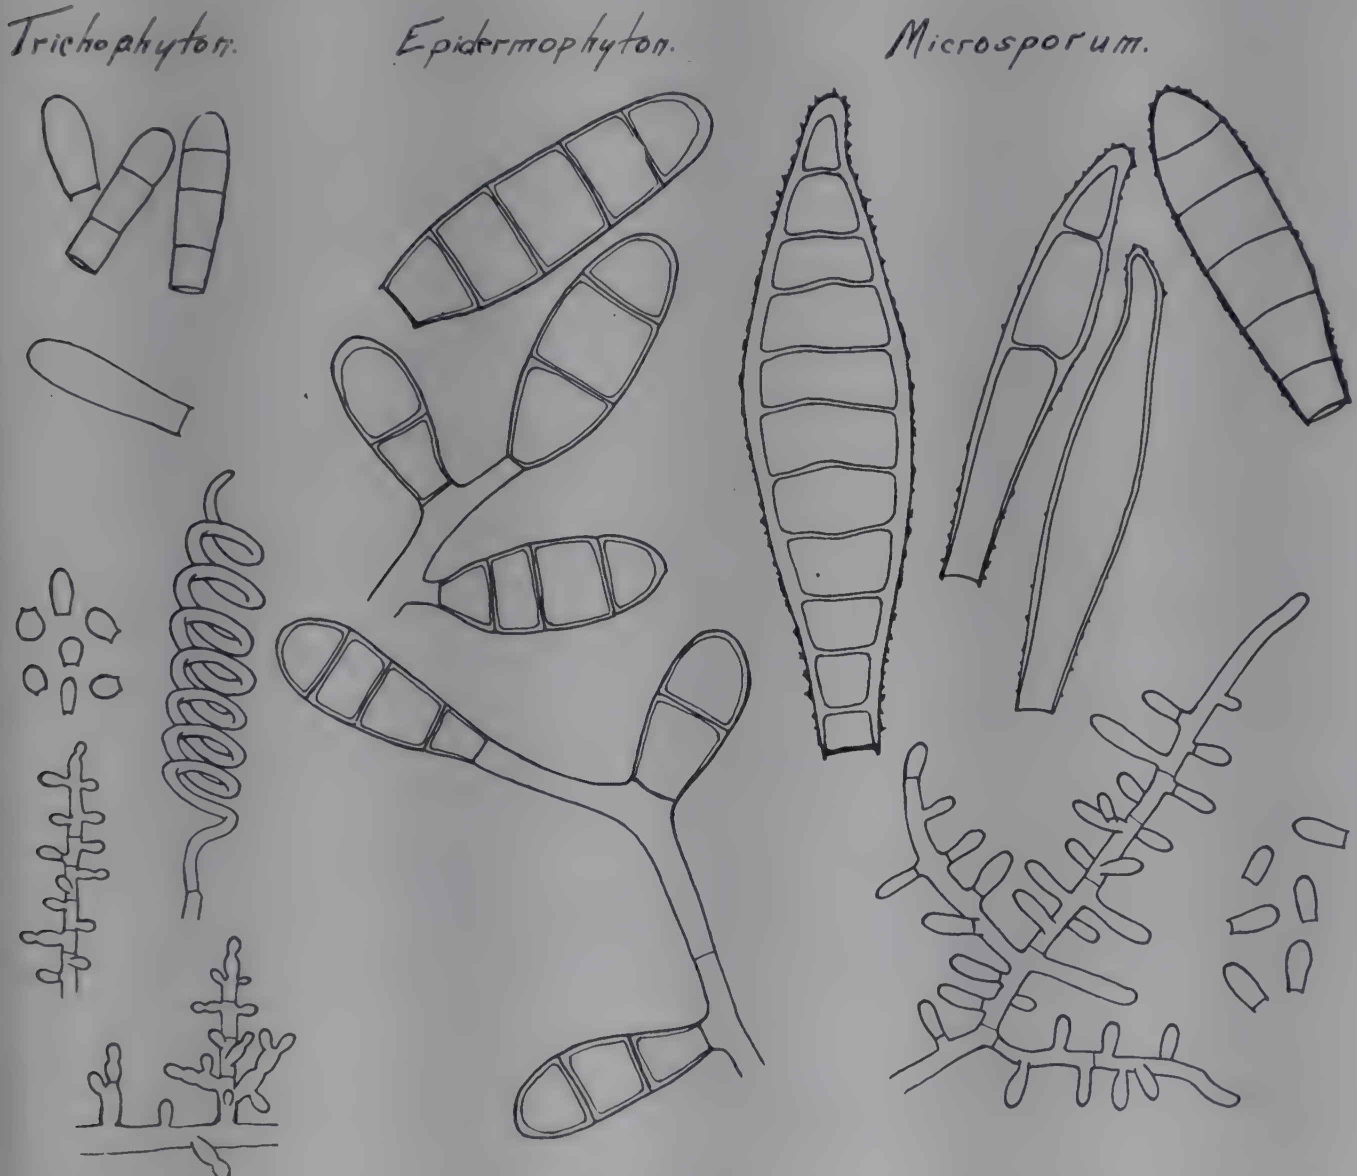

Fig. 414.—Differential characteristics of the three genera of dermatophytes. The macroconidia of Microsporum represent, from left to right, *M. canis*, *M. audouini*, and *M. gypseum*. (×450.) (Adapted from Emmons, C. W.: Arch. Dermat. & Syph. 30: 337, 1934.)

Trichophyton is characterized by conidia which average 2 by 2 to 4 microns, are single-celled, hyaline, thin-walled, subspherical to clavate (club-shaped), and have a broad base at the point of attachment to the conidiophore, and by macroconidia which are 4 to 6 by 10 to 50 microns, with a blunt distal end, one to several-celled, with smooth, relatively thin walls. The shape and septation of the macroconidia differentiate Trichophyton from Microsporum and Epidermophyton. The conidia are borne laterally on the hyphae or on simple or branched conidiophores (Figs. 414, 416).

Trichophyton mentagrophytes (Robin) Blanchard, 1896 *(T. gypseum, T. interdigitale)*, is the commonest species of the genus. It includes several varieties which produce colonies varying in texture from chalky to floccose (Fig. 417). The color of a colony varies usually from white to cream, but some strains develop pink to brownish shades. It is one of the etiological agents of athlete's foot, onychomycosis, kerion, and tinea circinata of the type acquired from animals.

Trichophyton rubrum (Castellani) Sabouraud, 1911, is characterized by narrow, clavate macroconidia and production of a red pigment. It is associated with athlete's foot, onychomycosis, and tinea cruris and has a tendency to become generalized over the body, particularly in skin folds and about the waist. Although it appeared at one time to be largely subtropical in distribution, it now commonly seen over the United States.

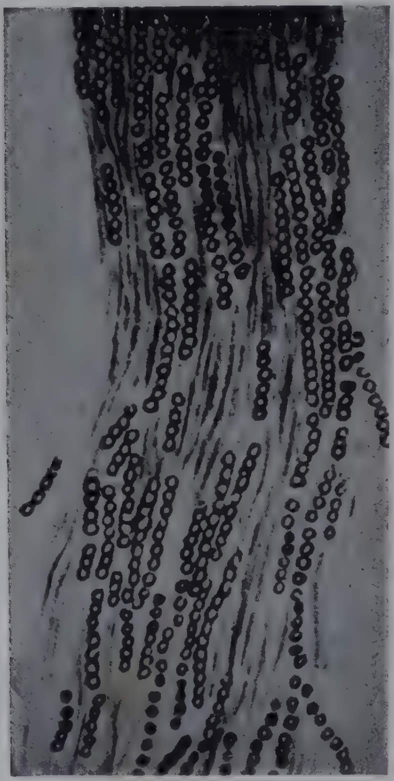

Fig. 415.

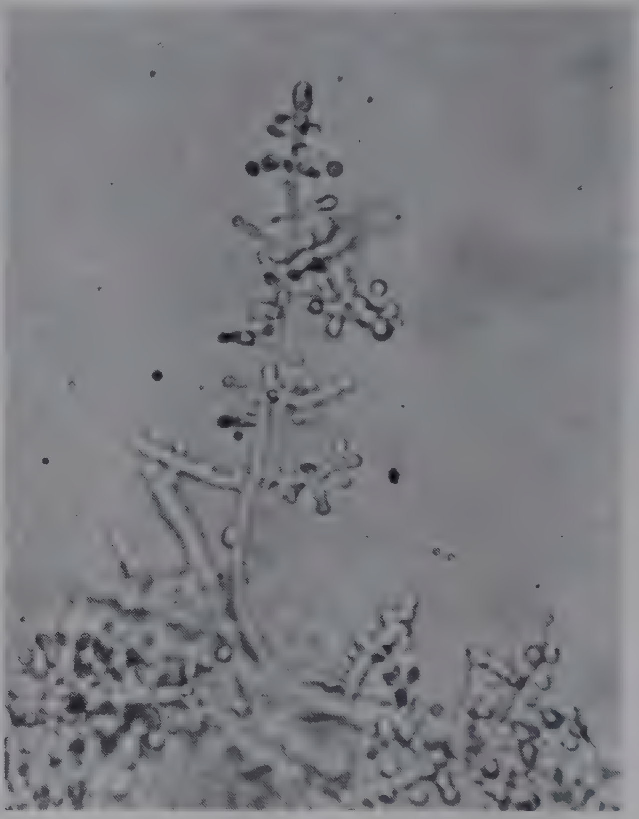

Fig. 416.

Fig. 415.—*Trichophyton gypseum asteroides* in hair. (From Bruhns-Alexander: Grundriss der mykologischen Diagnostik, Julius Springer, Berlin.)

Fig. 416.—Conidiophore and conidia of *Trichophyton mentagrophytes*. (×250.)

Trichophyton tonsurans Malmsten, 1845, is representative of a group of species associated primarily with ringworm of the scalp. Growth is slow, colonies develop short aerial mycelia, and the surface of the colony is folded, often in a characteristic concentric, radial, or cerebriform pattern. Conidia show somewhat more variation in size than the preceding species but are otherwise similar, and macroconidia are rare.

Trichophyton schönleini (Lebert) Langeron and Miloch., 1930, causes favus. Growth is slow, producing glabrous, wrinkled, and folded colonies with relatively poor production of spores. *Trichophyton verrucosum* Bodin, 1902 *(T. faviforme)*, resembles *T. schönleini* in culture characteristics, and represents the "faviform group" of dermatophytes which are primarily pathogens of cattle but are seen in men having contact with cattle. For a fuller description of these and other species the reader is referred to Conant and associates.*

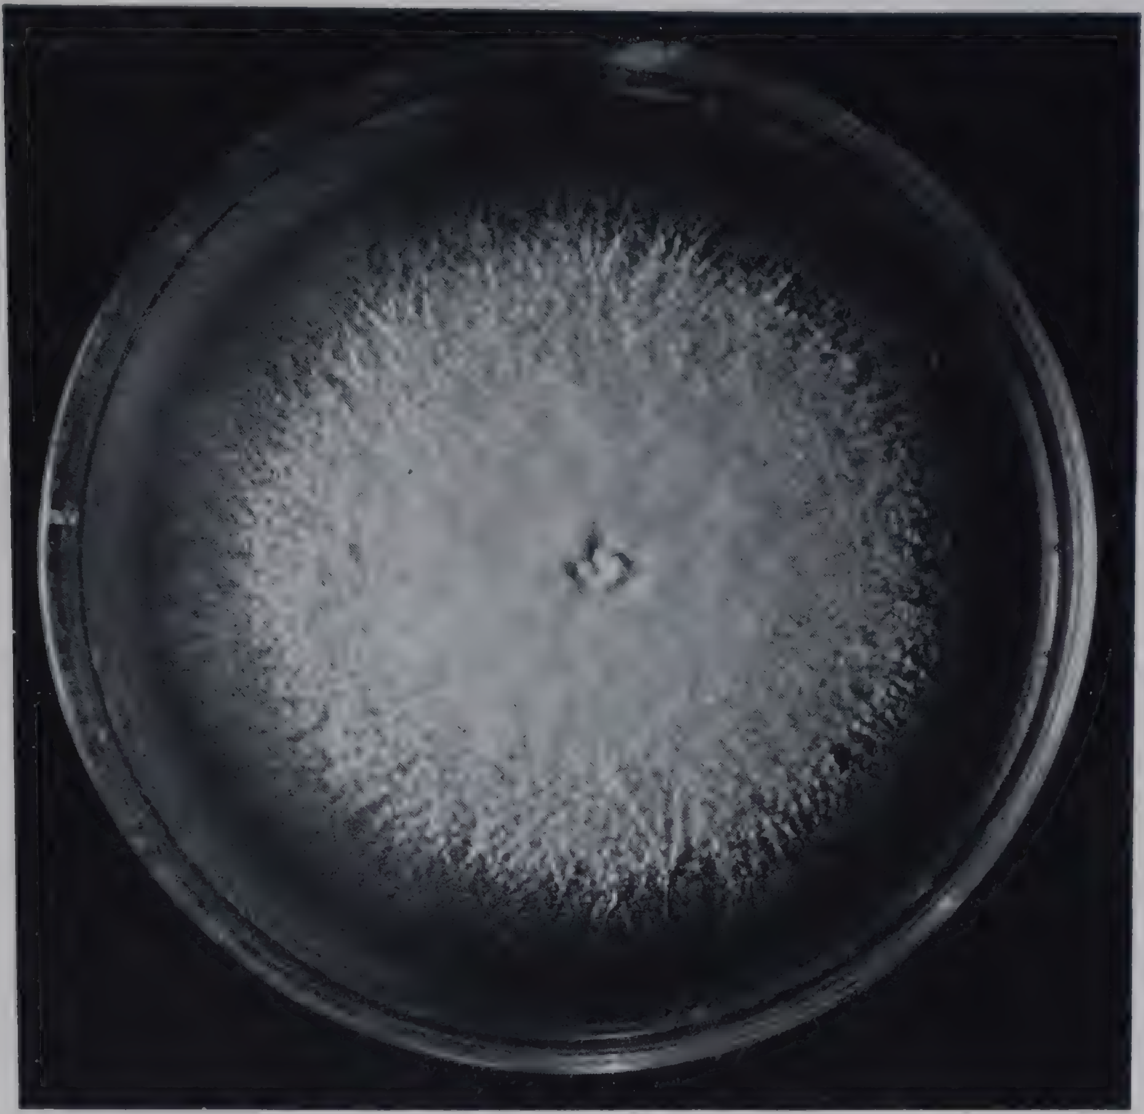

Fig. 417.—Colony of *Trichophyton mentagrophytes* after 2 weeks' incubation at 30°C. on Sabouraud's agar.

MICROSPORUM Gruby 1843

Microsporum causes ringworm of the scalp and occasionally circinate lesions of the glabrous skin. In lesions of the epidermis Microsporum cannot be differentiated from Trichophyton, but in lesions of the scalp there is a characteristic appearance in the hair. The hair shaft is invaded, as in Trichophyton, but the spores on the surface of the hair are arranged in a mosaic pattern easily differentiated from the linear arrangement of Trichophyton arthrospores (Fig. 418).

The genus is characterized in culture by conidia which are somewhat larger and more generally clavate than those of Trichophyton (2 to 3 by 4 to 6 microns) and more particularly by large spindle-shaped macroconidia 8 to 16 by 35 to 160 microns in size (Fig. 414). The walls of the macroconidia are thick and marked with spines or warts on the external surfaces, especially toward the narrow, pointed ends.

Microsporum canis Bodin, 1902 *(M. felineum, M. lanosum)*, is a zoophilic species which commonly causes ringworm in cats and dogs and these hosts are the usual sources of infection in the sporadic human cases of ringworm caused by this species. It grows rapidly, producing a floccose colony with a characteristic yellow color, and it bears large numbers of macroconidia. These have 8 to 15 cross walls which are sometimes diagonally oriented (Fig. 414). A varietal form differing in absence of the typical yellow color is sometimes isolated.

---

*Loc. cit., p. 1764.

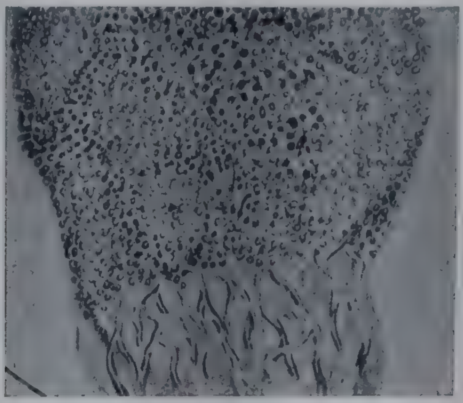

Fig. 418.—Hair infected with *Microsporum audouini.* (From Bruhns-Alexander: Grundriss Grundriss der mykologischen Diagnostik, Julius Spring, Berlin.)

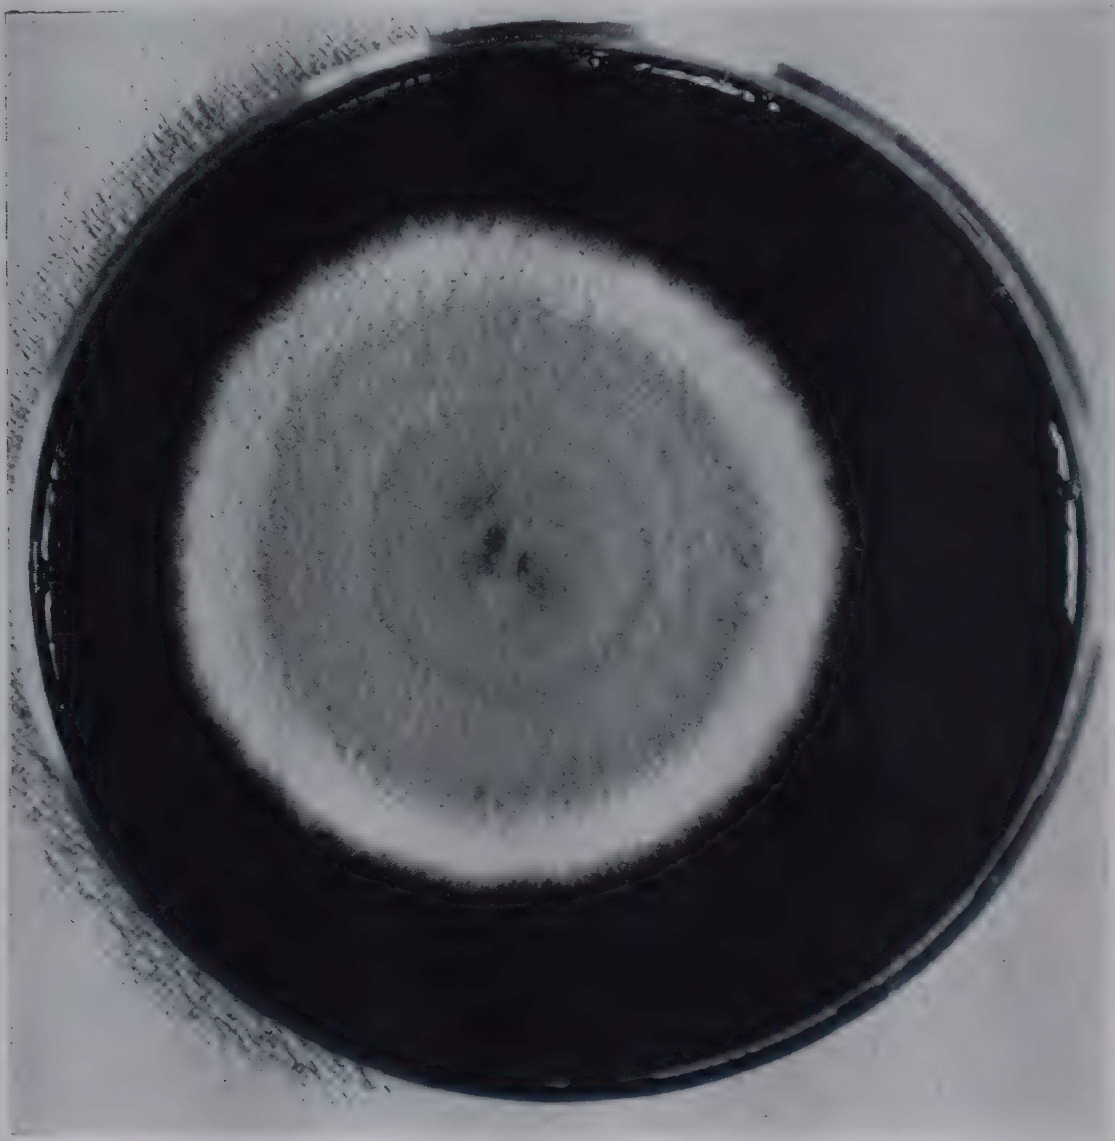

Fig. 419.—Colony of *Microsporum gypseum* after 2 weeks' incubation at 30°C. on Sabouraud's agar.

Microsporum audouini Gruby, 1843, is the cause of epidemics of ringworm of the scalp in children. Spontaneous recovery occurs at the age of puberty and the species is rarely isolated from adults. The fungus grows rather slowly and produces a gray to brownish, velvety colony and a reddish brown pigment in the reverse side of the colony. Sporulation is sparse and macroconidia are rare and usually small, bizarre in shape and with few septa (Fig. 414).

Microsporum gypseum (Bodin) Guiart and Grigorakis, 1928, grows rapidly and produces a fawn or buff to brown colony in which macroconidia are abundant (Fig. 419). These macroconidia are smaller than those of *M. canis,* have commonly 6 to 8 septa, and have rounded rather than pointed ends.

EPIDERMOPHYTON Sabouraud 1910

The genus contains a single species, *Epidermophyton floccosum* (Harz) Langeron and Miloch., 1930, which causes athlete's foot and tinea cruris. It does not invade the hair shaft. In culture, *E. floccosum* produces a greenish yellow flat colony in which only macroconidia are produced. The macroconidia are borne as sessile or short stipitate lateral spores on vegetative hyphae or in groups on simply branched conidiophores. They are egg-shaped to clavate, with thick, smooth walls and may be nonseptate or have 1 to 4 cross walls (Fig. 414).

CANDIDIASIS

(Moniliasis)

Candida albicans (Robin) Berkhout, 1923, is a yeastlike fungus found frequently on mucous membranes where it causes thrush in infants and vaginitis, especially during pregnancy. It is a secondary invader in most types of pulmonary disease, where its etiological significance may be difficult to evaluate. It also causes paronychia and epidermal erosions in skin folds. A small number of cases of endocarditis caused by *C. parapsilosis* (and rarely by *C. albicans*) have been reported.

The taking of specimens from the oral mucosa, skin, and blood presents no special problems. In the examination and culture of sputum it is important to collect a fresh morning specimen, for reasons given above. Material may be examined directly in 10 per cent sodium hydroxide or in a Gram-stained smear and planted on glucose-neopeptone agar with added penicillin and streptomycin.

Candida is of sufficient size (2.5 to 3.5 by 3 to 5 microns) so that its characteristic oval or elliptical cell, often with a bud attached at one end, or its hyphal form, may be found under the microscope without staining. However, sputum may be stained by the Gram method. There is some variation in staining reaction depending upon the age of the cell, but most young cells are strongly gram-positive. Candida is easily isolated in culture from sputum or body fluids or surfaces even in the presence of bacteria which might inhibit other pathogens. On glucose-neopeptone agar, Candida grows first as a yeast, forming a glistening, creamy white, heaped colony, the surface of which is often pitted with the scars of gas bubbles. The important pathogenic species is easily recognized by planting on corn-meal agar or the special medium of Nickerson and Mankowski.[1] Inoculate with a deep streak on a plate or slide culture and incubate at room temperature. *C. albicans* produces spherical chlamydospores which are distinctive (Fig. 420). *C. albicans* is further identified by production of acid and gas in glucose and maltose and of acid in sucrose and by growth in glucose broth without clouding or formation of a surface film.[1]

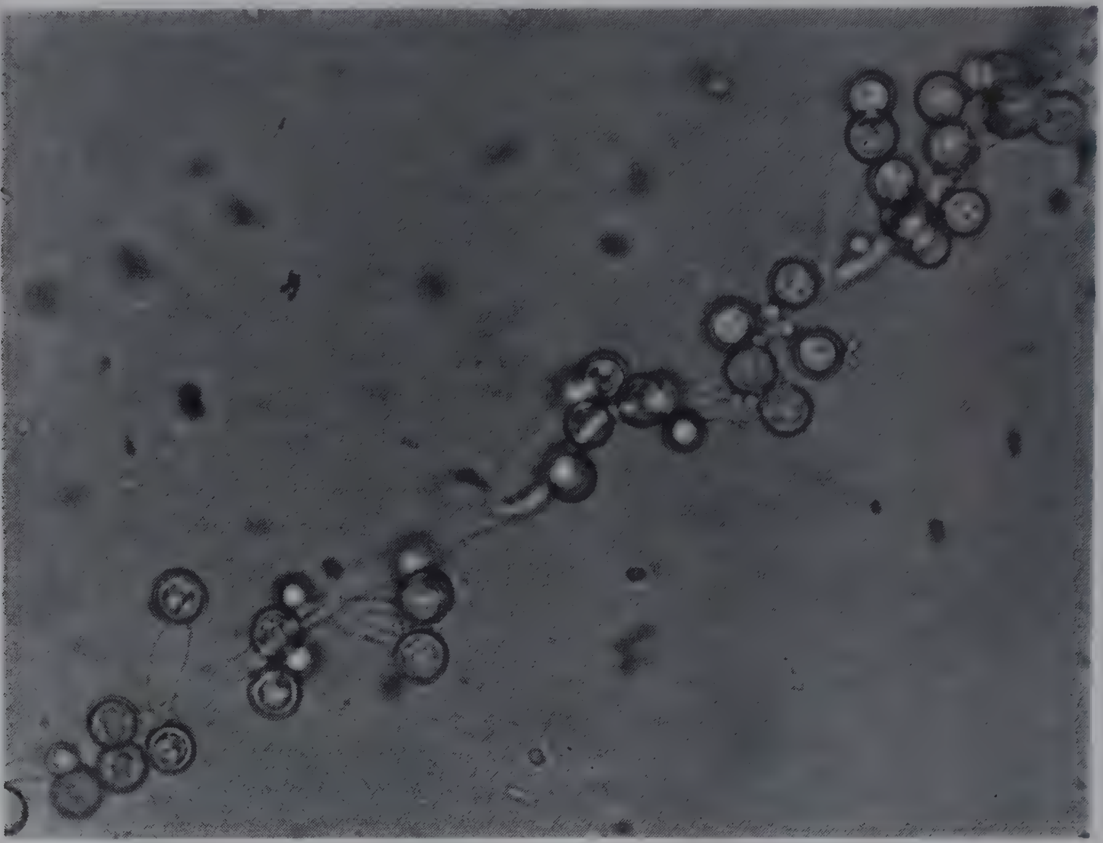

Fig. 420.—Chlamydospores of *Candida albicans*. (×500.)

ACTINOMYCOSIS

Actinomycosis is a systemic, chronic, granulomatous and suppurative disease which involves the face and neck in a little more than half the cases, the thoracic organs in about a fourth, and the abdominal organs, skin, or meninges in the remainder.

Small colonies of the fungus, which are often in the form of well-organized "sulphur granules" with peripheral "clubs" of eosinophilic material deposited around the hyphal tips, are characteristically found in the pus which discharges from sinus tracts leading from the lesion (Fig. 421). These granules can be seen with the unaided eye in pus as it flows down the side of a glass tube or on the surface of gauze dressings. Unless pus from unopened sinuses can be aspirated the granules from a draining sinus should be collected for examination and culture.

When crushed and stained by the Gram method, fragile gram-positive hyphae 0.5 to 1.0 micron in diameter, which branch but break up readily into diphtheroid elements, are seen (Fig. 422). For purposes of culture the granules should be washed rapidly in sterile saline and planted in semisolid glucose thioglycollate medium or on the surface of blood agar or other enriched medium in an anaerobic jar. Growth occurs at 30° to 37° C.

---

[1] Conant and others: Loc. cit

Actinomyces bovis Harz, 1877, the cause of actinomycosis, is microaerophilic. In culture its microscopic morphology is much like that seen in tissues. A branching mycelium can be demonstrated in a culture two or three days old, but in most strains the hyphae break up in older cultures into diphtheroid elements (Fig. 423). *A. bovis* must be differentiated from microaerophilic organisms having similar morphology which frequently appear in culture and which probably are saprophytic contaminants of the skin. These saprophytes grow more rapidly than *A. bovis* and produce a profuse growth

which settles to the bottom of a semisolid medium. Cultures remain viable after several weeks' incubation. *A. bovis,* on the other hand, remains in discrete colonies and must be transferred at 10-day intervals under ordinary conditions to maintain a strain. *A. bovis* is further differentiated by its ability to produce abscesses in young hamsters after intraperitoneal inoculation, while the saprophyte is not pathogenic.

MYCETOMA

A mycetoma is a granulomatous lesion in the subcutaneous tissues, usually of an extremity, characterized by swelling, the formation of sinus tracts, and the discharge of pus which contains granules composed of dense fungus colonies. The foot is most commonly involved (Madura foot) and the swelling results in a characteristic convex contour of the sole. Infection follows penetration of the skin by a splinter or thorn contaminated by the fungus.

One should speak of ''mycetomas'' since the clinical term covers infections of diverse etiologies. The fungi range from species of the Nocardia, which are of bacterial dimensions, to coarse Hyphomycetes such as Monosporium. Some of the fungi causing mycetoma have been isolated from soil and such a saprophytic occurrence of the others is assumed.

Nocardia madurae (Vincent) Blanchard, 1896, produces yellowish white granules in the tissues. These granules are firmer than those of actinomycosis and, when crushed, the component hyphae are not so easily dissociated. The hyphae are approximately 1 micron in diameter and are gram-positive and not acid-fast. In culture, *N. madurae* is aerobic and produces grayish-white to yellow, spreading waxy, glabrous colonies. Under some conditions of growth, colonies may be pink to red. *N. madurae* was first isolated in India, whence came the name, but it occurs also in the United States and elsewhere in the world.

Nocardia brasiliensis (Lindenberg) Castellani and Chalmers, 1913, also produces yellowish-white granules in tissue, but in culture produces a yellow to orange, heaped or cerebriform colony which may develop a chalky surface due to formation of short aerial hyphae. *N. brasiliensis* causes mycetoma in southern United States, Mexico, and Central and South America.

Nocardia pelletieri (Laveran) Pinoy, 1912, is found in tissues in the form of red granules, and in culture produces a coral to ruby red colony. The present criteria for identification of species of Nocardia and their separation from Streptomyces are inadequate but are currently under study.

Besides Nocardia, some 20 of the higher fungi cause mycetoma. Allescheria, Aspergillus, Penicillium, Madurella, Indiella, Glenospora, Cephalosporium, and Phialophora are each represented by one or more species. Ten species of Madurella producing black grains have been described, but it is probable that some of these should be reduced to synonymy.

Mycetomas caused by the higher fungi can be recognized by the greater diameter of the hyphae making up the ''grain.'' These are 2 to 4 microns in diameter although there are occasional larger intercalary cells, and many of the radiating hyphae are terminated at the periphery of the granule by cells reaching a diameter of 6 to 8 microns.

In the United States, *Allescheria boydii* Shear, 1921, which causes a white grain mycetoma, is the most important representative of this group. For more than 20 years only the single original case reported in 1921 was attributed to this fungus. However, during this period numerous cases of mycetoma caused by *Monosporium apiospermum* Saccardo, 1911, were reported. Comparisons of these two fungi showed that they are actually one. *A. boydii* is an Ascomycete and exhibits the full complement of spore forms known for the fungus. *M. apiospermum* (a member of the Class Fungi Imperfecti) is the name applied to those strains of the fungus usually isolated from mycetoma which lack the ascomycetous stage and reproduce by conidia only. *A. boydii* has now been isolated frequently from soil and it is interesting to note that these strains of saprophytic origin exhibit the full life cycle of the fungus.

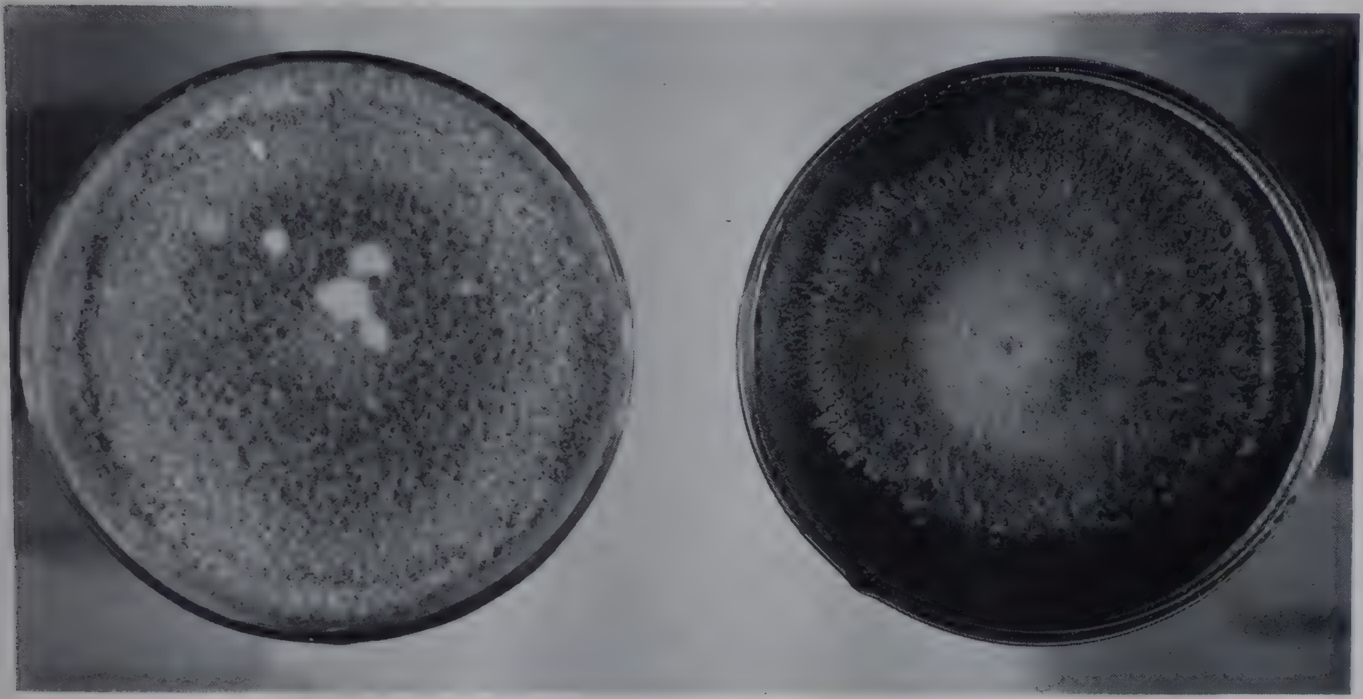

Fig. 424.—*Allescheria boydii* cultures 4 weeks old. Sabouraud's agar at left, corn-meal agar at right.

Grains from an unopened abscess should be planted upon Sabouraud's agar. If grains from a draining sinus are used they should be washed briefly in sterile saline and planted on a medium containing antibiotics. Cultures should be incubated at 30° C. The fungus grows rapidly, spreading widely over the slant, and producing a floccose gray to brownish-gray colony (Fig. 424).

Sporulation can be studied most conveniently upon corn-meal agar which reduces the amount of vegetative growth and stimulates sporulation. Two types of spores are produced. Conidia are one-celled, subspherical to short clavate, 5 to 7 by 8 to 11 microns; the base presents a broad surface where it was attached to the conidiophore (Fig. 425). They are borne terminally and singly at the ends of hyphae or short side branches. The conidiophores are sometimes associated into bundles called "coremia." The ascospore is elliptical and resembles the conidium sufficiently in size and shape so that it has been frequently overlooked in superficial examinations. Its slightly smaller size, 4 to 5 by 5.5 to 7.5 microns, and elliptical shape with no broad basal scar at the point of attachment serve to identify it. Ascospores are borne 8 per ascus within a spherical structure called an "ascocarp." The ascocarp wall (the perithecium) is composed of a single layer of specialized flattened cells. This perithecial wall bursts at maturity to liberate the ascospores (Fig. 426).

CHROMOBLASTOMYCOSIS

Chromoblastomycosis is a chronic infection of the skin and subcutaneous tissues characterized by warty sessile or pedunculated lesions and by swelling due to lymph stasis. It is seen most frequently in tropical and subtropical climates but this may be due to more frequent exposure to the traumatic introduction of the fungus via contaminated thorns.

Microscopic examination of superficial crusts and epidermal scales cleared in 10 per cent sodium hydroxide reveals brown fungus hyphae and sclerotic cells in the epidermis. Sections of a lesion show hyperkeratosis and cutaneous abscesses in which the fungus is present as brown, thick-walled subspherical cells, 5 to 12 microns in size, which reproduce by septation rather than budding. Cultures may be made by planting crusts, aspirated pus, or ground tissue from a biopsy on Sabouraud's agar fortified by antibiotics and incubated at 30° C.

A mycologic discussion of chromoblastomycosis is complicated by the fact that any one of three fungi may cause the same clinical entity and by the diversity of sporulation which these obviously related fungi exhibit.[1] The diversity is so great that the three fungi have been placed at different times and by various investigators in several different genera, yet they have characteristics in common which have led other mycologists to place them within a single species. In my opinion the three are closely related genetically and belong in one genus, but it is convenient at present to assign them to three species.

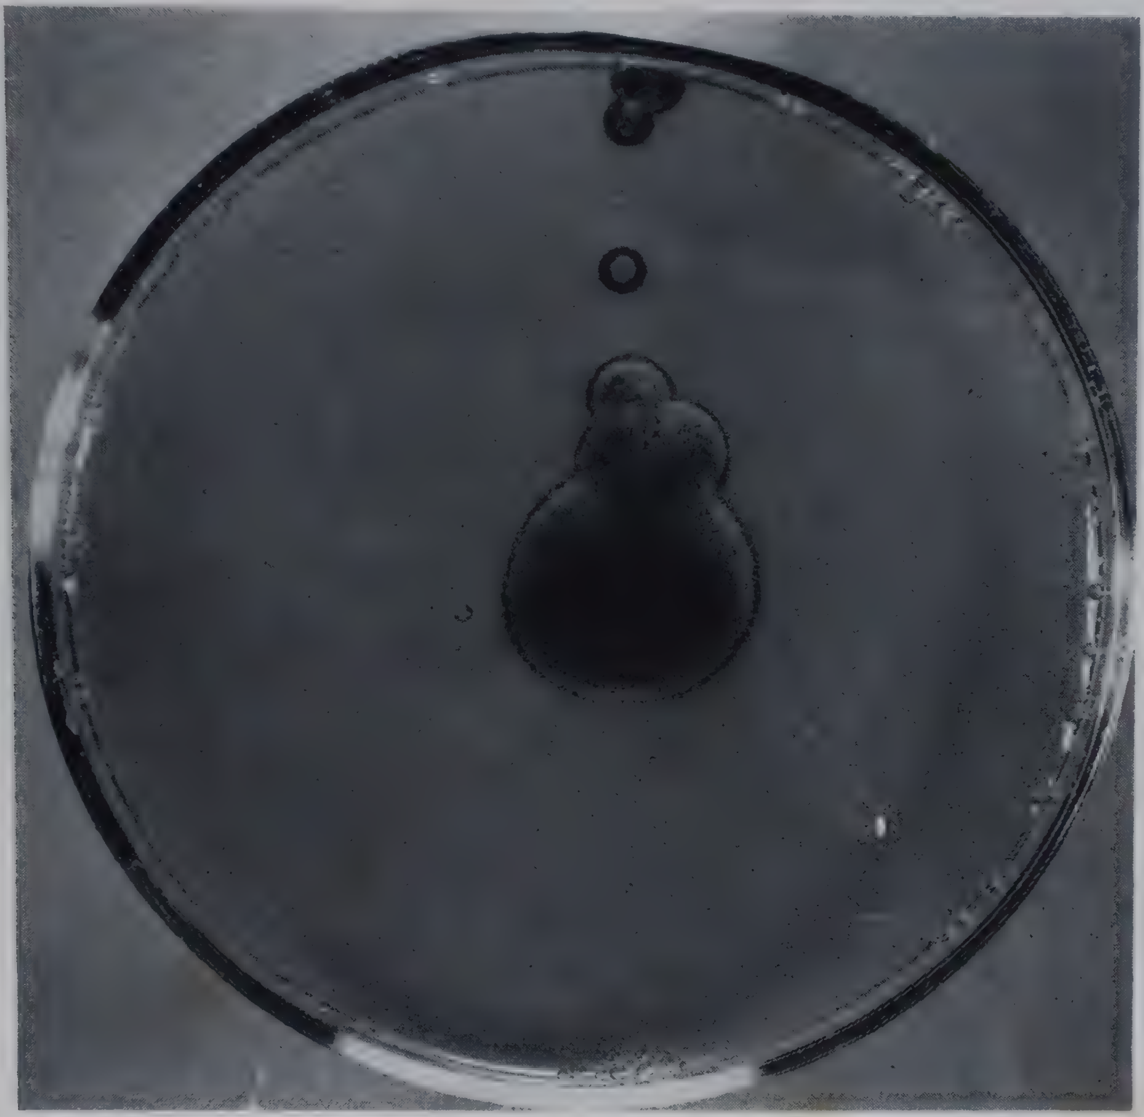

Fig. 427.—Colony of *Phialophora verrucosa* incubated 2 weeks at 30°C on Sabouraud's agar.

Phialophora verrucosa Thaxter, 1915 *(Cadophora americana, Fonsecaea pedrosoi* var. *phialophorica)*, is an olive-black to brownish-black mold which produces short, velvety aerial mycelium (Fig. 427). On Sabouraud's medium the colony is at first dome-shaped, but becomes flat as the colony slowly increases in size. Sporulation occurs in short, tubular- to flask-shaped cells called "phialides," in the flaring mouths of which colorless thin-walled spores, 1.5 to 2 by 2 to 3 microns in size, are budded off successively. Under certain conditions of culture these conidia increase considerably in size after their abstriction. They remain in a ball-like cluster at the mouth of the phialide if undisturbed. Rarely some strains, otherwise typical of *P. verrucosa*, produce branching conidiophores which bear chains of spores in a manner typical of the following species (Fig. 428).

---

[1] Carrión, A. L., and Silva, M.: Chromoblastomycosis and Its Etiologic Fungi, in Biology of Pathogenic Fungi, W. J. Nickerson, ed. Waltham, Mass., 1947, Chronica Botanica Co.

Phialophora pedrosoi (Brumpt) Cif. and Red., 1944 *(Hormodendrum pedrosoi, Fonsecaea pedrosoi)*, produces a colony which is indistinguishable from that of *P. verrucosa,* but the conidiophores bear brown spores laterally or in branching chains (Fig. 429). Most strains also produce a few spores exactly like those of *P. verrucosa* (Fig. 430). *P. compactum* is similar to *P. pedrosoi* except that spore chains are short and less easily dissociated. It has been isolated only a few times.

SPOROTRICHOSIS

The lesion of sporotrichosis develops as a subcutaneous, ulcerating nodule at the site of a thorn puncture. Secondary lesions develop in the lymph nodes draining the area. The disease has been reported frequently in small epidemics in men handling thorny plants. Several thousand cases were observed in laborers in gold mines in South Africa; the etiological agent was easily isolated from the timbers of the mines.[1]

Sporotrichum schenckii (Hektoen and Perkins) Matruchot, 1910, is present in tissues in the form of spherical- to cigar-shaped cells which reproduce by budding (Fig. 431). It is variable with respect to the Gram stain and is so infrequent in human lesions as to be difficult to demonstrate except by a selective stain such as Bauer or Hotchkiss-McManus. In culture, *S. schenckii* produces a flat, sometimes wrinkled or radially folded, usually almost glabrous, brown to black colony. Some strains develop a short aerial mycelium and many strains lose their pigment-producing ability after several subcultures.

---

[1] Sporotrichosis Infection on Mines of the Witwatersrand, Proceedings of Transvaal Mine Medical Officers Association, Transvaal Chamber of Mines, Johannesburg, 1947.

Conidiophores are delicate, tapering, lateral branches which bear at the tip a cluster of elliptical colorless conidia 2 to 4 by 2 to 6 microns in size. Sporulation continues toward the base and eventually occurs on undifferentiated hyphae. The conidia, after falling from the conidiophore, are characterized by a tiny apiculus at the point of former attachment to the conidiophore, and careful examination under high magnification will reveal scars on the conidiophore marking points which bore conidia.

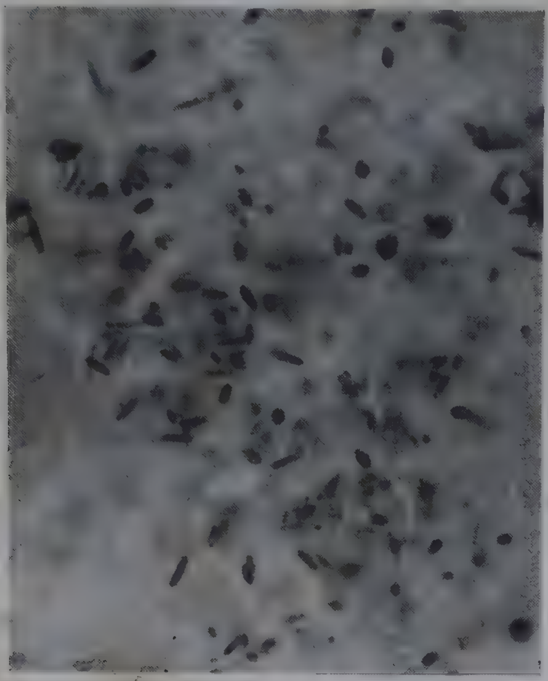

Fig. 431.—*Sporotrichum schenckii* in testis of experimentally infected rat. (×400.)

CRYPTOCOCCOSIS

Cryptococcic meningitis (Torula meningitis) is the most important form of cryptococcosis although the disease may become generalized and involve many tissues. Evidence suggests that the primary lesion is usually a small, inapparent, pulmonary granuloma which, in most cases, heals without sequelae.

Cryptococcus neoformans (Sanfelice) Vuillemin, 1901, *(Torula histolytica)*, can be demonstrated in spinal fluid (where it may be mistaken for a lymphocyte) by mixing the spinal fluid with dilute India ink. This makes the characteristic wide extracellular capsule of the spherical budding cell easily apparent. It can be seen also in the thick myxomatous pus from an abscess where it grows in great numbers, almost as in a culture. Its growth in such lesions and its wide capsule create an appearance in tissue sections which was once erroneously interpreted as lysis of host tissue.

In culture, *C. neoformans* produces a cream- to tan-colored moist colony which may be sufficiently mucoid to flow to the bottom of the slant. Growth occurs at 37° C. but is somewhat more rapid in most strains at 30° C. In culture, as in tissue, the cell is spherical, 4 to 15 microns in diameter, and reproduces by budding. Unlike a typical yeast which is egg-shaped and produces buds near the small end, *C. neoformans* remains spherical even when budding, and when young, produces buds at any point on its surface.

Fungi morphologically indistinguishable from *C. neoformans* are sometimes isolated from sputum. They can be differentiated by lack of virulence for mice, as mentioned previously.

HISTOPLASMOSIS

Histoplasmosis is a disease of the reticuloendothelial system and, unlike most other mycoses, the fungus causing it is predominantly intracellular. The disease is characterized by fever, emaciation, splenomegaly, hepatomegaly, lymphadenopathy, and ulcers of the mucous membranes and sometimes of the skin. Some or all of these signs and symptoms may be present in the generalized form of the disease which has a high mortality rate. It is apparent, from epidemiologic studies employing intradermal tests with histoplasmin and serologic and roentgenologic technics and by the study of small epidemics, that the majority of infections are inapparent or mild and self-limited, involving the lungs or thoracic lymph nodes. In eastern central United States, histoplasmin sensitivity is prevalent, varying according to locality from 30 to 90 per cent in the general population above two years. The curve representing the incidence of skin sensitivity, unlike that for tuberculin sensitivity, rises sharply in preschool and early school years. In the same geographic areas there is a high incidence of nontuberculous pulmonary calcification which may be related to benign histoplasmosis.

The histoplasmin intradermal test has been useful in survey and epidemiologic studies but is of limited diagnostic value in a geographic area where 85 per cent of the population react to the test. The complement fixation test may be of diagnostic value if a rise in titer can be demonstrated. Both the intradermal and serologic tests must be interpreted in light of the fact that there are cross-reactions with blastomycosis and to a lesser degree with other mycoses.

The relationship between geographic areas of prevalent histoplasmin sensitivity and the actual geographic distribution of histoplasmosis is not yet fully elucidated. Cases of histoplasmosis have been observed in many parts of the United States and of the world where the level of histoplasmin sensitivity is not high. This may well be due to a highly localized distribution of the etiological agent, *Histoplasma capsulatum,* which has a saprophytic existence in soil independent of human infection.

The fungus has been isolated many times from soil, first in areas where infected animals had been found and, on several occasions, from soil associated with small epidemics. Many of these epidemics were in men exposed to soil or dust containing excreta of chickens or pigeons, and the fungus has been isolated more frequently from soil collected around old chicken houses than from other sites. However, chickens are not known to be hosts of Histoplasma and are not easily infected experimentally. The relationship appears to be one of a suitable environment for saprophytic growth and not a host-parasite relationship.

Dogs, cats, rats, mice, opossums, fox, raccoons, and skunks have been found with histoplasmosis. Benign histoplasmosis is actually a frequent disease in dogs and cats in some endemic areas. In one such area where an extensive study was conducted, approximately 50 per cent of dogs were proved to have histoplasmosis by isolation of *H. capsulatum*. The hilar lymph nodes were most frequently involved and in some animals the fungus was isolated from no other tissue.

Fig. 433.—*Histoplasma capsulatum* colony incubated 2 weeks at 30°C. on Sabouraud's agar.

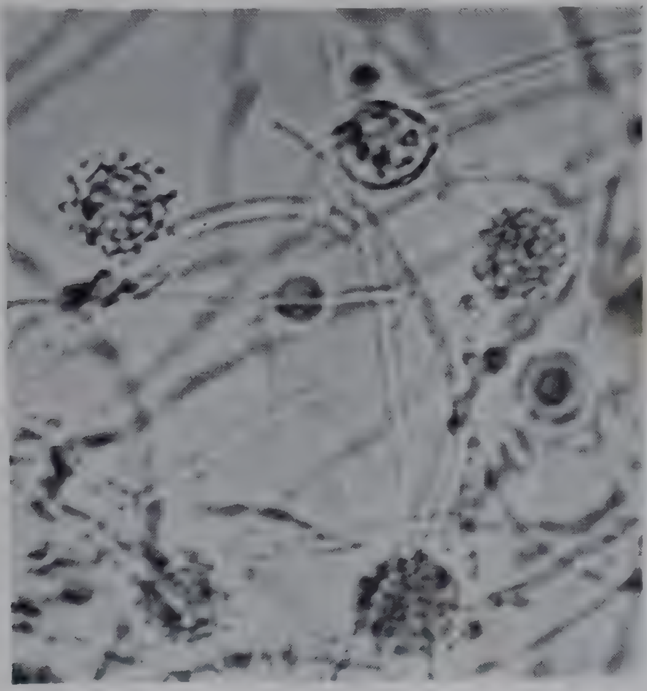

Fig. 434.—*Histoplasma capsulatum* macroconidia. (×600.)

Histoplasma capsulatum Darling, 1906, is a yeastlike fungus 2 to 3 by 3 to 4 microns (occasionally larger) found usually in monocytes (Fig. 432). It can be demonstrated by Giemsa or Schiff staining. Sputum, blood, bone marrow, excised lymph nodes, and scrapings from ulcers are suitable materials for microscopic examination and culture. Attempts to demonstrate and isolate the fungus from any of these sources are usually ineffective in mild cases.

The yeast or parasitic growth phase of *H. capsulatum* can be maintained in vitro by incubation at 37.5° C. on cystine-dextrose-blood agar. When cultures are made on Sabouraud's medium and incubated at 30° C. or room temperature, the fungus grows as a mold and produces a white to brown colony (Fig. 433) which bears two types of spores on short lateral branches. Conidia are spherical, 2.5 to 4 microns in diameter, with a minutely spiny wall. Macroconidia are spherical (rarely clavate), 8 to 12 microns in diameter with conspicuous fingerlike appendages on the surface (Fig. 434). After subculture many strains lose the ability to produce macroconidia. When a suspension of the mold is injected into a mouse or other suitable laboratory animal, the mold reverts at once to the yeastlike phase of growth.

The technic of animal inoculation for primary isolation from man is especially useful in histoplasmosis because of the slow growth of *H. capsulatum,* the suppression of growth by many contaminants, and the susceptibility of mice to a small inoculum. When cultures must be made from sputum, the use of a culture medium containing penicillin and streptomycin will inhibit most bacterial growth but will not inhibit contaminating fungi which often grow rapidly in sputum cultures. Contaminated material of this type can be injected into the peritoneal cavity of the mouse. The mouse should be killed in 3 or 4 weeks and cultures made on Sabouraud's agar from the spleen and liver.

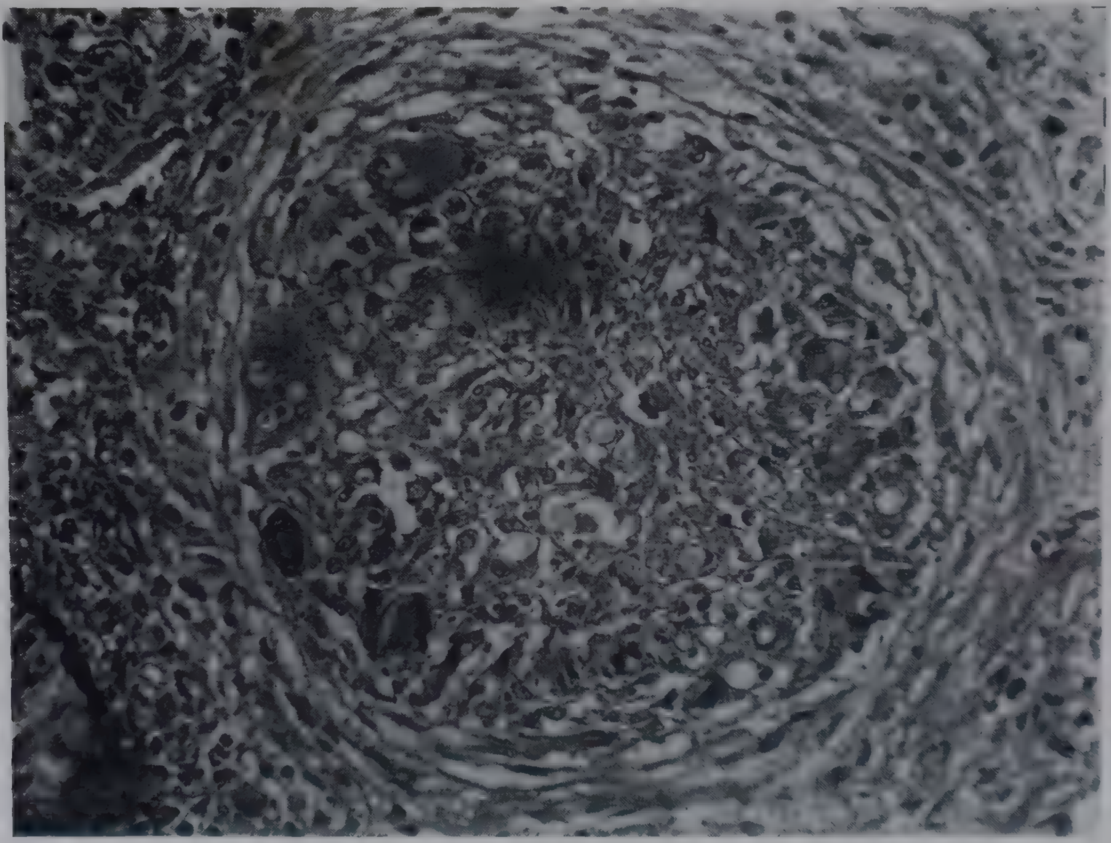

Fig. 435.—Blastomycosis of the lung, showing nodule with giant cells, *Blastomyces dermatitidis.* (Courtesy Dr. Oscar Felsenfeld.)

NORTH AMERICAN BLASTOMYCOSIS

North American blastomycosis is a systemic granulomatous disease in which the primary lesion may be dermal following traumatic implantation of the fungus, but probably is usually pulmonary. Although lesions may occur in many organs and tissues, the lungs are involved in almost all cases of systemic disease. In dermal lesions there is a characteristic raised border in which microabscesses containing the fungus appear (Fig. 435).

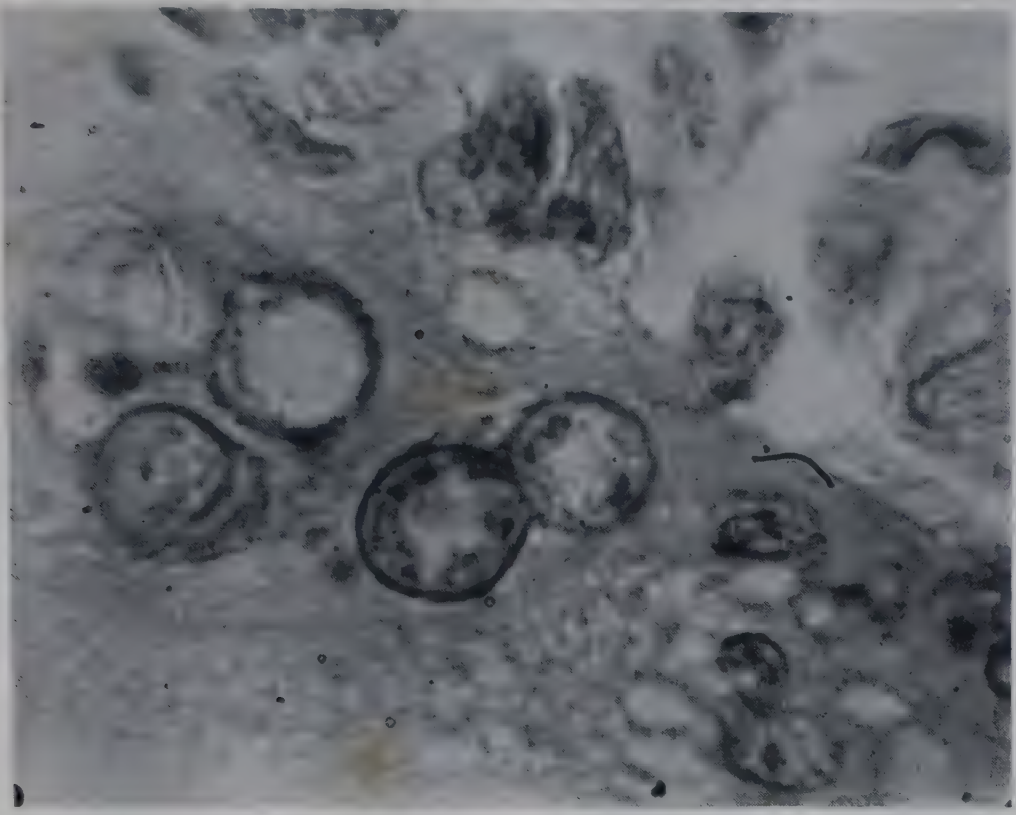

Fig. 436.—*Blastomyces dermatitidis*, budding cell microabscess of the skin. (×900.)

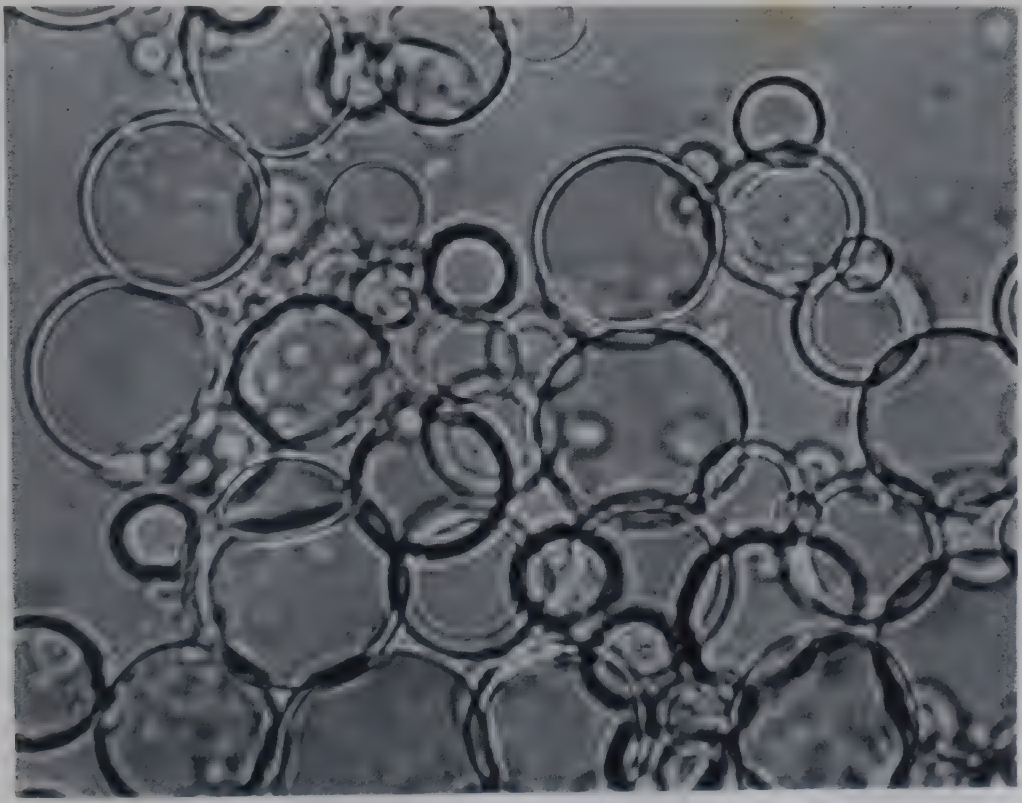

Fig. 437.—Artefact, myelin globules. (×1,000.)

Blastomyces dermatitidis Gilchrist and Stokes, 1898, is a rather thick-walled, yeastlike cell 8 to 12 microns in size. It reproduces by budding, but, unlike Histoplasma, Cryptococcus, and most common yeasts, the daughter bud communicates with the parent cell through a large opening (Fig. 436). Recent reports of small forms of Blastomyces, large forms of Histoplasma, and dual infections by these two fungi emphasize the necessity for a culture before a diagnosis can be made with certainty. Certain artefacts, such as myelin globules which are found in some sputum and tissues, may sometimes be mistaken for yeastlike cells (Fig. 437). Myelin assumes many bizarre budding and tubular forms in wet microscopic preparations. These bodies usually increase in size and number as the preparation stands after treatment with sodium hydroxide.

B. dermatitidis can be maintained in vitro in the yeastlike phase of growth by incubation at 37.5° C. on blood agar, but at 30° C. it is a white to brownish mold. It resembles Histoplasma, but does not produce two distinct types of conidia, and its conidia, which are 2 to 6 microns in diameter, have smooth walls.

SOUTH AMERICAN BLASTOMYCOSIS

South American blastomycosis is a frequent mycosis with a high mortality rate in Brazil and occurs less frequently in other South American countries. Unlike North American blastomycosis, primary lesions are most frequently seen on the oral or nasal mucosa, and involvement of the gastrointestinal tract and lymph nodes is common.

Blastomyces brasiliensis (Splendore) Conant and Howell, 1941, reproduces in the tissues by multiple budding and under certain conditions many small buds are produced simultaneously. As in the case of *B. dermatitidis* the tissue phase can be maintained in vitro by incubation at 37.5° C., but the fungus grows as a mold at lower temperatures. Sporulation is irregular and scanty and is usually lacking in old stock cultures.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis occurs in the arid Southwest of the United States, in northern Mexico, and in other arid regions of Central and South America. Both a benign and a severe systemic form occur, the benign form varying in severity from an inapparent infection to an acute respiratory infection characterized by fever, pleuritic pains, erythema nodosum, and the development of pulmonary cavities. This form is popularly known as San Joaquin Valley fever, desert rheumatism, etc. The severe form is a granulomatous disease of protean manifestations involving almost any organ of the body, and it has a high mortality rate. This form, coccidioidal granuloma, develops more often in Negroes, and other dark-skinned races, than in whites. In general, coccidioidomycosis assumes greatest clinical importance when a susceptible adult population enters an endemic area. In a stable native population it is for the most part an inapparent disease of childhood which appears to immunize against reinfection.[1]

Coccidioidomycosis occurs in dogs, cattle, sheep, and rodents. Apparently these animals as well as man are infected by inhalation of spores of the fungus which have grown saprophytically in the environment. The disease is not contagious. The fungus has been isolated from soil and, like other fungi causing systemic mycoses, is capable of saprophytic growth in soil.

---

[1] Smith, C. E.: M. Clin. North America 27: 790, 1943.

Coccidioides immitis Rixford and Gilchrist, 1896, is present in tissue in the form of spherical cells which reproduce by a process called "progressive cleavage" apparently identical to that seen in the sporangium of Phycomycetes. At maturity the protoplasm is divided by cleavage furrows into multinucleate masses which normally are then subdivided by walls into the definitive uninucleate spores, 2 to 3 microns in diameter. The wall of the sporan-

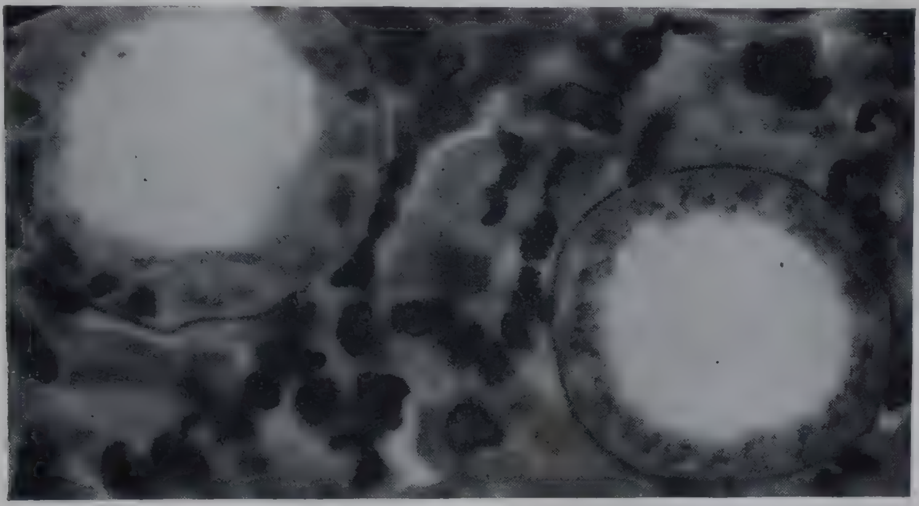

Fig. 439.—*Coccidioides immitis,* large vegetative cell and beginning of sporulation by "cleavage furrows." (From Emmons: Mycologia 34: 452, 1942.) (×1,000; reduced ¼.)

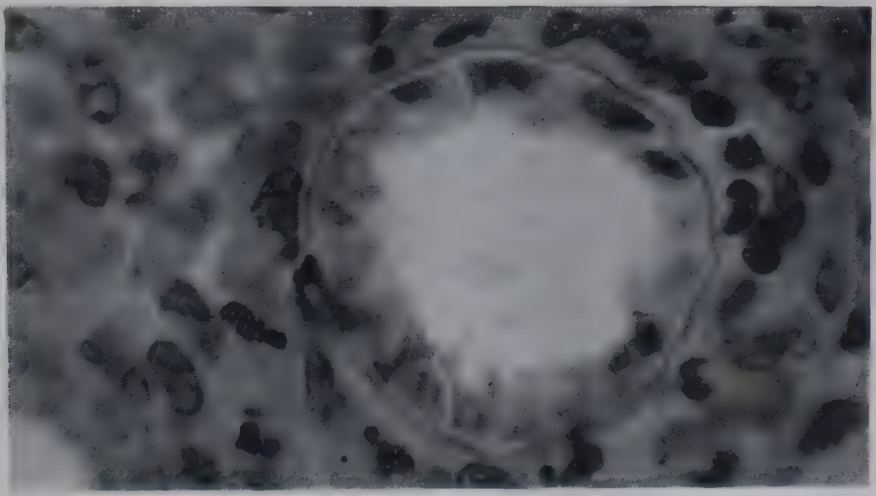

Fig. 440.—*Coccidioides immitis,* early stage in sporulation. (×1,000; reduced ¼.) (From Emmons: Mycologia 34: 452, 1942.)

gium then ruptures and the spores are liberated and grow to reach a mature size of 30 to 200 microns, depending upon the tissue and host species (Figs. 438 to 442). When Coccidioides grows in the wall lining a pulmonary cavity it sometimes produces a mycelium and arthrospores.

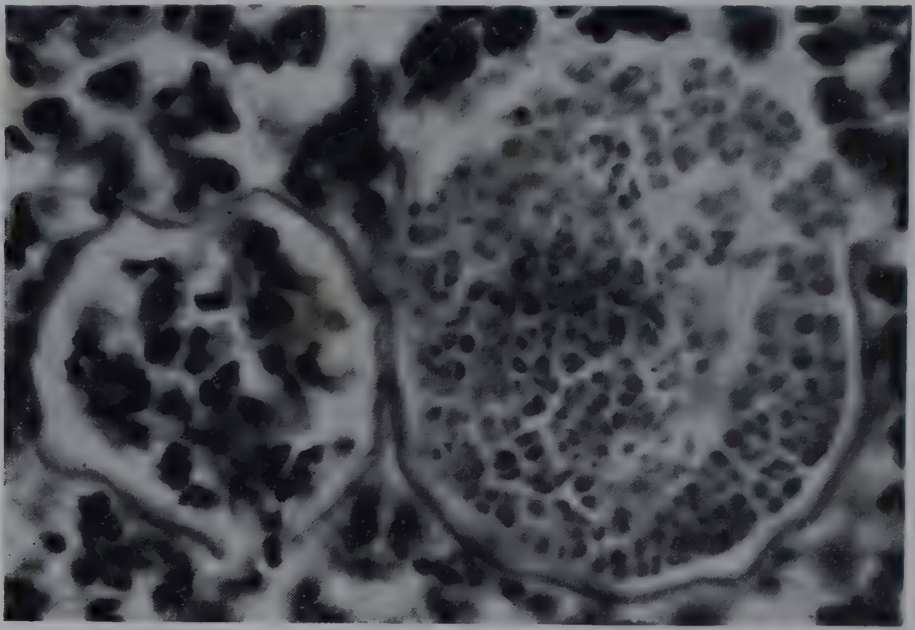

Fig. 441.—*Coccidioides immitis,* mature, ruptured sporangium and old emptied sporangium. (×1,000; reduced ¼.) (From Emmons: Mycología 34: 452, 1942.)

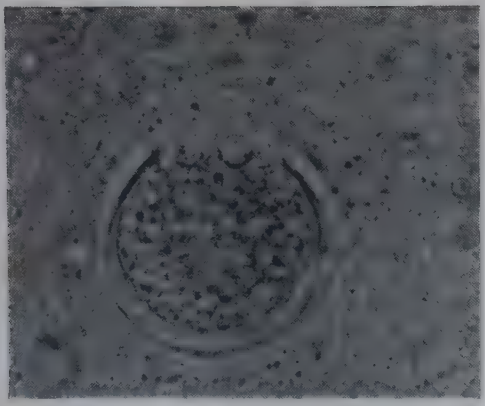

Fig. 442.

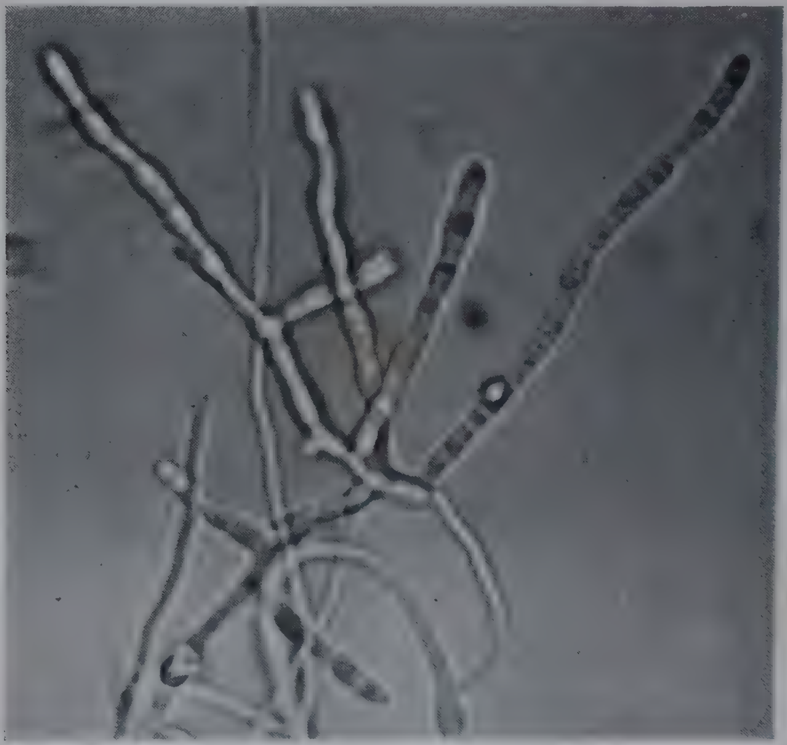

Fig. 443.

Fig. 442.—*Coccidioides immitis,* mature sporangium in pus. (×500.)

Fig. 443.—*Coccidioides immitis,* early sporulation in culture. (×1,000; reduced ¼.) (From Emmons: Mycología 34: 452, 1942.)

C. immitis is easily isolated in culture because of its rapid growth, even in the presence of other molds and bacteria. It grows at 37° C. but optimum temperature is lower and room temperature is adequate. In culture, *C. immitis* is a floccose, gray mold which produces enormous numbers of arthrospores 2.5 to 3 by 3 to 4 microns. The first arthrospores to appear in a culture (at 8 to 10 days) are borne on morphologically differentiated thick lateral branches, but eventually many undifferentiated hyphae sporulate by septation (Fig. 443). There is a characteristic condensation of cytoplasm which results in alternating spores and empty spaces in the hyphae. These arthrospores are easily dissociated and constitute a grave hazard in the laboratory. *C. immitis* should never be grown in plate culture and slant cultures should be manipulated under a hood.

ASPERGILLOSIS

Pulmonary aspergillosis, caused by *Aspergillus fumigatus,* is clinically important although one opinion holds that it is often secondary to another infection or to some anatomic anomaly. The fungus grows in fairly dense colonies in the lung (although it does not form organized granules as in mycetoma), may produce cavities, and characteristic hyphal fragments may be found in great numbers in sputum when one of these lesions communicates with a bronchus (Fig. 444).

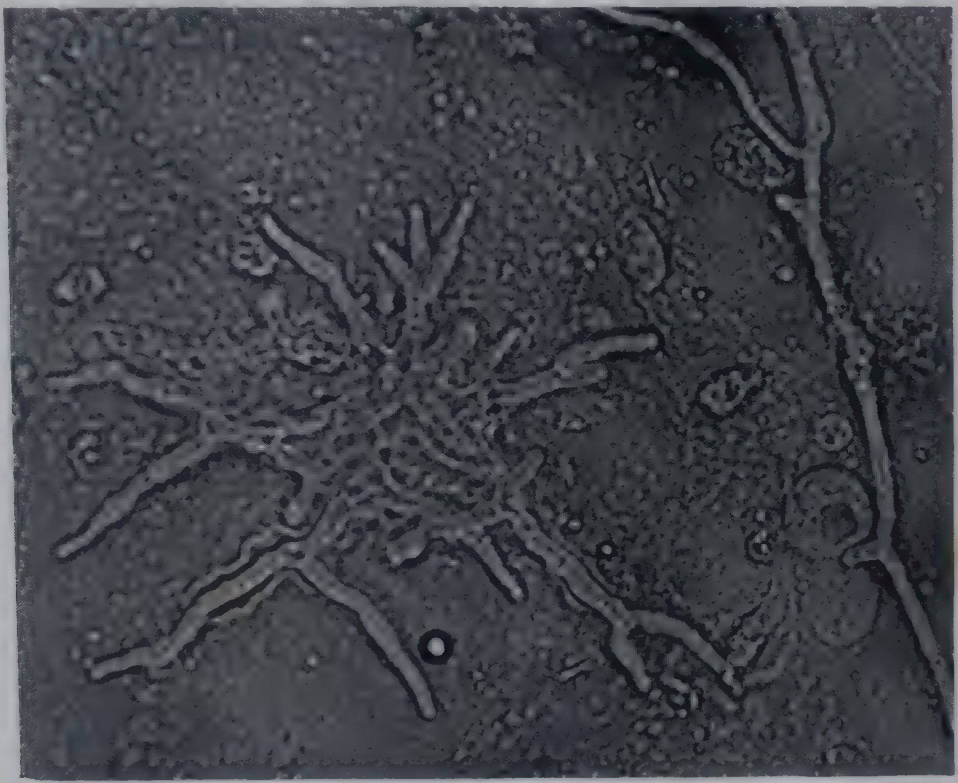

Fig. 444.—*Aspergillus fumigatus,* hyphae in sputum. (×1,000.)

A. fumigatus produces a rapidly spreading gray-green colony. One feature of the conidial heads differentiating them from other species of Aspergillus is the parallel orientation of the sterigmata which results in production of a columnar mass of conidia.

A. niger, the second most important species clinically, is a frequent cause of otomycosis. It is black in culture.

MUCORMYCOSIS

The diagnosis of mucormycosis is frequently made post mortem and is based upon the finding of wide, rarely septate hyphae in the tissues, usually of the central nervous system. In the absence of a culture, a specific diagnosis cannot be made, but the most frequently incriminated species is *Absidia corymbifera (Mucor corymbifer).*

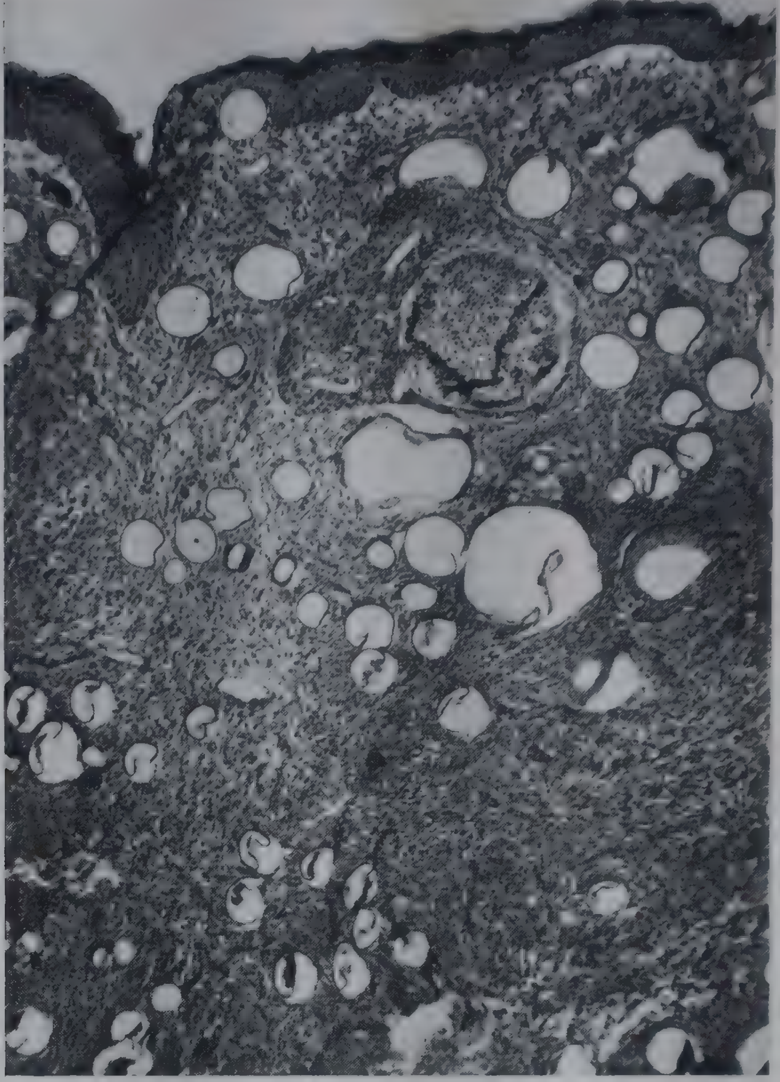

Fig. 445.—*Rhinosporidium seeberi.* View of a nasal polyp, showing one adult parasite and many young stages. The others are deformed, due to action of reagents. (Courtesy Dr. Juan Boggino, Paraguay.)

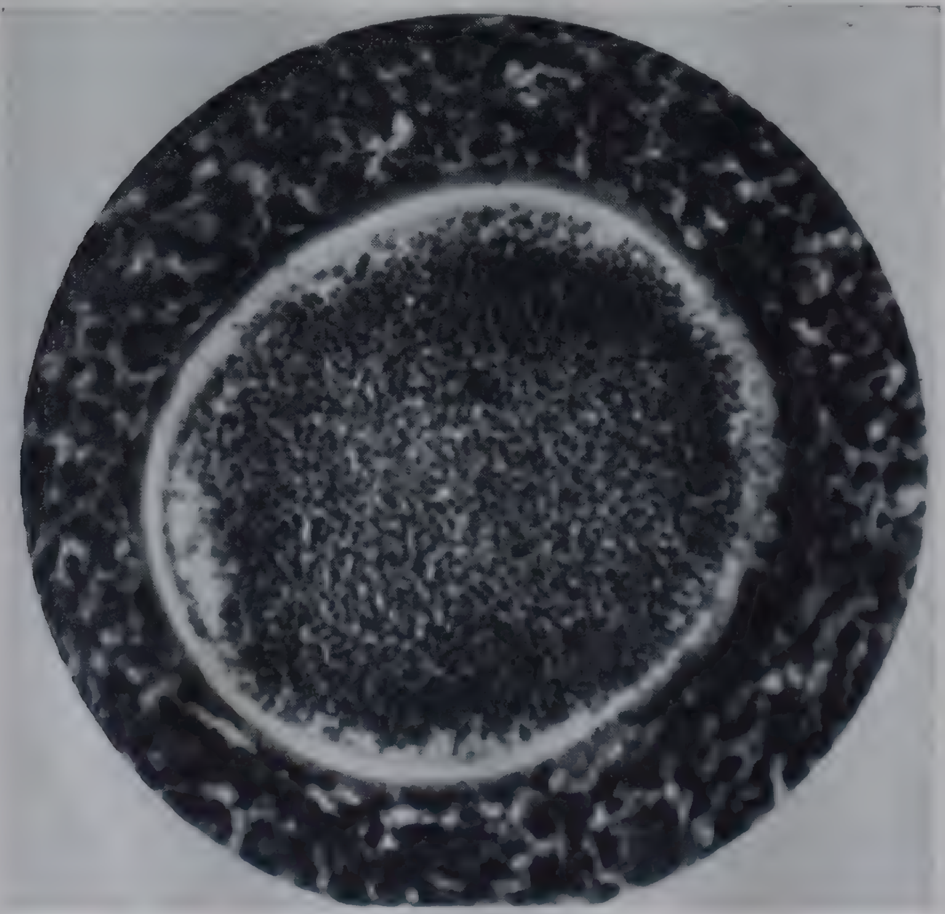

Fig. 446.—*Rhinosporidium seeberi.* A parasite which has almost completed its growth. (Courtesy Dr. Juan Boggino, Paraguay.)

RHINOSPORIDIOSIS

Rhinosporidiosis is a rare, chronic, benign disease of man, cows, and horses. It is manifested as polypoid granulomata of the nasal mucosa and, less frequently, of other mucosal surfaces or of skin.

Rhinosporidium seeberi (Wernicke) Minchin and Fantham, 1905, was thought to be a protozoan until Ashworth advanced the opinion that it is a fungus. It has not been grown in culture and its taxonomic position is still in doubt. In tissue it is a spherical cell reaching a diameter of 300 microns which, at maturity, becomes filled with sporelike bodies (Figs. 445, 446).

CHAPTER XII

PARASITOLOGY AND TROPICAL MEDICINE*

Definitions

Parasitology is the study of parasites. **Parasites** are any living beings, vegetable or animal, which live in part or throughout their entire existence on the surface of or within other living organisms naturally stronger than the parasites. They breed at the expense of the **host,** which is the living organism that harbors the parasites. Hosts may belong to either the animal or vegetable kingdom. The type of host determines the division of parasitology into animal parasitology and vegetable parasitology. Animal parasitology comprises the parasites of animals; vegetable parasitology, parasites of vegetables. This chapter will consider only animal parasitology, including human parasitology.

Parasites may belong to the animal kingdom or to the vegetable kingdom. The first are called **zooparasites,** the latter, **phytoparasites.**

Arthropodology is the study of arthropods. **Arthropods** are characterized by their articulated legs, chitinous exoskeletons, and segmented bodies. Arthropodology may be divided into **acarology,** the study of acarina, and **entomology,** the study of insects.

Grades of Parasitism

There are intermediate phases or grades of parasitism: free, commensal, mutualistic, symbiotic, and parasitism.

Free.—Free-living organisms live on decomposed organic material (**saprophytes**) without establishing any direct relationship to the living body.

Commensal.—Commensal parasitism implies certain advantages of living without causing any damage to the other living animal. This is illustrated by certain small fish which lodge on the outside of certain jelly fish.

Mutualism.—Mutualism means obtaining certain advantages by associating one life with another. An example is the sea crab, which is covered by a sponge. The crab carries the sponge from place to place which helps in clearing the water and in taking on food, and protects it from the voracity of higher animals.

Symbiosis.—Mutualistic animals can live separately, but in symbiosis the two lives are intimately fused and actually constitute a single individual; examples of symbiosis are those lichens formed by the fusion of an alga and a fungus.

---

*This chapter has been written with the assistance of Dr. Pedro Kourí, Director. Institute of Tropical Medicine; Professor, Parasitology and Tropical Medicine; Dean, Faculty of Medicine, Havana University, Havana, Cuba; Director, Laboratorios Kuba, Havana, Cuba.

Parasitism.—In parasitism, the parasite derives advantages by living on another entity, the **host,** with which it is associated.

Pseudoparasites

Pseudoparasites or artefacts are macroscopic nonparasitic objects erroneously diagnosed as parasites, or microscopic matter simply in transit through the digestive tract.

Life Cycle of Parasites

Parasites with direct life cycles (one host) are *monoxenous;* those with indirect cycles (more than one host) are called *heteroxenous.* Monoxenous parasites need no intermediate host in their development. Heteroxenous parasites are *diheteroxenous* when requiring only one intermediate host and *polyheteroxenous* when having more than one intermediate host; for example, *Ascaris lumbricoides* is a monoxenous parasite, *Taenia saginata* a diheteroxenous parasite, and *Diphyllobothrium latum* a polyheteroxenous parasite.

Reproduction of Parasites

Reproduction of Protozoa.—Some protozoa reproduce by bipartition and others by gemmation; some by schizogony and others by sporogony; in others, the two processes are alternate, first schizogony and then sporogony: **heterogony**.

In **bipartition,** the protozoa divide into two equal series. This is observed in the amebae, flagellates, and other protozoa. In **gemmation,** common to the lower vegetable forms, such as fungi and some bacteria, the mother cell projects a branch which gives rise to a new element similar to the mother cell.

In **schizogony,** the protozoan divides into various parts. This, like bipartition, is an asexual type of reproduction.

Sporogony is a form of sexual reproduction of the protozoa in which male elements with spermatozoid function are present, as are female elements which are fertilized. The parasites of malaria present both types of reproduction, schizogony and sporogony. Schizogony takes place in the human organism and sporogony in the mosquito. (See pages 1889 ff.)

Reproduction of the Trematodes.—Most of the trematodes are hermaphroditic. Certain types, such as the schistosomas, have separate sexes. In addition to the sexual type of reproduction, the trematodes also have a special type of asexual reproduction, gemmation, which is observed in the larval form, but not in the adult.

Reproduction of the Cestodes.—Cestodes are successive hermaphroditic. Each flatworm shows reproduction by gemmation in the adult form, and partly also in the larval stage.

Reproduction of the Nematodes.—Most of the nematodes are of different sexes. Some, no doubt, like *Strongyloides stercoralis,* have parthenogenetic reproduction, although this has been denied by certain authors.

Reproduction of the Arthropods.—Generally, the arthropods contain both males and females, but some species present normal parthenogenesis and others accidental parthenogenesis with respect to the male.

Dissemination of Parasites

Parasites are widespread in nature. Eggs and larvae of helminths and cysts of protozoa leave their hosts in the feces, sputum, urine, etc., and abound in nature. They contaminate water and vegetation. Man acquires these parasites passively at times by ingesting water, vegetables, and other food contaminated with infestive forms, such as embryonated eggs of nematodes, cysts of protozoa, or through ingestion of intermediate hosts such as the meat of hogs, fish, crabs, etc., which are parasitized by the infective larval forms.

Certain organisms, like the *Wuchereria bancrofti,* emerge actively from their chitinous coverings and bore through the skin. Others are injected into the host by the bite of an insect, such as Plasmodium, Trypanosoma, etc. Some are left upon the skin by hematophagous arthropods at the moment of biting, such as Spirochaetae, Rickettsiae, etc. Other parasites are transmitted by direct contact, such as the treponemata of syphilis and yaws, Sarcoptes, etc.

Eggs and cysts leave the body with the stools, sputum, and urine, to continue their evolution. Certain parasites, however, such as Plasmodium, Trypanosoma, Filaria, cannot continue their life cycles except through the intermediation of hematophagous ectoparasites (mosquitoes, flies, Hemiptera), which extract them from the blood.

There are, in nature, healthy or convalescent ''carriers,'' which are the reservoirs of parasites, and these reservoirs may disseminate and maintain the lives of such parasites.

LABORATORY METHODS FOR THE DIAGNOSIS OF PARASITISM

Laboratory methods for the diagnosis of parasitism can be divided into direct and indirect. Direct methods permit one to see the parasite or the elements from which they are derived; indirect methods include investigating cytologic and immunologic reactions of the invaded organism, such as eosinophilia, antibody formation, etc.

(1) Direct Methods: Absolute Diagnosis

To make an absolute diagnosis of parasitism, it is necessary to see the parasite in any of the stages of its evolution, the eggs, larvae, adults, trophozoites, cysts, or the elements derived from them, liquids, membranes, hooklets, pigments. A simple macroscopic examination is often sufficient in many cases to make an absolute diagnosis. At times it is necessary to magnify the objects found. For this purpose, simple lenses or binocular stereoscopic microscopes or compound microscopes with high magnification are used.

Material for examination is quite variable, and it is necessary to carry out various procedures: examination of the sputum, nasal secretions, gastric juice, duodenal fluid, feces, rectal secretion, urine; material obtained by biopsy, at autopsy, in the operating room, or by puncture; spreads made from the spleen, sternum, cystic liquids, abscess pus, exudates from ulcers, etc. Examination of bile obtained by duodenal intubation is very important in the absolute diagnosis of certain parasitoses of the biliary or intestinal channels.

An outline of direct methods is given in Table 172.

TABLE 172

- Direct Method Absolute Diagnosis
  - Macroscopic examination or examination with slight magnification
    - by simply looking at it
    - with a hand lens
    - with binocular stereoscopic microscope
    - screening of the feces
  - Microscopic examinations
    - direct preparations
      - dark-field condenser (ultramicroscopic)
      - bright-field condenser
        - examination of fresh specimen or by stain of moist specimen
        - examination by staining fixed smears
    - concentration methods
      - mechanical
        - blood
          - thick drop
          - centrifugation
        - stools
          - solutions of high density
          - solutions of low density
      - biological
        - coprocultures: hydrotropism, phototropism
        - xenocultures: by reproduction, by concentration
        - other cultures: blood, excreta, exudates, etc.
        - experimental inoculation

Macroscopic Examination.—Certain parasites can be seen macroscopically. Parasites of *Taenia saginata,* the most frequent parasite of man, can be identified in most cases by finding proglottids, which emerge actively from the anus. These proglottids may emerge alone or admixed with fecal material. *Enterobius vermicularis* can be seen frequently with the naked eye in the stools of parasitized individuals. Sometimes the patients bring for identification parasites which they have seen in their stools, on their bodies, or on their underclothing.

In macroscopic examination of pus from cutaneous fistulas there may be seen characteristic yellow granules of actinomycosis which can be confirmed by direct microscopic examination of the fresh specimen between cover glass and slide.

Most of the larger ectoparasites are recognized by simple macroscopic examination or by the use of a hand lens or binocular stereoscopic microscope. These are such organisms as larvae of myiasis, pediculi (*capitis, vestimenti,* and *pubis*), anopheles, reduvidae, ixodidae, etc.

Ascaris lumbricoides may be expelled by mouth or at the anus and can be recognized at a glance.

Screening.—At times the segments of Taenia or the oviferous female of Enterobius are found mixed in stools and in order to see them it may be necessary to dilute and screen the fecal material.

If the stools are not liquid, dilute with water in the same container.

Agitate vigorously and pass them through a collander with 1 mm. apertures.

Wash them freely in running water and then place the collander over a bucket with a flat bottom, white or black, and let the water fall over the outer convex surface of the collander so as to catch all the small particles and parasites retained by it.

When examining the contents of the bucket the parasites can be found if present in the stools. Mucous membranes can also be found, as can vegetable remnants, confused by beginners with true parasites (pseudoparasites).

For the identification of these elements, lenses or a binocular stereoscope microscope can be used when a simple macroscopic examination is insufficient to identify them.

Microscopic Examination.—Examine a drop of the fresh material, stools, blood, pus, etc., between cover glass and slide, for microscopic examination for eggs and larvae of intestinal parasites, embryos of filaria, trypanosomes and plasmodia in blood, protozoa and their cysts, fungi, etc. At times it is necessary to add to a drop of the fresh material a drop of strong Lugol solution, as in the study of intestinal protozoa and their cysts, or a Lugol-eosin mixture, or weak solutions of supravital stains like neutral red, methylene blue, brilliant cresyl blue, etc.

In affections of the skin and its appendages the examination is made of scales, nails, hair, etc., mixed with one or more drops of 40 per cent potassium or sodium hydroxide, using the high-power magnification of the microscope. Mycelial filaments, spores, etc., can be seen.

Examination of Stained Spreads.—Giemsa stain diluted in the proportion of 1 or 2 drops of the stain to each c.c. of neutral or slightly alkaline distilled water can be used to stain and demonstrate the finer elements of blood or visceral spreads, after methyl alcohol fixation, or for the staining of the thick drop of blood which has been previously hemolyzed. The thick drop is used for examination for parasites of malaria, trypanosoma, leishmania, filaria, etc.

Staining by Gerlach or van Gieson methods of spreads of Ammon's horn as well as silver impregnations of frozen sections of these nerve structures and staining by Ziehl-Neelsen method of paraffin sections of Ammon's horn will demonstrate Negri bodies in rabies. Such preparations are examined with the oil immersion system.

Heidenhain's iron-hematoxylin and its modifications as well as the Mann method for staining spreads of stools or of muco-pus of moist specimens fixed with mercurial fixatives are used in the study of the finer structures of intestinal protozoa and their cysts. This method is at times indispensable in making a differential diagnosis of the various species. Gram's method should be used systematically in the investigation of intestinal protozoa. This is an excellent method for diagnosis as noted in the publications of Kourí and Basnuevo. Silver impregnation is used* for the study of spirochetes in general, especially the *Treponema pallidum* and *T. pertenue*. A dark-field examination of the sera from such lesions should also be made.

Concentration Methods

When the parasites and elements derived from them are present in fluids such as blood, urine, bile, or in excretions, it is necessary to use concentration methods to demonstrate them. There are mechanical and biological concentration methods. Mechanical methods are applicable to blood parasites and biological methods to intestinal parasites.

---

*Krajian method is recommended.

Mechanical Methods.—Blood.—The thick drop of blood hemolyzed and stained with Giemsa stain can be considered a concentration method for the investigation of malaria plasmodia, trypanosomata, leishmanias, spirochetes of relapsing fever, microfilariae, etc. Other methods of concentration of parasites in blood are based upon centrifugation of large quantities of blood either hemolyzed or not hemolyzed, for the investigation of microfilariae and trypanosomes.

Stools.—There are many concentration methods for eggs, larvae, and cysts. All are based on the use of a large amount of fecal material which is rendered homogeneous with water or saline solutions and screened. This separates the large quantity of thick solid material which is retained upon the screen. Cysts, eggs, and fine forms pass through the screen and are collected into a conical tube and centrifuged. They then can be found in the sediment. Some authors—Usami and Kamada—have demonstrated that the screen may hold back a large number of eggs and cysts and that it is necessary to examine the thick particles which fall to the bottom, decanting the supernatant fluid. This should be repeated several times.

Many concentration methods are carried out with solutions of a lower density than that of eggs and cysts (see pages 1811 and 1812), concentrating the eggs and cysts at the bottom of the tube; others use solutions of a higher density than that of the eggs, the upper portion of the fluid then being examined.

Biological Methods.—Coproculture.—Coproculture is carried out for the diagnosis of parasitism of *Strongyloides stercoralis, Necator americanus, Ancylostoma duodenale,* and the schistosomas, or bilharzias, when the larvae and the eggs are held within the stools. Generally for coproculture the stools must be mixed with animal charcoal or with pulverized and sterilized dirt and water, although Kourí's experiences have shown that good results may be obtained without using any of these substances. In coproculture, advantage is taken of the property shown by certain parasites to be attracted by water, positive hydrotropism, or by light, positive phototropism. When a little water at 28° to 32° C. (82° to 90° F.) is directed to a mass of pasty stool, after a certain time if the stools contain larvae of Ancylostoma and Strongyloides these larvae leave the stool and move toward the water. Here they concentrate. Examination of a drop of this fluid will reveal them, whereas direct examination of the stools would not have. Coproculture is simply a method of biological enrichment, based upon the tropism of larvae.

In the case of schistosomiasis with only a few eggs in the stool, if the feces are diluted with water the larvae are set free after a certain time, and accumulate on the surface of the liquid, being attracted toward the more illuminated portion by its phototropism. At times coproculture serves as an enrichment not only for concentration of larval forms by tropism, but also for actual multiplication of the parasites. This is true of the *Strongyloides stercoralis* which completes its sexual cycle in the coprocultures.

Xenoculture (Xenodiagnosis of Brumpt).—Brumpt gave the name of xenodiagnosis to a procedure worked out by him in 1905 for diagnosis of trypanosomiasis of certain vertebrates where the parasites are scarce in the blood. If intermediate habitual or vicarious hosts suck the blood of certain vertebrates, a diagnosis of trypanosomiasis can be made in the vertebrates by finding the evolutionary form of the trypanosomes in the intestines of these intermediate hosts. This procedure is in reality a hemoculture in the digestive tract of the intermediate hosts where these flagellates multiply actively. This is called *xenoculture.* At times multiplication of parasites does not occur in the digestive tract of the host, but instead there is concentration in the extracted or sucked-out blood. This occurs, for example, when the microfilariae which may be found in large numbers in the blood are extracted by the Culex mosquito from the patient bitten by the mosquito. This attraction of embryos of filaria by its intermediate hosts is a means of diagnosis in cases in which the embryos are scarce in blood.

Xenocultures can also be used for differentiation of various spirochetes which are morphologically identical. For example, cosmopolitan relapsing fever is due to the *Borrelia recurrentis* and transmitted by lice; relapsing fever carried by the sheep tick is transmitted by various species of the genus Ornithodorus; African relapsing fever is due to *Bor. duttonii,* and is transmitted by the *Ornithodorus moubata* and by the *O. savigny;* American relapsing fever due to the *Bor. venezuelensis* is propagated by the *O. venezuelensis* (*O. rudis*) and by the *O. talaje;* Spanish relapsing fever due to the *Sp. hispanicum* has for its vector host the *O. marocanus.* All these spirochetes are morphologically identical, but have different vector hosts; they are therefore all biologically different spirochetes.

Other Culture Methods.—Inoculation of blood, stools, and exudates in special culture media is used as a diagnostic method in certain parasitoses.

Blood Culture.—Blood culture is a method of inoculating blood on artificial media and is used as a diagnostic measure in certain protozoal diseases, such as leishmaniasis, sodoku, when these parasites are scarce in the blood.

Culture of Stools.—When intestinal amebiasis is suspected and the direct coprologic examination even with concentration has failed to reveal them, cultures of the stools must be made, using a small portion in special media. As has been pointed out, culture or inoculation of stools is a different mechanism from coproculture because in cultures a small portion of the stool is inoculated to allow the parasites to reproduce, and in coproculture multiplication of parasites does not occur, but a concentration due to tropism. In reality the word coproculture signifies culture of the stools and should be applied to the actual culture. Some other name should be used in place of coproculture, for example, *tropodiagnosis,* because this method is based upon the tropism of the larvae. The stools can be left on the laboratory table at room temperature in the fresh state with the object of studying the development of the eggs of the nematodes, the formation of the embryo, etc.

Exudates.—In suspected lesions of mycosis, leishmaniasis, sodoku, etc., in which direct examination and stained specimens have proved negative, inoculation on special media may successfully make the diagnosis.

Experimental Inoculation.—Another means of diagnosis of parasitic diseases is experimental injection of the suspected material into laboratory animals; for example, kittens and puppies for amebiasis, chicks for intestinal protozoa, rats for sodoku and trypanosomiasis, guinea pigs for icterohaemorrhagic spirochetosis, etc.

Duodenal Intubation.—Macroscopic and microscopic examinations of fluids obtained by duodenal intubation permit the diagnosis of certain parasitoses of the biliary tract and the duodenum with much greater rapidity and security than examination of the fecal material. This has been demonstrated by Bacigalupo, Toullec, and Riou, and Kourí and associates. Distomiasis hepatica by *Fasciola hepatica* and *Clonorchis sinensis,* the lambliases, strongyloidiasis, necatoriasis, etc., are parasitoses in which duodenal intubation renders a great service from the diagnostic point of view. Pseudoparasitism by ingestion of eggs of *F. hepatica* is distinguished from true parasitism by examination of the bile obtained by duodenal intubation. In erratic parasitism, gastric, duodenal, or biliary, with *Ascaris lumbricoides,* microscopic examination of the bile and its flocculent contents can reveal an abnormal localization of this parasite.

Differential diagnosis between *Necator americanus* and *Ancylostoma duodenale* is difficult to prove from the eggs found in the stools, but it is possible if adult forms of the parasite are found and this finding is combined with the examination of bile obtained by duodenal intubation. Occasionally larvae of Strongyloides and the vegetative forms of lamblias are found in the bile and duodenal liquid of individuals whose stools have been negative for these parasites.

(2) Indirect Methods

Indirect methods for the diagnosis of parasitism differ from direct methods in that they do not permit a view of the parasites, but rather an investigation of their effects on the cellular and immunologic reactions of the host in the presence of active and aggressive parasitoses. A definitive diagnosis of the parasitism is not always possible by these methods.

Cellular reactions comprise blood eosinophilia; local eosinophilia; leukopenia with monocytosis; anemia; local inflammatory reactions, acute, subacute, and chronic; remote reactions such as lymphatic gland enlargements, hepatomegaly, changes in the bone marrow; hyperplasia, metaplasia, and neoplasia. Blood eosinophilia in a tropical country makes one think of parasitism, and an investigation for parasites should then be made by direct methods. Anemia might be due to many causes, among them the anemias due to Necator and Ancylostoma. Monocytosis is frequently seen in malaria.

Flocculation Reactions

Various flocculation tests are in use, principally the Kahn, VDRL, Meinecke, Sellek-Frade, Basnuevo, etc.

The Henry-Melano Flocculation Test.—In 1927, Henry[1] presented his melano- and ferro-flocculation tests. He advanced the theory that the

---

[1] Gaz. hevd. Sc. méd., Bordeau 48: 311, 1927.

''melanotic'' and ''yellow iron pigments'' formed in the organs of malarial patients were active substances rather than inert deposits; that they were malarial antigens or endoantigens and either gave rise to the formation of endoantibodies or disturbed the colloidal state of the serum in such manner as to impart to it certain flocculating peculiarities. Because true malarial pigment was difficult to obtain, he chose choroidal melanin and certain organic iron compounds as antigens for his test. He regarded the attenuation or entire disappearance of the reaction in sera which were obtained during a paroxysm as being due to the fixation of the endoantibodies, already present, by an overwhelming amount of new endogens produced from the massive destruction of erythrocytes during the attack.

Technic.—

Mix 1 part of serum with 4 parts of a suspension of melanin, formolized at 1:2000, either in distilled water or in 0.3 per cent saline, for sera which flocculate spontaneously in a 1:5 dilution of distilled water.

At the same time prepare serum controls and antigen controls in the usual manner. Stopper the various mixtures and incubate for 3 hours at 37° C.

Allow to stand for 30 minutes at room temperature and read the reaction macroscopically.

Flocculation of melanin indicates a positive reaction. Flocculation in the serum control tube is called by the author ''surflocculance'' and supposedly occurs in some normal sera and nonmalarial sera.

Since the interpretation of the reaction is difficult macroscopically, Henry later advocated the use of the photometer of Vernes, Bricq, and Yvonne, for the quantitative equivalence of the optical density, developed in the tubes during incubation.

The fero-flocculation test, which at first was run concurrently with the melanin reaction, was abandoned by its authors because of its lesser sensitivity and the difficulty of procuring uniform iron preparations.

Proske and Watson Protein Tyrosin Reaction.—Proske and Watson[2] devised a simple accurate colorimetric test obviating the necessity for a photometer. The procedure is based on the fact that proteins possess a chromogenic property which can be measured quantitatively against the color produced by pure tyrosin in the presence of a phenol reagent. This chromogenic value is constant for a given protein, and the intensity of color produced can be used as a measure of the amount of the protein examined.

Serum euglobulin is precipitated from the serum to be examined by adding 13.5 per cent sodium sulphate solution according to the method of Howe. The tyrosin-chromogen index (TI) is determined by comparison with standards prepared from pure tyrosin (Pfanstiehl).

Proske and Watson found in 2,500 normal blood sera that the tyrosin index or euglobulin fluctuated between 50 and 80 while that for sera from malarial patients ranged from 80 to 280 or higher. The test was found to be indicative of the presence of malaria in 97.4 per cent of known malarial cases examined, as compared with 81.9 per cent positive thick blood films examined at the same time.

---

[2] Pub. Health Rep. 54: 158, 1939.

Like the Henry test and its modifications, this test is nonspecific, but its high sensitivity in malaria may make it a useful adjunct to the laboratory diagnosis of this disease. It may also be helpful in the differential diagnosis of other pathologic conditions characterized by increase in serum globulin.

Reagents.—

14 Per Cent Sodium Sulphate Solution.—

Dissolve 70 gm. of sodium sulphate, c.p., anhydrous
in 300 c.c. of freshly prepared distilled water.

Dilute to 500 c.c. with distilled water, at a temperature of 37° C. Store in an incubator at 37° C. Solution is stable indefinitely.

5 Normal Sodium Hydroxide.—

Dilute saturated, carbonate-free sodium hydroxide solution to 20 per cent (20 parts per 100).

Tyrosin Standard Solution.—

5 c.c. contain 1 mg. tyrosin. See page 305.

Phenol Reagent of Folin and Ciocalteu.—See page 305.

Technic.—

Unknown.—

Place 3 c.c. of 14% sodium sulphate solution in a small test tube (75 by 100 mm.).

Using an accurately calibrated pipette, add 0.1 c.c. of unheated, clear, nonhemolyzed, nonchylous serum.

Mix by inverting a dozen times, avoiding air bubbles.

Stopper the tube and place in an incubator at 37° C. for 3 hours.

Centrifuge at 1500 r.p.m. for 10 minutes.

Completely pipette off the supernatant fluid.

Wash the precipitate twice with fresh sodium sulphate solution by centrifugation.

This is necessary in order to remove traces of albumin and pseudoglobulin that may have been caught in the precipitate or may adhere to the walls of the tube, and which will also react with the phenol reagent, giving too high readings.

Dissolve the washed precipitate in 1.75 c.c. of distilled water.

Add 0.1 c.c. of 5 normal sodium hydroxide.

Stock Standard.—Use a test tube graduated at 20 c.c.

Place 2 c.c. of the tyrosin solution in the tube.

Add 5 c.c. of distilled water
and 1.0 c.c. of 5 normal sodium hydroxide.

Heat both the unknown and the standard in boiling water for 10 minutes and allow to cool.

Add to the unknown 0.15 c.c. and to the stock standard 1.5 c.c. of the phenol reagent, and dilute the standard to the 20 c.c. mark with distilled water.

While the color is developing, set up a series of small tubes, 75 by 10 mm., and mark the tubes with a wax pencil 100, 90, 80, 70, 60, 50, 40, 30, 20, and 10. Prepare *substandards* in these tubes according to the following schema:

Substandards—per cent	100	90	80	70	60	50	40	30	20	10
Stock standards—c.c.	2.0	1.8	1.6	1.4	1.2	1.0	0.8	0.6	0.4	0.2
Distilled water—c.c.	0.0	0.2	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8

Compare the color intensity of the unknown with these standards. If the color of the unknown falls between two whole gradations, the color value is intermediate between the two. For example, if the unknown falls between 60 and 50, then the reading is 55.

Observe the following precautions: All glassware must be chemically clean, but sterility is unnecessary. The serum pipettes should have fine tips, because small droplets of serum adhering to blunt tips may cause considerable error. Sera should be clear. Hemolyzed sera give too high tyrosin values owing to their globin content; chylous sera give too low values owing to the fact that chyle interferes with the protein precipitation.

Some Serologic Tests

Precipitin Reactions.—If the serum of an individual carrier of hydatid cysts is mixed with hydatid cystic fluid, in proper proportions, in twenty-four hours at room temperature a copious precipitate occurs. No alteration occurs in the mixture when negative sera are used. This precipitation is due to the presence in positive sera of a precipitin or antibody which, when in contact with its corresponding antigen, hydatid fluid, forms a copious precipitate.

Tests of Active Cross Immunity.—This is a biological test which is used for the classification and identification of trypanosoma and piroplasmas and of spirochetes which may morphologically be identical to other species in their same genera. A sheep is inoculated with a known strain of trypanosomes, or of either of the other two organisms, and develops the disease. This same animal is then inoculated with the trypanosome under study. If the animal again develops the disease, that is, from the new inoculation, then the organism used belongs to a different strain from the first. If the sheep does not acquire the infection from the second inoculation, then the organism in question is the same as that used for the first inoculation. In other words, if the strains are in reality identical both morphologically and biologically, then no disease develops from the second inoculation. Proof of infection is made by transferring the inoculation to another animal, since the parasites are too scarce to be found in the blood by means of a simple microscopic examination. This test is based on the active immunity which certain spirochetes, trypanosomes, and piroplasmoses confer on the host. However, lack of specificity detracts from the value of the test, as in syphilis and yaws.

Physical Alterations

The Ascoli Miostagmin Reaction.—Not only is biological testing of sera important in the indirect diagnosis of parasitism, but also the physical alterations observed in certain parasitoses. In certain parasitic diseases such as hydatidosis, ancylostomiasis, syphilis, etc., a decrease in the surface tension of the sera is noted, and consequently an increase in the number of drops in a given volume and at a given temperature. This is detected by the stalagmometer of Traube. A mixture of an antigen such as hydatid fluid and an antibody such as the serum from a hydatidosis patient produces a decrease in surface tension in the serum. Consequently the number of drops in such mixtures is greater than the number of drops in a mixture of the same antigen and normal serum. This reaction has been called *miostagmin* ("fewer drops").

Blood Sedimentation in Parasitoses.—The sedimentation test has been used in certain parasitoses, for instance by Giovani Souderi in Sicily, who noted an increase in blood sedimentation in ancylostomiasis, and by Bacigalupo in Buenos Aires who saw no change in sedimentation rate of the blood in six cases of necatoriasis. This writer believes that the increased sedimentation rate which he has seen at times in parasitic anemias is due to the anemia and not to the parasitosis. Our experiences with the anemias due to *Necator americanus* show that in this condition there is an accelerated sedimentation rate, which is retarded and becomes normal with the administration of iron in large doses. This therapy at the same time causes the anemic state to return to normal, with a lessening of the number of parasites as judged by the decreasing number of eggs in the stools after administration of iron.

This test can be recommended in parasitic diseases, especially in hookworm disease, in hepatic distomiasis, hepatic amebic abscess, hydatidosis, malaria.

CONCENTRATION OF STOOLS

Fülleborn Method

For the examination of *Ancylostoma duodenale, Necator americanus, Ascaris lumbricoides,* and *Trichuris trichiura* eggs, a very good method is that proposed by Fülleborn, known as the "Hamburg Cover Glass Method." In this method, the infection and its severity can be determined somewhat by the number of eggs found.

One should always use the same magnification in looking for eggs so that the mind's eye will have the same picture of relative size. Use a No. 3 ocular with a Leitz No. 4 objective followed by Leitz No. 6, or the equivalents in other makes of microscopes. In order to find eggs in the urine, the urine must be centrifuged.

Use a special metal box devised by Fülleborn which has a depression in the center which holds about one gram of stool. After this depression is filled with stool, add a small amount of concentrated sodium chloride solution and mix thoroughly, adding enough sodium chloride solution to fill to the mark on the box which holds about 20 c.c. (The sodium chloride is made up in a large Florence flask half full of water. Add a large quantity of the salt so that it will be a supersaturated solution. Be sure to shake it at least five minutes before using.)

This gives a dilution of 1 to 20. It requires one hour for the Trichuris eggs to come to the surface. Place on top of this fluid three cover glasses; let them float, allowing the material to stand ten minutes; if looking for Trichuris, one hour. With wide-toothed forceps, pick off the cover glass without turning it and drop it on a slide without compression.

Determine the number of eggs present by a special ruled cover glass 18 millimeters square in size, which is exactly one-seventh of the entire upper surface of the saline solution. Multiply the result by seven; this will give the number of eggs in one gram of stool. If the egg quantity in one gram of stool is over 10,000, proceed as in counting red blood cells. Count ten different parts of each preparation, each one square millimeter in size. 3 × 10 will equal 30 counts. Each square represents an area of 18 × 18 or 324 square millimeters. Obtain the average counted in 30 squares and multiply by 324.

Telemann Method

There is another method, called the Telemann[1] method, which is suitable for all eggs, as well as the above varieties.

Take five pea-sized pieces of stool from five different parts on a glass rod. Mix with 50% hydrochloric acid and rub thoroughly. Add a small amount of ether, and shake. Place a fine mesh piece of copper gauze about five inches square inside a glass funnel. Let the fluid run through the copper gauze into a centrifuge tube. Centrifuge two or three minutes. You will then note an upper layer of ether, a lower layer of detritus; the eggs will be at the bottom. Pour off the supernatant fluid very carefully. Pick up the sediment with a pipette and examine on a glass slide.

---

[1] Deutsche med. Wchnschr. 34: 1510, 1908.

Hunter Modifications of the Acid-Ether Sedimentation Technic of Telemann

These two methods were suggested by Hunter and associates.[2] Acknowledgment of these modifications came in a personal communication from Col. Hunter, to whom we express our gratitude. The modifications devised by him are called the AMS III method and the 406 MGL method. Col. Hunter has used both these methods routinely and has found the MGL superior to the zinc sulphate technic for protozoa and worms. The AMS III is better than the MGL for the recovery of helminth eggs and larvae. "It was designed for schistosomiasis, but we have used it on over 20,000 stools here in the Far East where it has been run in parallel with the MGL and have found it to be excellent all around technique for eggs."

THE AMS III METHOD

Reagents.—

Hydrochloric Acid-Sodium Sulphate Mixture.—

Prepare hydrochloric acid of a specific gravity of 1.089 by adding 45 c.c. of concentrated 37% hydrochloric acid to 55 c.c. of water.

Prepare sodium sulphate of a specific gravity of 1.080 by dissolving 9.6 gm. of anhydrous sodium sulphate in 100 c.c. of water.

Add equal parts of the hydrochloric acid and sodium sulphate solutions. The final mixture has a specific gravity of 1.080. Each solution must be adjusted to the proper specific gravity, if needed, before mixing the final mixture.

To obtain the best possible results, it is advisable to dry the sodium sulphate before using. Dry it in a hot-air oven for 2 hours at 130° C. and cool in a desiccator. Weigh immediately upon removing from the desiccator.

Triton NE (Triton X30).—

This is a wetting agent.[3]

Ether.—

Technic.—

Partial comminution of the entire stool with an appropriate amount of water can be accomplished in the stool box. A suitable amount of water will make it possible to recover 10 to 12 c.c. of strained emulsion, which when centrifuged will yield 1 to 1.5 c.c. of fecal sediment.

Strain through 2 layers of gauze moistened with hydrochloric acid-sodium sulphate mixture into a 15 c.c. centrifuge tube.

Wash 3 times by brief centrifugation, 1½ to 2 minutes at 1,700 to 2,100 r.p.m., decanting the supernatant fluid each time and mixing the sediment with fresh acid-sodium sulphate mixture.

After decanting, add 5 c.c. of hydrochloric acid-sodium sulphate plus 3 drops of Triton NE plus 5 c.c. of refrigerated ether.

Shake for 30 seconds and centrifuge one minute.

Remove the tube, break the ring at the interface with an applicator, and decant. Swab the tube down to the sediment with a cotton swab, being careful not to touch the sediment.

Add tap water to the 0.4 c.c. mark, mix the sediment, and pour as much as can be read onto a slide.

Cover with a 24 by 40 mm. cover glass.

An applicator stick may be used to draw the few drops of sediment to the lip of the tube. It is especially useful in controlling the amount of sediment that escapes onto the slide.

Examine under the low power of the microscope. There should be a minimum of debris and the eggs should stand out clearly. Some of the mature eggs may exhibit viable miracidia.

---

[2] Bull. U.S. Army Med. Dept., Feb., 1943.

[3] Triton NE may be obtained from Rohm and Haas Co., Philadelphia, Pa.

THE 406 MGL METHOD

Partial comminution of the entire stool, with an appropriate amount of water, can be accomplished in the stool box. A suitable amount of water will make it possible to recover 10 to 12 c.c. of strained emulsion, which when centrifuged will yield 0.5 to 1 c.c. of fecal sediment.

Strain through 2 layers of gauze. Collect the emulsion in a 15 c.c. centrifuge tube.

Centrifuge and decant the supernatant fluid. Additional washings are advantageous.

Mix the remaining fecal sediment thoroughly with 10 c.c. of 10% Formalin. Allow 10 to 30 minutes for fixation. This reduces distortion of protozoan cysts.

Add about 3 c.c. of ether to the formolized specimen.

Stopper the tube and shake vigorously.

Centrifuge at relatively low speed for about 2 minutes.

Completely decant the ether, superficial debris, and Formalin, using an applicator stick to free the superficial debris from the centrifuge tube.

Mix the sediment remaining in the centrifuge tube thoroughly with the fluid that drains back from the tube wall, and pour onto a glass slide. Avoid an excess.

Place a small drop of 2% iodine solution near the top of the sediment, and mix by using the edge of a cover slip.

Push the edge of the cover slip into the drop, allowing the fluid to run under the cover slip and at the same time pushing the coarse debris aside. This step is critical in obtaining a suitable microscopic preparation.

Loughlin and Stoll Modification of the Telemann Technic

Stoll and Loughlin[1] described a modification of the Telemann method. This modified technic consistently demonstrated infertile Ascaris eggs. It also possesses a similar degree of effectiveness for hookworm, fertile Ascaris, Trichuris, *Hymenolepis nana,* and *Schistosoma japonicum* eggs. This method does not inherently preclude the demonstration of eggs which cannot float in solutions of high speed gravity, nor does it cause such loss of eggs from the material to be examined as occurs in the Telemann procedure.

Measure 4 c.c. (or grams) of feces into a dilution counting flask which has been filled to the 56 c.c. mark with water.

Add several glass beads (6 mm.) and after giving the preparation an initial shaking, set aside for several hours or overnight (preferably refrigerate); complete the comminution of the feces by vigorous shaking, so that all the eggs are free.

Shake to produce a thorough distribution of the eggs in the fecal suspension and transfer immediately 1.5 c.c. of the suspension to a 15 c.c. pointed centrifuge tube.

Add 3.5 c.c. of 20% hydrochloric acid,[2] put a rubber stopper in the tube, and shake for one minute; allow to stand for two minutes.

Add 5 c.c. of a freshly prepared mixture of equal parts of ether and xylol and again shake for one minute.

Centrifuge at 1800 to 2000 r.p.m. for two minutes and allow the centrifuge to come to a stop gradually without interference.

Separate the semifloating coagulum from the walls of the tube with a thin wooden applicator.

Decant quickly, permitting the sediment in the bottom of the tube to remain undisturbed. Then, while holding the tube almost horizontally, clean any adhering coagulum from the inside of the tube with an applicator covered with gauze.

Add one drop of a N/10 solution of sodium hydroxide to the sediment, mix thoroughly with a capillary pipette, transfer the entire suspension to a glass slide and place a cover glass on it. If the density or amount of residue warrants it, make two drops of the material and cover each with a coverslip in order to secure a preparation which will allow the eggs to be seen easily. Stoll and Loughlin prefer a 1½ by 3 inch slide and a 22 by 30 mm. or 25 mm. square coverslip.

---

[1] Am. J. Trop. Med. 26: 517, 1946.

[2] 20 c.c. of concentrated hydrochloric acid diluted to 100 c.c. with distilled water. The net concentration of HCl in the centrifuge tube is reduced to 14%.

Examine the whole preparation for eggs. Those found are from 0.1 gram of the original fecal specimen.

For Egg Counting.—At will, or whenever eggs are demonstrated, the displacement flask preparation may be used for routine dilution egg counting. In order to secure an approximate decinormal sodium hydroxide suspension without appreciably altering the original dilution, one hundredth the volume of 10 N sodium hydroxide[3] is added. Thus, if 1.5 c.c. have been removed from the 60 c.c. suspension, 0.58 c.c. of the 10 N sodium hydroxide is added. One can proceed at once with dilution counting, although it is best to allow the flask with its contents to stand for an hour after shaking.

The use of hydrochloric acid of specific gravity 1.030 in this method provides satisfactory acid disintegration of the feces and permits eggs of all species to be easily sedimented by centrifugation. The addition of the xylol diminishes the adhesive properties of the coagulum of the fecal debris and prevents foaming common to the use of ether alone.

Willis Method of Concentration of Stools

The method is based on the property of eggs of certain worms to float to the surface of a concentrated salt solution, and to adhere to a glass surface.

In a glass cylinder, no larger than 2.5 cm. in diameter, carefully and thoroughly emulsify no less than one gram of fecal material with saturated solution of sodium chloride. The salt solution should be freshly prepared. Add more of the salt solution, and continue the emulsification until the container is filled to the top and a meniscus forms. Wait at least five minutes for the eggs to float to the meniscus. Then carefully place a glass slide over the surface of the solution and allow it to remain for 10 to 30 minutes. Take care to admit no bubbles.

Carefully remove the slide and turn it upside down without spilling the liquid which contains the eggs. Cover with a thin cover glass and examine under the microscope.

This is an excellent general concentration method, but it is of doubtful value in examining for eggs of the trematodes.

Acetic Acid and Ether Concentration Method for the Examination of Feces*

In a comparative study of various methods of concentration for the examination of feces the following method has been found to give greater amount of concentration, with the added advantage of eliminating most of the detritus in the material concentrated. The technic is practical and very simple. It requires only a few minutes to complete the work and make the examination. The method is based on the addition of a 5 per cent solution of acetic acid to diluted fecal matter. The purpose of this acid is to dissolve the carbonaceous matter and to clear the mucous material which may be present; it may also hydrolyze the fatty substances to some extent. Ether, which is added, dissolves the excess fatty substances and, by infiltrating the suspended particles, renders them lighter, facilitating their separation to the top of the mixture and the settlement of eggs, cysts, cells, and other heavier particles by centrifugalization.

Soften about 1 or 2 gm. of fecal material, if necessary, and suspend in about 10 c.c. of 5% solution of acetic acid in a test tube.

Shake thoroughly for a few seconds.

Allow to stand for about a half minute to permit the heavy particles to settle to the bottom of the tube.

Filter through a single or double layer of gauze and collect the filtrate in an ordinary test tube. The tube should be about one-third full.

---

*Am. J. Trop. Med. 8: No. 1, 1928.

[3] Prepared by dissolving 40 grams of sodium hydroxide sticks in distilled water q.s. to 100 c.c. Note that this concentration is caustic.

To the filtrate in the tube, add an equal volume of ether, and stopper the mouth of the tube tightly with a rubber stopper.

Shake vigorously until a thorough mixture is obtained. This can be judged by an emulsion-like appearance of the material. This shaking is usually complete in from 15 to 30 seconds.

Immediately centrifuge the tube for two, three, or five minutes. This procedure separates the material into four well-marked layers. The topmost layer is the ethereal extract. Immediately below this is a plug of detritus, which is made up of coarser particles, proteins, and soap. The acid solution is below this plug, and a small amount of sediment is at the bottom of the tube.

The three upper layers, the ethereal extract, detritus plug, and acid layer, can be easily removed by a gentle jerk of the tube, leaving the sediment adhering to the bottom of the tube. If this is done carefully, the sediment will remain in contact with the tube.

Collect the sediment with a capillary pipette and place on a slide.

Drop a cover glass over the sediment and examine under the microscope. The material may be fixed and stained.

This method gives a much higher degree of concentration than do many other methods. It facilitates the rapid detection of eggs, protozoa cysts, and cellular elements by its high degree of concentration and by the clearing of detritus from the preparation. It can be used by any laboratory technician with ease and confidence.

Formol-Ether Stool Concentration, Ritchie[1]

Mix stools with about 10 volumes of tap water.
Strain through gauze into 15 c.c. centrifuge tubes.
Centrifuge the strained emulsions.
Wash the sediments with tap water.
Repeat the centrifuging and the washing.
Decant the supernatant fluid.
Add 10 c.c. of 7.5% Formalin to the sediment.
Let stand for 10 to 30 minutes.
Add about 3 c.c. of ether.
Stopper the tubes and shake vigorously.
Centrifuge at low speed for about 2 minutes.
Free the superficial debris from the tube wall with an applicator stick.
Then decant all the supernatant mixture.
Examine the sediment under a microscope.
Add 2% iodine and examine again.

This method gives favorable results with protozoa and helminths. It is possible to add the Formalin to the stools at the time of their collection and carry out the centrifuging and flotation later in the laboratory. In this case, the Formalin serves as a preservative for the parasites and their eggs.

Zinc Flotation Method of Concentration of Eggs in Parasitologic Examinations

A preliminary communication by Faust, D'Antoni, Odom, Miller, Peres, Sawitz, Thomen, Tobie, and Walker[2] gives credit for the centrifugal flotation technic and counts of parasitic eggs to John Tobie. This flotation method ultimately adapted was as follows:

Mix a small amount of feces (about the size of a pecan) with about 10 parts of water.

Strain 10 c.c. of the suspension through a *wet* cheesecloth in a funnel into a Wassermann test tube.

---

[1] Bull. U.S. Army Med. Dept. **8**: 326, 1948.

[2] Am. J. Trop. Med. **18**: 169, 1938.

Centrifuge for 45 seconds to one minute at top speed.

Pour off the supernatant fluid.

Add 2 or 3 c.c. of water and break up the sediment by shaking or tapping.

Add more water to fill the tube.

Centrifuge and repeat this washing and centrifuging until the supernatant fluid is clear. Pour off the last supernatant fluid.

Add 3 to 4 c.c. of a solution of zinc sulphate, specific gravity of 1.180.

This is a 33 per cent solution of granular zinc sulphate in water (386 gm. of granular zinc sulphate to 1 liter of distilled water). Shake. The material should be up to within one-half inch of the rim of the tube.

Centrifuge for one minute at top speed.

Remove the surface film by means of a platinum loop. Place on a slide and add 1 drop of D'Antoni's iodine stain. Agitate by hand and mount. Examine.

It has been found by this method that all the eggs, even operculated eggs, will rise to the top.

Ronald-Elsdon Dew* in discussing this method advises that specimens containing much mucus are not suitable for this technic, as the mucus floats *in toto,* and there is little gain in concentration. He recorded the findings of 1,539 specimens in which this technic was compared with the direct fecal film. The over-all gain by the use of this technic was 179 per cent. Some eggs do not float well, for instance Taenia and *Schistosoma mansoni.* They can often be found in the sediment of the final "spin."

Baroody's Modification of the Faust Method for Concentration of Cysts and Eggs

Faust's method for the detection of cysts and eggs embodies the use of zinc sulphate method for flotation purposes. Baroody[1] called attention to the fact that the routine method of Faust does not call for enough stool sample to permit finding cysts of *Endamoeba histolytica* when they are present in small amounts. He therefore modified the Faust method by taking a larger quantity of stool and in this way succeeded in finding cysts where he had failed to do so with the original Faust method. His modified technic is a combination of Baroody and Most's water centrifugal sedimentation method,[2] page 1811.

Technic.—

Place about 10 gm. of feces in a 125 c.c. Erlenmeyer flask containing about 75 c.c. of warm water (about 40° C.); stopper the flask and shake until emulsified.

Strain through 1 layer of wet gauze into a 50 c.c. centrifuge tube (teated bottom).

Centrifuge for one minute at 2500 r.p.m. and pour off supernatant fluid. Add warm water to the sediment from a regulated faucet (force of the water will disperse the fecal particles and cleanse them) and centrifuge again at the same time and speed. Decant supernatant fluid; repeat one more washing and centrifugation; again decant supernatant fluid.

Add about 10 c.c. of warm water and agitate sediment by shaking; then pour quickly all of contents into a 15 c.c. centrifuge tube. Centrifuge for one minute at 2500 r.p.m. and decant supernatant fluid.

Add about 10 c.c. of zinc sulphate solution (33 per cent, specific gravity 1.180) to the sediment and stir with applicator sticks. Add zinc sulphate nearly to top of tube. Centrifuge for one minute at 2500 r.p.m. Eggs and cysts will float to the surface.

Take several loopfuls (bacteriologic loop) from surface and place on slide; add 1 drop of D'Antoni's or Lugol's iodine and cover with a cover slip. Examine for eggs of helminths and cysts of protozoa under low-power objective of microscope.

---

*Tr. Roy. Soc. Hyg. 41: 213, 1947.

[1] J. Lab. & Clin. Med. 31: 1372, 1946.

[2] J. Lab. & Clin. Med. 31: 815, 1946.

It will be noted that in this method a much larger sample of feces is utilized, thereby increasing possibility of detection in lightly infested cases or when cysts and eggs are rare in the stool. Cysts may exist in "packets" and can be missed from a remote small section. The use of warm water (about 40° C.) has advantages over the use of regular or so-called cold water. The use of warm water eliminates a high percentage of the scum which has been observed when cold water was used. After the water is added the scum rises to the surface within one minute, remains floating after the centrifugation, and eventually is discarded with the supernatant fluid. Each additional washing brings up less scum until it is practically all discarded. When the zinc sulphate is added, the surface of the liquid is fairly clean and makes a good field for microscopic examination. The initial use of the large 50 c.c. test tube instead of the smaller test tube is important because it is necessary to receive a large sample from the original 10 gm. of stool. With the larger tube the proportion of sediment to the size of the tube decreases the number of washings and centrifugations in arriving at a clear supernatant fluid; three or four washings usually give this desired result and a clean zinc sulphate preparation.

This method is particularly useful in looking for the cysts of *Endamoeba histolytica* as well as Strongyloides larvae. It is of particular value when cysts, eggs, and larvae are rare in the fecal specimens.

Baroody's method is recommended because any acid-ether technic will destroy immature *Schistosoma japonicum* eggs, thereby offering at least a partial explanation of the many negative results encountered.

Further, in the laboratory diagnosis of *Clonorchis sinensis,* the diagnosis was made by the Baroody method when zinc sulphate and brine flotation methods were negative. Acid-ether technic was also positive.

Water Centrifugal Sedimentation Method for Demonstration of Schistosoma Japonicum Eggs

Method of Baroody and Most[1]

Place 10 to 15 gm. of the feces in a 125 c.c. Erlenmeyer flask containing about 100 c.c. of lukewarm tap water. Insert a No. 4 rubber stopper and shake vigorously for 1 or 2 minutes or until the particles are in fine suspension.

Strain the emulsified feces through two layers of wet gauze into a 50 c.c. centrifuge tube with teated bottom (tube dimensions: height, 4¾ inches; diameter, 1 inch).

Centrifuge at 1500 r.p.m. for 30 seconds. Apply the brake of the centrifuge gradually.

Decant the supernatant fluid and add tap water at about 40° C. to the 50 c.c. mark on the tube. Insert a rubber stopper and shake several times until the sediment is finely dispersed. The warm water causes a scum to rise to the surface. This is desirable.

Repeat the centrifuging and washing until the supernatant fluid is clear; three washings and three centrifugations are usually sufficient.

After the last washing and centrifugation, pour off the clear supernatant fluid; the packed sediment remains. Gently tap the finger against the side of the tube to disperse the packed sediment which will settle to the bottom of the tube by gravity within a minute.

With a rubber-bulbed pipette place 4 drops of mixed sediment on a glass slide and cover with a large cover glass size 22 by 50 mm. Make at least two slides.

Examine under the low power objective of the microscope for eggs of Schistosoma.

Schistosoma japonicum eggs are oval, 70 to 100 by 50 to 60 microns, may or may not have a rudimentary spine, and in blue-white light they appear greenish orange. *Schistosoma mansoni* eggs are elongated, 114 to 175 by 45 to 68 microns, and have large lateral spines. In both species, if the eggs are visible, the miracidia will exhibit movements within the eggshells, and the activity of the flame cells may be seen under higher magnification.

---

[1] J. Lab. & Clin. Med 31: 815, 1946.

If the slides are negative for schistosoma eggs, add about 10 drops of water to the remaining sediment in the tube, leave overnight in a warm place, and examine the following day for miracidia. The entire contents of the tube can be placed on a large slide and examined under a dissecting microscope. This phase of the examination requires less than 2 minutes.

Excluding the last procedure, not more than 5 minutes are required for the examination of each slide, and not more than 15 to 20 minutes are required for the entire method.

Other eggs, cysts of protozoa, and larvae of helminths may also be found and identified. For protozoan cysts, add a drop of Lugol's or D'Antoni's iodine to the slide.

Preserved concentrated specimens can be made quickly by adding 10 per cent Formalin to the sediment in the tube at the end of the fresh examination.

This water centrifugal sedimentation method is a simple rapid one, requiring no chemical reagents, and only a minimum amount of standard laboratory equipment. The method is to be recommended especially in treated cases particularly when the other concentration methods have been tried and have proved unsuccessful.

ANAL SWABS

Special Procedure for Recovering Eggs in Oxyuriasis

It is a well-known fact that the eggs of *Enterobius vermicularis* are not deposited in the intestinal canal, as are those of hookworms, ascarids, and many other worms, but are expelled by the gravid female after it has migrated out of the anus and onto the perianal region. For this reason, the examination of samples of stools for pinworm eggs is a haphazard and unreliable method of diagnosing pinworm infestation. The stools of the vast majority of patients with pinworms will not reveal pinworm eggs, and although the occasional positive findings are significant, the negative findings afford no information as to the existence or absence of infestation. In an interesting contribution on this subject, Wright and Cram* state that in 102 examinations of the stools of persons infested with pinworms, they found pinworm eggs in only fourteen cases, and most of the patients were persons heavily infested with worms, as determined by subsequent treatment. In other words, the results were misleading in about seven of every eight cases.

In order, therefore, to make a reliable diagnosis of this disease, the anal swab, as suggested by Hall,[1] or any of the other swab methods given here should be used. Various types of swabs have been used by various workers, notably cotton, chamois, and rayon swabs. Celluloid swabs, depending on a scraping action instead of an entangling or enmeshing action in collecting eggs, have been given consideration by various authors. Serbinow and Schulmann[2] used a pointed, spatula-shaped match moistened with 0.5 to 1 per cent solution of sodium hydroxide, which was passed lightly over the anal folds; the material was examined in sodium hydroxide or water. Bogojawlewski and Lewitzki in 1929 used an ordinary match moistened with 1 per cent sodium hydroxide and examined the scraping in 1 per cent sodium hydroxide; when the initial scraping was negative, the edge of the slide, as well as the match, was used in scraping.

[1] Am. J. Trop. Med. 17: 445, 1937.

The NIH Swab (Hall).—

Hall first suggested the use of a metal scraper but later worked out a very satisfactory cellophane swab. This is made by taking a piece of transparent cellophane about 3 cm. square, folding it across the middle to form two equal rectangles, placing a glass rod about 8 to 10 cm. long by 4 mm. wide, with rounded ends, between the halves of the folded square and at right angles to the fold about one-third of the distance from one end of the fold, folding down the short end diagonally and wrapping it about the short end of the rod, and fastening the folded cellophane to the rod with a small rubber band. The rod was first pushed through a perforated rubber cork of a size suitable for corking a test tube. This combination of cellophane, glass rod, rubber cork, and test tube constituted a simple setup which met several requirements for a satisfactory swab for large-scale operations. The swab was used dry, and pinworm eggs adhered to it or were scraped into the folds over the tip. Thus it acted both as a swab and a scraper. To make the examination for eggs, the cellophane was pushed forward over the tip of the glass rod for a short distance, and the cellophane tip which had been used for swabbing was cut off beyond the rod tip with a pair of fine scissors, the tip being held at the time in a mixture of decinormal sodium hydroxide and stain; the cellophane tip was then flattened out with the rod and a pair of forceps, one or two drops of additional sodium hydroxide were put on the cellophane, and the preparation was covered with a cover glass. The eggs adhering to the cellophane or released under it were readily found by microscopic examination through the thin transparent cellophane, and no separation of the eggs from the contact part of the swab by any form of manipulation was needed. There are two types of cellophane, the plain transparent and the moisture-proof transparent. The moisture-proof cellophane flattens somewhat less readily on removal from a swab prepared or used several days or weeks previously than does the plain transparent cellophane. Hall suggests the use of the moisture-proof cellophane. The cellophane flattens a bit more readily if the slide preparation is warmed. The new type of swab suggested by Hall is called the NIH swab.

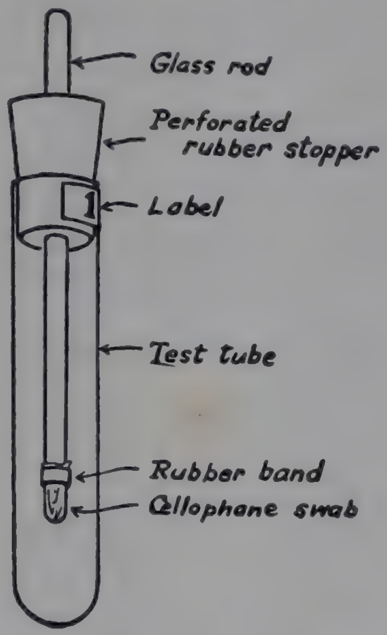

Fig. 447.—The NIH swab (Hall).

---

[2] Arch. f Schiffs- u. Tropen-Hyg. 31: 482, 1927.

After the cellophane is removed, the rod and cork are returned to the test tube and the forceps are flamed. The test tube setup should be sterilized, preferably by dry heat, in order to kill and distort any eggs present and so to guard against infection or contamination when the cellophane is replaced and the swab used again.

The use of decinormal sodium hydroxide and a stain in the examination of various types of swabs, including the cellophane swab, has been found advantageous since the solution tends to saponify fats in the feces and thus to set free the worm eggs in fecal material.

A warning note on the use of these cellophane NIH swabs has been issued by Reardon.* She states that artefacts which simulate eggs of *Enterobius vermicularis* are frequently found in this cellophane. These artefacts are not superficial but are embedded in the cellophane film and cannot be dislodged by surface scratching. They show a hyaline outline, ovoid, sometimes rounded, resembling very closely a pinworm egg. Size variation is great, but usually falls within the range of the pinworm egg so that size and appearance constitute potential sources of error in diagnosis of oxyuriasis.

In addition to the NIH swab just described, the following methods were summarized by Watson and MacKeith.[1]

The **Graham swab** introduced by Graham[2] in which adhesive tape (Scotch tape) is applied to the perianal region with the finger or a glass rod, the tape being subsequently flattened, adhesive surface downward, on to a slide for microscopic examination.

The **TP swab** introduced by Watson and MacKeith (1946). This device employs tissue-paper or toilet-paper in place of ordinary cellophane, the paper being applied either with the finger or by using a glass rod and rubber band. It is afterward rendered transparent by placing it, applied surface upward, in a drop of clearing agent such as oil of wintergreen. Another drop of clearing agent is added and the preparation covered with a cover glass. The eggs do not clear for some considerable time and are therefore readily visible against the transparent background.

The **glass pestle method** devised by Schüffner and Swellengrebel[3] which consists of a piece of thick-walled glass tubing of about 1 cm. diameter having a globe blown at one end, half the surface of which is rough ground. The moistened globe is applied to the perianal skin with a rotary motion and then dipped in a drop of water on a slide; the drop may be examined immediately or allowed to dry and examined later after clearing with a drop of cedarwood oil.

The **direct slide method** introduced by Petersen and Fahey.[4] This merely consists of the application of an ordinary microscope slide to the anal mucosa and the mucocutaneous junction, the moisture of the anal margin being sufficient to make any eggs present adhere to the slide. The slide may be examined direct or after addition of decinormal sodium hydroxide solution.

The **camel's-hair brush method** introduced by Watson and MacKeith (1946). This is an adaptation of the method used by Nolan and Reardon[5] for collecting household dust for examination for threadworm eggs. The brush is moistened with water and applied with a stroking motion to the anal folds and perianal skin. For examination it is gently dipped into a few drops of decinormal sodium hydroxide solution on a deep well-slide.

The **petrolatum cloth method** devised by Hellsten[6] in which the perianal region is wiped with a petrolatum cloth, the material obtained shaken up with a mixture of water and ether, centrifuged, and the suspension examined for eggs.

METHODS OF PRESERVATION OF GROSS SPECIMENS OF PARASITIC EGGS OR EMBRYOS

Stools containing parasitic eggs or embryos are best preserved by adding 40 per cent Formalin to a thin watery suspension of the material, so that the latter contains about 2 per cent of Formalin. The majority of eggs are quite well preserved in this manner, although some of the thin-shelled eggs, such as *Hymenolepis nana,* show considerable distortion. Specimens of feces containing the rhabditiform embryos of *Strongyloides stercoralis* may be kept for several years; the structure may be lacking in some of the embryos, but may remain characteristic in others. It may be of interest to note that the Formalin does not arrest the development of the eggs of *Ascaris lumbricoides.* Morris[1] reports one specimen of feces which, after four years' preservation in Formalin, still showed living embryos in Ascaris eggs.

Adult specimens may also be preserved in 2 per cent Formalin.

Permanent Preparations of Flatworms

These may be prepared in several ways:

1. Method of Mink and Ebeling[2]

The fecal material is mixed with physiologic salt solution heated to about the body temperature (37° to 40° C.). The worms move about, and the smaller, such as *Hymenolepis nana,* are the more readily seen. With forceps the parasites are transferred to a second dish of clear salt solution, in which they become free of mucus and feces. They are now transferred to one of three solutions for fixation: (1) Alcohol, 50 to 70 per cent, with or without glycerin; (2) Zenker's solution (which consists of bichloride of mercury, 5.0 gm.; potassium bichromate, 2.5 gm.; sodium sulphate, 1.0 gm.; distilled water to 1,000 c.c.), or (3) a 2 per cent Formalin solution; in any of these the material remains 14 to 16 hours. Zenker's fluid causes considerable shrinking and a yellowish discoloration. Formalin is best, since the natural color of the parasite is preserved fairly well with little or no shrinkage. The fixative should be allowed to act not more than fifteen hours, when the parasites are transferred to the following medium:

Syrup (glucose, 48 parts, water, 52 parts)	1,000.0 c.c.
Methyl alcohol	200.0 c.c.
Glycerin	100.0 c.c.
Camphor, q.s. (to keep sterile).	

The specimens may be left in this solution indefinitely, though they are usually sufficiently cleared in four to five hours. The material is now placed on a slide in glycerin jelly. After the latter has hardened (twenty-four hours or more), the cover glass is sealed with cement.

2. Boggs Method

The worm is washed free of feces, and is left in water or salt solution until it dies, so that it may be fixed while relaxed. It is then placed in a solution of 20 per cent glycerin in 80 per cent alcohol, which both fixes and clears the specimen. It is kept in this fluid in a partially covered dish until the alcohol is entirely evaporated. The specimen is then clear. It is transferred to a glass slide, and the excess of glycerin is removed by blotting paper. Glycerin jelly is then placed on the specimen, which is covered with a cover glass. In twenty-four to forty-eight hours, after the jelly has solidified, the preparation is sealed with microscope cement. To prevent curling of the specimen, it may be spread on a piece of heavy filter paper before immersing it in the glycerin-alcohol solution; it may be necessary to put a light weight on the cover slip until the jelly hardens.

---

[1] U.S. Naval Med. Bull. 3: 267, 1909.

[2] Bull. Johns Hopkins Hosp. 22: 299, 1911.

Glycerin jelly is prepared as follows:

Gelatin (gold mark)	14.0 gm.
Distilled water (boiling)	120.0 c.c.
Dissolve in the hot water and add:	
Glycerin	120.0 c.c.

Cool to 50° C. and add the whites of two eggs. Heat gently without stirring. Strain the mixture through a fine-meshed wire sieve, and filter through cotton while still warm. Add water to make the volume 240 c.c. and 1 c.c. of pure carbolic acid as a preservative. The jelly solidifies on cooling. For use, melt it by immersing the flask containing it in hot water.

3. Creosote Method

The material is placed in 70 per cent alcohol, and then in 95 per cent alcohol, for fifteen to thirty minutes. It is then transferred to Beechwood creosote, in which it remains until the tissue is cleared. The time required varies with the size of the specimen and with the degree to which water was withdrawn by the alcohol. Finally, the specimen is mounted in balsam.

4. Permanent Mounts of Helminth Eggs in Aqueous Preserving Fluids

It is often desirable to prepare permanent mounts of helminth eggs by a simple technic which will eliminate the shrinkage and distortion that frequently occur in the longer process of dehydration and subsequent mounting in gum damar. In the following technic suggested by Walker,[1] the eggs are mounted permanently on the slide in 4 per cent formaldehyde:

1. Place the slide on a turntable and ring a cell with Murrayite.

2. Fill the cell immediately with the preserving fluid (4 per cent formaldehyde) containing the eggs. An excess of the preserving fluid should be placed in the cell to prevent trapping air bubbles.

3. Place a circular cover glass in position immediately. With gentle pressure of the index fingers rotate the cover glass through an arc of approximately 30 degrees, thus pressing the edge into the soft cement. Usually the cover glass will adhere, even though the rim may have become wet with the overflowing preserving fluid.

4. Allow the slide to dry overnight and then re-ring it to insure a more permanent seal.

5. Twenty-four hours later the slide can be rinsed in running water, dried with a cloth, and labeled.

Similar permanent mounts of adults and larvae of *Trichinella spiralis* have been made by preserving them in an aqueous solution of 4 per cent formaldehyde and 30 per cent glycerin.

Murrayite adheres readily to the cover glass, even though the cover glass has been moistened previously with the preserving fluid. This is a distinct advantage, since in the use of other ringing cements it is necessary that the edges of the cover glass be absolutely dry. Murrayite is a spirit-proof cement used in sealing museum jars and microscopic fluid mounts. It was invented by Dr. C. Hay Murray, of Liverpool, and is sold by one or more American Biological supply houses.

5. Lacto-Phenol

Lacto-Phenol.—

Glycerin	2 parts
Lactic acid	1 part
Phenol	1 part
Water	1 part

---

[1] Science, June 17, 1938.

Technic.—Place whole worms in lacto-phenol solution and allow them to remain in the solution indefinitely. This solution renders the worms transparent and preserves them. It is highly recommended. *Caution.*—If the lacto-phenol solution is improperly made, it will digest the worm instead of preserving it.

6. Gum Acacia-Chloral Hydrate Medium, Ratcliffe*

Prepare a series of dilutions of gum-chloral in 10 per cent Formalin beginning with a 10 per cent solution and increasing concentrations by 2 per cent for each subsequent step, or make up each dilution as it is needed.

Gum-chloral is prepared as follows:

Distilled water	50 c.c.
Gum arabic ACS (must be clean)	40 gm.
Glycerin	20 c.c.
Chloral hydrate	50 gm.
Acetic acid	8 c.c.

Dissolve the gum arabic in the water cold, then dissolve the chloral hydrate with gentle heat, add the glycerin and acetic acid.

Concentrate fecal suspensions that have been thoroughly fixed in neutral Formalin until each drop of fluid contains 10 to 12 eggs. Each cubic centimeter of this will yield about 10 slides.

Pipette 5 c.c. of the concentrated fecal suspensions into 15 c.c. vaccine bottles. Add an equal quantity of 10 per cent gum-chloral-Formalin, tilting the bottles to allow this fluid to run in along the lower side. In all dilutions of the series, gum-chloral is heavier than any fecal suspension tested and will occupy the lower half of the column of fluid. No not shake the bottles or stir the contents.

Cap the bottles and leave them at room temperature or in an incubator at 37° C. until the fecal material has completely settled. Then remove the clear fluid above the feces with a fine-pointed pipette attached to a vacuum pump, and add an equal volume of the next higher concentration of gum-chloral solution.

Continue this process until the eggs are suspended in full-strength gum-chloral medium. When the last sedimentation is complete and excess fluid removed, mix the contents of each bottle thoroughly before starting to prepare mounts.

Use clean slides and cover glasses. Circular cover glasses 12 to 15 mm. in diameter give better mounts than larger sizes. Squares are unsatisfactory for most specimens. Mounts are prepared by two persons working as a team; one transfers drops of the mixture to the slides, the other adds the cover glasses. With some practice one will come to judge the size of the drop which will spread completely under the cover glass without excess. For transferring the material to slides, a heavy platinum loop about 4 mm. in diameter is superior to a pipette. The loop delivers a drop of about the correct size with few air bubbles. Cover glasses must be applied quickly to the mounts. Otherwise the medium hardens and spreads poorly.

Dry mounts in a horizontal position in an incubator at room temperature. Any air bubbles under the cover glass usually are extruded during drying. Thereafter, slides may be treated as if prepared with balsam or Clarite. The medium is readily soluble in water, however.

This schedule requires several months for completion, but actually the time given to the specimens is only the matter of minutes for each change of solution. Results amply compensate for the effort. By this method Ratcliffe has prepared mounts of the eggs of *Schistosoma mansoni, Clonorchis sinensis, Fasciola hepatica, Diphyllobothrium latum, Hymenolepis nana, Taenia saginata, Ascaris lumbricoides, Trichuris trichiura* and *Enterobius vermicularis.* In these slides small numbers of the eggs of some species are distorted, but the majority remain intact and are seen in greater detail than in temporary mounts of Formalin-fixed feces. The only failure thus far has been with hookworm eggs, all of which became badly distorted.

---

*Science 99: 2576, 1944.

Adult *Necator americanus* and other small nematodes, mites, ticks, lice, and the larvae and pupae of flies are easily infiltrated and mounted by this method. These organisms remain soft and are easily arranged on slides. When mounted under small round cover glasses, supports do not seem to be necessary.

PVA Medium, Morrison*

Polyvinyl alcohol 51-05 (Dupont Elvanol)	35 gm.
Distilled water	80 c.c.

Blend with a stirrer at 80° C. Then heat on a water bath at 95° C., just below boiling, until solution is effected.

Add

Chloral hydrate	25 gm.
Lactic acid	15 gm.

After mounting the specimen, dry at approximately 40° C. for a few days and then ring the cover glasses with a varnish after the slides are made.

PRESERVING FLUIDS

When a parasitologic examination cannot be carried out immediately, the stool is mixed with about 10 times its volume of 10 per cent Formalin. Formol-fixed material, however, is not very suitable for detailed protozoologic studies. Schaudinn's method is preferred if it is possible to carry it out with the facilities available. This fixative is also indispensable for the preparation of permanent hematoxylin-stained slides. Recently Schaudinn's fluid with the addition of polyvinyl alcohol (PVA) has been recommended (see page 1822).

For the latter purpose several slides, preferably with frosted edges, are prepared. Write the name and number of the patient with graphite pencil on the frosted glass. If the stool is hard, drop some saline on the farther end of the slides. For liquid stools, use a thin coat of egg albumin.

Mix the sample with the saline or spread over the egg albumin with the aid of a wooden applicator. Drop the slides immediately into a modified Schaudinn solution (page 1822).

Keep the fixative in a Koplin jar. Put the slides into it back to back. When 2 slides are made from each stool specimen, the material from as many as 5 stools can be fixed in 1 jar.

Keep the slides in the fixative for at least 8 hours, but not longer than 48 hours. They can then be mailed or sent by messenger to another laboratory for staining, if this is not carried out locally.

RECOMMENDED PROCEDURE FOR THE DETECTION OF INTESTINAL PROTOZOA

Recommended procedures for the detection of intestinal protozoa are (1) direct smears, (2) zinc flotation, and (3) permanent hematoxylin-stained slides.†

1. Direct Smears

Prepare at least 2 slides.

On one end of one slide, place a drop of saline.

On the other end, place a drop of D'Antoni's iodine (page 1821).

On the second slide, place 1 drop of D'Antoni's iodine at one end and at the other end a drop of 0.5% methylene blue in saline.

Emulsify small amounts of the stool in each drop.

Cover each drop carefully with a separate cover slip in such manner that the drops remain separated.

---

*Warren F. Morrison, General Biological Supply House, Chicago, Ill. Personal communication.

†O. Felsenfeld, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, 1948, The C. V. Mosby Co.

Inspect the saline suspension immediately.

The other preparations may be examined after a few minutes (2 to 4), but before they dry.

If the examination is carried out quickly, a warm stage is not necessary.

2. Zinc Flotation

The technic of Faust and associates in the modification of Otto and co-workers* is used.

Mix a portion of the fecal specimen, about the size of a bean, with 33.1% zinc sulphate, specific gravity 1.18, in a small vial 5 cm. deep and 1.8 cm. in diameter.

Fill the vial with this solution until the meniscus is rounded over the edge of the tube.

Place a cover slip on the surface and let stand 1 hour.

Place a drop of D'Antoni's iodine on a slide and put the cover slip on it in such a way that the slide which lies on the surface of the stool-zinc sulphate emulsion rests on the drop of iodine.

Examine under a microscope.

3. Permanent Hematoxylin-Stained Slides

Any recommended procedure may be used. Slides fixed in Schaudinn's fluid are used for this staining. See pages 1823 ff. for the methods.

If the examination includes a search for helminths and their eggs, the formol-ether flotation is substituted for the zinc flotation.

The amount of material available for examination is decisive for the methods to be used. If only proctoscopic or rectoscopic swabs are available, permanent hematoxylin-stained slides are the sole method of investigation. Such specimens usually contain pus cells and macrophages which cannot be easily distinguished from protozoa in iodine-tinged or Quenzel-stained preparations. Formed stools more frequently contain cysts than trophozoites. Thus more emphasis must be laid on flotation technics when such specimens are studied. Formalin is a better preservative for cysts than PVA, which often causes shrinkage, but is excellent for keeping trophozoites unchanged.

The importance of permanent hematoxylin-stained slides cannot be emphasized enough. Frequently laboratory workers not too familiar with protozoology are compelled to make a decision if a patient does or does not harbor intestinal protozoa. If permanent preparations are available, one always can submit them to a parasitologist for consultation.

At least 5 consecutive stool specimens taken at least two days apart, collected during a time when no antibiotic or chemotherapeutic agents were given, must be examined before a patient is declared "negative" (Becerra). After treatment, weekly and later monthly examinations are recommended for one-half year.

FIXATIVES USED IN PROTOZOOLOGY

Schaudinn's Sublimate Alcohol Solution

95% alcohol	1 part
Concentrated watery solution of bichloride of mercury	2 parts

(With or without addition of a small amount of acetic acid)

This solution of bichloride of mercury is made by dissolving about 8 grams of the sublimate in 100 c.c. of boiling distilled water. After cooling, a few crystals separate out.

---

*O. Felsenfeld and V. Young in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, 1948, The C. V. Mosby Co.

This is a very valuable solution. It is advisable to heat it to 50 to 60° C. before use. Smears remain in it 5 to 10 minutes, pieces of tissue according to size, one-half hour or longer.

Wash specimens in water; or, better, in 50% alcohol.

Carry over into iodine-alcohol, a 70% solution of alcohol to which tincture of iodine has been added until the color becomes light brown. Leave the smears in this solution for 15 minutes, then place for one-half hour in 70% alcohol. Wash and harden. Stain according to choice.

Carnoy's Solution

Absolute alcohol	6 parts
Chloroform	3 parts
Acetic acid	1 part

This is a good solution for preservation of cysts and spores, to fix protozoa in tissue. It is especially recommended to fix Arthropods. For embedding, the material can be put directly in chloroform and in concentrations of alcohol and paraffin. Stain according to choice.

Fleming's Solution

Chromic acid, 1%	15 parts
Osmic acid, 2%	4 parts
Acetic acid	1 part

For smears, time is 5 to 10 minutes; for small pieces of tissue, one hour to several hours.

Wash in water, then in 50 to 70% alcohol for hardening.

Stain with iron hematoxylin or aniline stains.

Herman's Platinum Chloride Osmic Acid Solution

Platinum chloride, 1%	15 parts
Osmic acid, 2%	4 parts
Acetic acid	1 part

This is a very good solution for differentiation of protoplasmic structures.

Picric Acetic Acid Solution

Concentrated watery picric acid solution	97 parts
Acetic acid	3 parts

To make the picric acid solution, add 1 gram picric acid to 100 c.c. of hot distilled water and filter after cooling.

This is designed for large protozoa, ciliates and Gregarina, one-half hour; and for large pieces of tissue, one to twelve hours.

After fixation, wash in 50 to 70% alcohol. For staining, use carmine and hematoxylin solution.

Bouin's Solution

Concentrated watery picric acid solution	15 parts
Formol (commercial 40% formaldehyde solution)	5 parts
Acetic acid	1 part

STAINING AMEBAE AND OTHER INTESTINAL PROTOZOA

Examination of Fresh Material

For the examination of fresh material it is necessary to use only a small amount of the fresh stool between the slide and cover glass. Examine with the low power and then with the oil immersion objective. In acute cases amebae are very numerous. The cysts are often mistaken for air bubbles by beginners. Differentiation must be made from Blastocystis. The addition of a solution of iodine one part, potassium iodide two parts, and water 100 parts, or 2% eosin solution, helps the examination. Eosin stains the background but does not stain the amebae and flagellates. Iodine stains the nuclei brown.

It is very important to examine for cysts. The Dutch investigators, Bayer and Kuenen, use a concentration method to demonstrate cysts. Another method by Riparte and Petit is as follows:

Copper chloride	1.0 gram
Copper acetate	1.0 gram
Formalin	50.0 c.c.
Camphorated water (1 part camphor, 2 parts alcohol, 200 parts water, filtered)	250.0 c.c.
Distilled water	700.0 c.c.
Acetic acid	6.5 c.c.

Rub up a hazelnut-sized piece of stool with 2 to 5 c.c. water, then add 50 c.c. of the above solution and shake. Filter through a gauze filter. Put it into a separatory funnel. Add 15 c.c. ether, shake, removing the stopper two or three times, and let stand. In a few seconds, the ether-impregnated detritus settles at the bottom. In this lower layer are found the cysts, and the eggs of worms, which can be concentrated by centrifugalization for a few minutes. The sediment can be examined fresh or stained.

LUGOL STAIN

Fresh Preparations Stained With Lugol Solution

Follow the same method as above, but first mix the drop of fecal suspension with a drop of strong Lugol solution, then cover with a cover glass.

Strong Lugol Solution

Metallic iodine	1 gm.
Potassium iodide	2 gm.
Distilled water	50 c.c.

Dissolve the potassium iodide in as little of the water as possible, then add the iodine to this solution. Shake constantly while slowly adding the remainder of the distilled water. Filter through filter paper after 24 hours.

D'Antoni Iodine Stain for Wet Preparations of Intestinal Protozoa[1]

D'Antoni has given an excellent method of using potassium iodide for preparing an iodine stain for use in wet preparations containing intestinal protozoa.

To a 10 per cent standardized potassium iodide solution is added 1.5 gm. of powdered iodine crystals per 100 c.c., in order to provide an amount of iodine considerably in excess of saturation and to compensate for volatilization. The solution is allowed to stand for four days and is then filtered.

D'Antoni emphasizes the following points in the preparation of this stain:

1. Solution should be weighed to the fourth decimal place in standardizing the potassium iodide.
2. Iodine concentration will remain constant only if powdered iodine is used in the solution.
3. To insure saturation, the solution should be allowed to stand for four days before it is used.
4. The solution should always be filtered before being used.
5. Filtered bottles of solution should be kept in tightly closed glass-stoppered bottles for periods not exceeding four weeks. However, unfiltered stock solutions can be kept for long periods of time even if stoppered only lightly, and from these, filtered solutions can be made up at a moment's notice.

Wet preparations of the stool, either unconcentrated or concentrated, are stained as follows:

a. The Smear: To a large fecal slide add 2 drops of saline and, with a wooden applicator, smear on a small portion of feces until a consistency is reached where book print is still legible through the film. Place a cover slip over half of the smear and then place a drop of iodine stain on the uncovered half. Put a cover slip over this stained portion.

---

[1] Am. J. Trop. Med. 17: No. 1, 1937.

b. The Concentrate: To the jar containing feces add a quantity of water equal to the amount of feces. Shake vigorously and filter through a single thickness of cheesecloth into a 13 by 100 mm. test tube. Centrifuge for 30 seconds, pour off the supernatant fluid, and add water until the tube is half full. Shake, and then pour off enough of it so that, on second centrifugation, a sediment will remain which covers the rounded portion of the bottom of the test tube. Add water and centrifuge the solution a second time. Discard the supernatant fluid, and add an amount of iodine which is about twice that of the sediment. Shake this mixture and pour directly on a glass slide, and, after placing a cover glass on top, examine the mixture.

This method stains *Endamoeba histolytica* very well, with the peripheral nuclear chromatin and central karyosome in very vivid contrast to the more darkly stained nonchromatin material. Glycogen masses are only slightly darker than the surrounding cytoplasm. Other protozoa stain equally well. Eggs are not overstained except those of *Ascaris lumbricoides* which are previously heavily bile stained.

D'Antoni found that powdered iodine was preferable to iodine crystals in making up his solution because, when powdered iodine was used, the saturation point was almost reached within four days and the solution remained constant even if allowed to stand in the open air. Neither of the above results was obtained if crystals were used.

It is important to prepare the 10% potassium iodide solution accurately. Because of its simplicity and accuracy, the specific gravity method is recommended for this standardization.

Preparation of Fecal Smears, Fixed, Wet, and Stained

Demonstration of Trophozoites of Intestinal Amebae— the Polyvinyl Alcohol (PVA) Technic

The PVA-Fixative Technic in the Diagnosis of Amebiasis.—

Donaldson[1] has given a summary of this method which furnishes the physician in the laboratory with a means of preserving these fragile organisms for a subsequent examination and study. He described a two-vial method of shipping specimens. In one vial is mixed a small portion of freshly passed stool with the PVA-fixative. The other vial is empty and should receive a small portion of the fecal specimen for other studies, such as fresh examination or cyst examination. Both vials should be sent to diagnostic laboratory with appropriate identifications.

Preparation of the PVA-Fixative.—

Reagents.—

1. Modified Schaudinn's Solution	
Glacial acetic acid	5.0 c.c.
Glycerol	1.5 c.c.
Schaudinn's solution (2 parts saturated aqueous solution of mercuric chloride and 1 part 95% ethyl alcohol)	93.5 c.c.
2. Polyvinyl Alcohol (PVA) Powder (Produced by E. I. du Pont de Nemours & Co., Inc., Electrochemical Department, Niagara Falls, N. Y., and designated as "Elvanol 90-25").	5 gm.

Heat the modified Schaudinn's solution to 75° C., and while mechanically stirring, add slowly the PVA powder. After cooling, the solution should be clear and free of lumps. The PVA-fixative remains satisfactory for several months and can be used either at room temperature or heated to 50° C.

Preservation of Specimens With PVA-Fixative.—

Specimens can be fixed and preserved either directly or on microscope slides or in vials. Fix the specimens immediately after passage from the patient, before the organisms lose their characteristic morphology.

---

[1] J. Am. Med. Tech. 9: 70, July-Aug., 1949.

On microscope slides: A drop of the dysenteric stool or other material is placed on a microscope slide and mixed with three drops of the PVA-fixative. The mixture is then smeared over approximately two-thirds of the glass surface. The slide is maintained in a horizontal position until the film is thoroughly dried (preferably overnight at 37° C.). The dried films remain satisfactory for staining for many months.

In vials: A quantity of the specimen is introduced into a vial containing three or more parts of the PVA-fixative and thoroughly mixed. Smears for staining can be prepared immediately (or months later) by spreading a drop or two of the mixture over the surface of a slide. Do not have the smears too thick. Smears must be thoroughly dry.

Staining of the PVA Films.—

The long Heidenhain iron-hematoxylin procedure gives best results. The Tompkins-Miller[2] technic is a more rapid technic that gives uniformly good results and in most instances is satisfactory for diagnosis.

In all the hematoxylin procedures the dried films are first placed in the 70% alcohol iodine in order to remove the mercuric chloride crystals. Ten to 20 minutes in this solution is sufficient. The remaining steps depend upon what technic is being employed. Protect the stained film with a mounted cover-slip; however, the uncovered films can be satisfactorily examined with the oil immersion objective.

The advantage of this fixative technic is that it makes possible the successful staining of organisms occurring in fluid specimens. The solution serves as an adhesive as well as a preservative and prevents the loss of organisms during the staining procedure.

Heidenhain Iron-Hematoxylin Method

1. Fix in a mixture of 2 parts saturated aqueous solution mercuric chloride (corrosive sublimate) and 1 part alcohol, 20 to 60 minutes.[3] (Put specimen on cover glasses, not slides. Smear with needle. Float on surface of Petri dish containing fixative, face downward, then turn them around with forceps, face upward. They sink.)

2. Pour off sublimate alcohol; put back into bottle. Pour on idio-alcohol. (Alcohol 70% and tincture of iodine enough to give light port-wine color.)

3. Let stand 20 to 30 minutes. Pour off.

4. Place in 70% alcohol one hour or longer (24 to 48 hours). Pour off.

5. Iron alum 4%. This is *ferric* alum [$Fe_2(SO_4)_3 \cdot (NH_4)_2SO_4 \cdot 24H_2O$]. One hour. Pour off.

6. Stain one hour in Heidenhain hematoxylin, 1%.

Heidenhain hematoxylin is made by dissolving 1 gram hematoxylin in 10 c.c. of 95% alcohol and diluting to 100 c.c. with distilled water. It should not be used for at least four weeks.

Wash in water. This should be thoroughly carried out using two separate containers holding at least one liter of water each. As James states, if the preparations are not thoroughly rinsed, an excess of the mordant is carried over into the hematoxylin solution, making decolorization difficult, and the amebae are likely to appear a dirty yellow with indistinct nuclei, instead of showing a clear gray cytoplasm with sharply defined and clear-cut black or deep purple nuclei.

James claims that it is not necessary, though advisable, to allow the hematoxylin solution to ripen for four weeks before using. If it is thoroughly aerated by allowing a current of air to pass through it overnight, it will be ready for use in the morning. The diluted solution should be filtered after use into a clean bottle. Later, this filtered diluted solution should be used with an equal part of the original stock solution, diluted one-half, then filtered again into the second bottle, and so on until the original stock solution is used, when there will be two bottles of stain. These can be used undiluted repeatedly. They improve with use until the hematoxylin is finally precipitated. This can be detected by adding a few drops of the stain to a test tube half full of tap water. If the resulting color is yellow or green, the stain is no longer useful; if the color is blue or violet, the stain is still good. Only a good quality of distilled water should be used for diluting the stock solution; tap water or alkaline water will precipitate the hematoxylin or, rather, the hematin, which is the active staining principle. The staining solutions should be kept in brown glass bottles, away from the light.

---

[2] Am. J. Clin. Path. **17**: 755, 1947.

[3] Wm. M. James (J. A. M. A. **102**: 1175, 1934) has found that fixation in a modified Schaudinn's fluid, consisting of two parts of physiologic solution of sodium chloride saturated with corrosive mercuric chloride and one part of 96% or absolute ethyl alcohol, plus the addition of from 2.5 to 5% of glacial acetic acid, has given better results than the aqueous solution saturated with corrosive mercuric chloride, without the acetic acid. The weaker acetic acid solution is better for the delicate trophozoites in acute and subacute dysentery, and the stronger solution gives better fixation for cysts. He believes that from twenty to sixty minutes is too long a time for fixation of thin stool smears, since most authorities find that from five to ten minutes is ample. He prefers to fix at room temperature as the heated fixing solutions produce artefacts, as has been pointed out by Leland Cleveland.

7. Differentiate with 2% iron alum in a dish with a cross marked on the bottom to designate one, two, three, and four minutes' immersion. Take out the thinnest after one minute; the thicker specimens are differentiated longer.
8. Place in water.
9. Wash in running water for twenty minutes.
10. Place the various ingredients for the final dehydration in small bottles:

60% alcohol
80% alcohol
80% alcohol
96% alcohol
Absolute alcohol
Xylol
Xylol

11. Dehydrate as for paraffin sections.
12. Mount in Canada balsam or gum damar.

Ziegler Modification of the Heidenhain's Iron-Hematoxylin Method

This modification, described by Ziegler[1] and further emphasized by Tompkins and Miller,[2] embodies a basic change by the application of 2% aqueous phosphotungstic acid for differentiation. This gives uniform permanent film preparation which can be made more rapidly than by the preceding method.

Fixation.—

Prepare fresh fecal films on slides or cover glasses and fix while wet. Slides are more durable for routine use. Fixation while the film is wet and fresh is of considerable importance, because drying results in degeneration and distortion of the protozoa. The saline modification (see footnote on page 1823) by James is a very good departure.

Fix in Schaudinn fluid in saline solution, five minutes.

Remove residual mercury in 70% alcohol, with iodine added to obtain "port-wine" color, one minute.

Remove residual iodine in 70% alcohol, two changes, one-half minute each.

Mordant in 4% aqueous ferric ammonium sulphate, three to five minutes.

Wash in running tap water, one minute.

Stain in week-old 0.5% aqueous hematoxylin, one minute.

Remove excess stain by dipping in water.

Differentiate in 2% aqueous phosphotungstic acid, two minutes or more.

Place in tap water, one minute, until the hematoxylin is blue.

Dehydrate in 95% and in absolute alcohol, one minute each.

Clear in xylol, one minute.

Mount in gum damar.

Rapid Technic for Staining Amebae, Schaudinn

Use slides free of grease and oil. Make very thin smears. Do not allow the smears to dry at any stage of the process.

---

[1] Arch. Path. 37: 68, 1944.
[2] Am. J. Clin. Path. 17: 755, 1947.

Reagents.—

Fixative.—

Mix 2 parts of warm Schaudinn fixative (saturated aqueous solution of mercuric chloride $HgCl_2$) and 1 part of absolute ethyl alcohol.

Iodine-Alcohol Mixture.—

Equal parts of iodine and 70% ethyl alcohol.

70% and 50% Alcohol.—

Iron Alum.—

Ferric ammonium sulphate	2 gm.
Distilled water	100 c.c.

Heidenhain Hematoxylin.—

Hematoxylin	1 gm.
Alcohol, 95% ethyl	10 c.c.

Dissolve and add 100 c.c. distilled water.

Xylol.—

Technic.—

Fix in the modified Schaudinn fixative (warm) for 2 minutes.

Place in iodine-alcohol for 2 minutes.

Place in 70% alcohol for 1 minute.

Place in 50% alcohol for 1 minute.

Wash in distilled water for 1 minute.

Place in *hot* iron alum for 2 minutes.

Wash in running tap water for 2 minutes.

Stain in Heidenhain hematoxylin (hot) for 1 minute.

Rinse in distilled water.

Decolorize in iron alum on a glass plate under the microscope until structure appears.

Wash in running tap water for 2 minutes.

Dehydrate in 50% alcohol for 1 minute, then in 70% alcohol for 1 minute, then 95% alcohol for 1 minute.

Complete the dehydration in 100% alcohol for 2 minutes.

Clear in xylol for 2 minutes.

Mount in gum damar or Canada balsam and examine with the oil immersion objective.

Staining Intestinal Protozoa, Modified Method of Cuendet[1]

Cuendet modified the original iron-hematoxylin technic, replacing the Heidenhain hematoxylin with a new staining solution.

Reagents.—

Stain.—

Alcohol, 95%	10 c.c.
Hematoxylin crystals (certified)	1 gm.
Glycerine, c.p.	10 c.c.
Distilled water	80 c.c.

Dissolve the hematoxylin crystals in the alcohol with a little heat, or by use of a mortar and pestle. Add the glycerine and the distilled water. If the solution is a deep red color it is neutral and no further treatment is necessary. If it is yellowish-brown to deep brown it is acid. Neutralize by adding 1% solution of potassium carbonate a drop at a time with constant shaking until the deep red color of the neutral solution is imparted to the foam. If the solution is purple to red-violet, it is alkaline. Neutralize by using N/5 hydrochloric acid. Expose the neutral staining solution in a clear glass bottle to daylight, allowing it to ripen for 2 or more weeks before using.

Schaudinn Fixative.—

Mix, freshly each day, 2 parts of saturated solution of mercuric chloride ($HgCl_2$) and 1 part of 95% alcohol.

---

[1] Lab. Digest **10**: 8, 9-10, Jan., 1947.

Iodine-Alcohol Solution.—

70% alcohol with enough Lugol solution to give it a dark port-wine color.

Mordant.—

Dissolve 4 gm. ferric ammonium sulphate ($FeNH_4(SO_4)_2.12H_2O$ violet crystals) in distilled water and dilute to 100 c.c. with distilled water.

2% Ferric Ammonium Sulphate Solution (Iron Alum).—

Dissolve 2 gm. ferric ammonium sulphate in distilled water and dilute to 100 c.c. with distilled water.

Graded Alcohols, 50%, 70%, 80%, 95%, and 100%.—

Xylol.—

Gum Damar.—

Technic.—

The best consistency for feces from which smears are to be made is that of a thin porridge; smears are best made by using a soft bristle brush to spread the specimen. If concretions or solidly formed feces are presented for examination, proper consistency is obtained by grinding the material in a mortar with blood serum as a diluent. Smears are then made and placed immediately in hot (56° C.) Schaudinn's fixative.

Heat is an essential part of the technic. Inactivator temperature (56° C.) is ideal. Replace the water lost by evaporation of the solutions, from time to time, and occasionally replace the solutions.

Great care must be strictly observed so that smears are never allowed to dry at any time in the entire process, from the actual making of the smears to the final mounting.

Fix fresh wet smears in hot (56° C.) Schaudinn's solution for at least 2 minutes.

Remove smears, wipe the backs and edges dry with a clean cloth, dip in and out of iodine-alcohol solution until mercuric chloride is removed.

Wash the mercury-iodine compound from the smears in gently running tap water. This requires 1 or 2 minutes. To place slides in gently running tap water, hold the smear under a small stream of water from a faucet; or, better results are obtained and time is saved by introducing a small rubber tube between the slides in a Koplin jar and regulating the flow of water with the tap. A small battery of stop-cocks on a water line over a drainboard or sink will permit washing several jars of slides at once.

Place smear in hot (56° C.) mordant for 5 minutes. This step may require 2 to 5 minutes. The staining time should be the same as the time in the mordant. In most cases, 5 minutes' immersion in the mordant and 5 minutes in the stain give best results.

Remove smear from mordant and dip in distilled water. Place in hot (56° C.) staining solution for 5 minutes.

Remove and wash in gently running tap water as described above. Differentiate in 2% cold aqueous ferric ammonium sulphate (iron-alum). Dip the smear in and out of the iron-alum solution, and note when the excess stain has been removed. When this is accomplished, there will be only a trace of the stain visible in the drops of solution which fall from the slide. A little practice is necessary before this step is mastered.

After differentiation, wash in gently running tap water for 1 or 2 minutes. Dehydrate in graded alcohols, 50, 70, 80, 95, and 100%. Dry the back, edges, and other parts of the slide not containing the specimen each time the slide is transferred from one alcohol to another, then dip in and out of the alcohol until a thin, even film of alcohol covers the smear. If the smear looks streaked or oily, it still contains more water than alcohol, and more time is indicated for immersion in that alcohol.

Transfer the smear, after removing the excess alcohol, into xylol. Dip in and out until a thin, even film covers the spread surface. Transfer to a second jar of xylol and prepare the slide for mounting. Gum damar is preferred as a mounting medium because it will not turn yellow with age, and it dries and hardens quickly. Canada balsam may be used, however, although it hardens slowly, and preparations will become yellow within about four or five years.

Quensel Stain for Protozoa[1]

Reagent.—

Mix 20 c.c. of a saturated solution of Sudan III in 80% ethyl alcohol and 30 c.c. of filtered saturated methylene blue, medicinal solution.

Filter into 50 c.c. of 10% solution of cadmium chloride, c.p., in distilled water.

Shake gently for 20 minutes.

Filter.

Superimpose filter paper, residue up, on another filter paper, and leave overnight to dry.

Transfer precipitate to fresh filter paper and wash with 25 to 30 c.c. of distilled water.

Dissolve the washed precipitate in 250 c.c. distilled water.

If crystals form, filter.

Technic.—

Mix a small amount of the fecal material on a slide in a large drop of Quensel stain.

Cover with a cover glass.

Amebae stain various intensities of blue in 5 to 20 minutes. Nuclear walls and karyosomes show distinctly under high dry or oil immersion lenses.

According to Packard,[2] the stain is too concentrated. Intensity depends upon the methylene blue. It is good practice to make various dilutions of the methylene blue in water and determine the final dilution in that manner. Diluting to 500 c.c. instead of to 250 c.c. is suggested by Packard.

A Rapid Method for Preparing Permanent Slides of Intestinal Parasites

Method of Johnson[3]

Reagents.—

95% Ethyl Alcohol.—

Schaudinn's Fixative.—

Prepare a saturated aqueous solution of mercuric chloride, c.p., and filter through filter paper.

To each 100 c.c. of this solution add 50 c.c. of 95% alcohol.

Before using, add 20 c.c. of glacial acetic acid, c.p., to each 150 c.c. of the mixture. Use the fixative only once.

4% Iron Alum.—

See p. 1823. This solution can be used for several weeks provided it is not cloudy and does not contain a precipitate.

0.25% Iron Alum.—

Prepare fresh from the 4% solution by pipetting 12.5 c.c. of the 4% solution into distilled water and diluting to 200 c.c. with distilled water. This must be used within 24 hours after it has been diluted.

0.5% Hematoxylin.—

Dissolve 1 gm. hematoxylin (certified)
in 10 c.c. of absolute alcohol.

Dilute to 200 c.c. with distilled water.

Allow to stand for 6 weeks in an Erlenmeyer flask loosely plugged with cotton. The solution must be exposed to sunlight.

Technic.—

Under no conditions must the slides be allowed to dry during the procedure.

Place all solutions in Koplin jars.

Prepare thin smears from fresh, warm (recently voided) stools or rectal swabs, on clean slides. Always prepare several smears from each specimen.

Immerse in Schaudinn's fluid. Keep the jar on a water bath during the fixation at 60° C., for 10 minutes.

---

[1] Manual of Tropical Medicine, Philadelphia, 1945, W. B. Saunders Co.

[2] Fridel Packard, New York City: Personal communication.

[3] Am. J. Trop. Med. 15: 551, 1935.

Transfer to 95% alcohol containing enough tincture of iodine to give it a rich port-wine color—5 minutes.

Transfer to 70% alcohol—5 minutes.

Rinse with tap water—3 minutes.

Immerse in 4% iron alum—15 minutes.

Rinse with tap water—2 minutes.

Stain with 0.5% hematoxylin—10 minutes.

Immerse in 0.25% iron alum—12 minutes.

Dehydrate by passing the slides through 50%, 75%, 85%, 95%, and absolute alcohol 5 minutes in each jar.

Clear in xylol—5 minutes.

Mount in Clarite under a cover glass.

Method of Ratcliffe, Modified by Felsenfeld and Young*

Reagents.—

Schaudinn's Fixative (above).

Mallory's Phosphotungstic Acid Hematoxylin.—

Phosphotungstic acid, 10% aqueous	10.0 c.c.
Haem-ammonium	0.1 gm.
Distilled water	90.0 c.c.

Age one to three weeks before use.

Technic.—

Make smears on slides and place them in a Koplin jar containing Schaudinn's fluid. Leave them in the fixative for at least 4 hours, but not longer than 48 hours.

Carry out the staining in Koplin jars.

Transfer to 95% alcohol containing enough tincture of iodine to give it a rich port-wine color—5 minutes.

Transfer to 75% alcohol—5 minutes. The slides may remain overnight in this alcohol, if necessary.

Distilled water—5 minutes.

Mallory's hematoxylin, at least 30 minutes. The slides may remain in this stain overnight or for as long as 48 hours.

Distilled water until the smears become blue. This usually requires 5 to 12 minutes.

Dehydrate in 70%, 95%, and absolute alcohol, 5 minutes each.

Clear in xylol—5 minutes.

Mount under a cover glass with Clarite.

Gram Stain

The Gram stain is highly recommended by Kourí for staining amebae.

Rapid Permanent-Mount Stain for Intestinal Protozoa

Method of Lawless†

Reagent.—

Acetone	50 c.c.
Glacial acetic acid	50 c.c.
Formaldehyde solution USP	10 c.c.
Schaudinn's solution (page 1819)	890 c.c.

Add to this solution 1.25 gm. of acid fuchsin
and 0.5 gm. fast green FCF.

Mix.

The solution is ready for use.

Store in a tightly stoppered bottle, preferably a brown one.

The solution remains stable for at least two months or more.

---

*Res. Clin.-cient 14: 11, 1945.

†Am. J. Trop. Med. & Hyg. 2: 1137, 1953.

Technic.—

Using an applicator stick, spread a thin layer of fecal material on a glass slide. At no time during the staining procedure must the fecal smear be allowed to dry.

Completely cover the preparation with the reagent, using a medicine dropper or a dropping bottle with a glass stopper.

Heat gently over a burner until steam is first observed. Two or three slow passes of the fecal smear through a flame is usually sufficient. Do not boil and do not allow staining solution to flame.

Wash immediately, gently, under tap water.
Place in 50% alcohol for 30 seconds.
Place in 70% alcohol for 30 seconds.
Place in 95% alcohol for 15 seconds.
Place in absolute alcohol for 15 seconds.
Clear in xylol for 1 minute.
Mount in gum damar or Canada balsam.

Staining Reaction.—

The staining characteristics of the intestinal protozoa are similar to those with iron hematoxylin. Nuclear detail and chromatoid substance are particularly clear. Cysts of all species stain well, and also the trophozoites.

The background should be bluish-purple, the parasites a variable blue to purple.

CULTURE METHODS FOR ISOLATION OF PATHOGENIC AMEBAE

A number of different culture methods have been suggested for the isolation of the pathogenic amebae. Bayless, of Cleveland, has compiled the following condensed review of the facts on the various methods for cultivation:

1. Liver infusion agar covered with horse-serum-saline diluted 1:6.
2. Coagulated egg slant covered with horse-serum-saline or egg-white-saline.
3. Dehydrated blood serum with egg-white-saline or horse-serum-saline.
4. Coagulated egg slant covered with defibrinated blood in saline.
5. Inactivated human serum diluted with Locke's solution.
6. Liver infusion with hydrolyzed hemoglobin or washed red blood corpuscles.
7. Loeffler's serum slant covered with horse-serum-saline.
8. Three per cent hemoglobin agar covered with horse-serum-saline.

Embryo juice, ascitic fluid, testicle broth may be used instead of serum.

Observe sterile precautions.

Inoculation: with exudate, stool concentrate, washed cysts or sediment from culture.

Incubation: optimum 35° C. but a fall of a few degrees is safer than a rise above this point.

Subculturing interval: varies with strain and medium usually after 48 to 96 hours.

Survival: varies with different media; cysts washed and stored in saline survive indefinitely at ice box temperature.

Examination: the use of the warm stage gives best results.

Boeck and Drbohlav Medium No. 1

Cultivation of *Endamoeba histolytica* was first accomplished by Boeck and Drbohlav.[1] This culture medium consists of

Agar	14 grams
Salt	6 grams
Distilled water at 45° C.	900 c.c.

Mix one part with two parts of blood that has been heated for one-half hour at 100° C. with the addition of 1 per cent grape sugar.

Boeck and Drbohlav Medium No. 2

Locke's solution.—

Distilled water	1000.0 c.c.
Sodium chloride	9.0 gm.
Calcium chloride	0.2 gm.
Potassium chloride	0.4 gm.
Sodium bicarbonate	0.2 gm.
Glucose	2.5 gm.

Sterilize in the autoclave at 15 pounds pressure for thirty minutes.

Locke's Serum-Egg Medium.—

Mix the whites and yolks of four eggs thoroughly. Add 50 c.c. Locke's solution.

Mix thoroughly and filter through gauze.

Place in 5 c.c. quantities in 15 c.c. homeopathic vials. Pound in number 4 corks. Screw on the caps. Slant in the autoclave and sterilize at 15 to 20 pounds pressure for thirty minutes.

Slants should have surfaces 1 or 1½ inches long.

Preparation of the Blood Serum.—

Inactivate the serum by heating in a water-bath at 56° C. for one-half hour.

If the serum is not sterile, dilute with 2 or 3 parts of Locke's solution.

Filter through a Berkefeld filter, and test the filtrate for sterility.

Serum prepared in this manner may be placed in sterile ampules and sealed hermetically. These ampules may be kept in the refrigerator indefinitely.

Preparation of the Medium for Inoculation.—

Dilute the blood serum so that the final concentration of serum and Locke's solution is 1 part serum to 8 parts Locke's solution.

Cover the tubes with this mixture to a depth of 1 cm. above the slant.

Incubate for sterility before using.

Medium of Cleveland and Sanders[2]

Dissolve 33 gm. of Difco Endamoeba medium in 1000 c.c. of distilled water.

Distribute into tubes in quantities sufficient to make a medium slant with no butt.

Sterilize in the autoclave at 15 pounds pressure for 20 minutes.

Allow to harden in the desired position.

Add a mixture of 1 part horse serum and 10 parts of phosphate buffer pH 8.0 to each tube to a height of three-fourths of the slant.

Before inoculation, add 1 or 2 loopfuls of sterile rice powder.

Medium of Balamuth[3]

To 36 gm. dried egg yolks add an equal volume of distilled water.

Mix well.

Add 125 c.c. of 0.8% sodium chloride solution. Mix thoroughly.

---

[1] Am. J. Hyg. 5: 371, 1925.

[2] Am. J. Hyg. 23: 114, 1936.

[3] Am. J. Clin Path. 16: 380, 1946.

Boil for 10 minutes, stirring constantly.

Dilute to the original volume with distilled water.

Press through a double layer of muslin.

Dilute to 125 c.c. with 0.8% saline solution.

Sterilize in the autoclave at 15 pounds pressure for 20 minutes.

Cool to a temperature below 10° C. and filter through a Buchner funnel using medium grade filter paper.

Add an equal amount of phosphate buffer pH 7.5 to the yolk mixture.

Phosphate Buffer, pH 7.5.—

Mix 43 c.c. of 17.48% dipotassium phosphate solution
and 7 c.c. of 136.09% monopotassium phosphate solution.
Add 14 parts of distilled water to 1 part of this mixture.

Prepare a solution of Wilson or Lilly liver concentrate by making a 5% suspension, filtering, and autoclaving.

Add 1 part of the liver extract to 9 parts of the buffered yolk infusion.

Distribute in tubes in 7 to 10 c.c. quantities.

Sterilize in the autoclave for 20 minutes at 15 pounds pressure.

Before use add a loopful of sterile rice powder.

The medium can be prepared from fresh egg yolks as follows:

Boil 4 eggs for 15 minutes.
Discard the whites.
Add to the yolks 125 c.c. of 0.8% saline solution.
Proceed as above, except that a routine filter paper may be used for filtration through the Buchner funnel.

COMPLEMENT FIXATION TEST FOR DIAGNOSIS OF AMEBIASIS

Method of Bozicevich, Hoyem, and Walston[1]

Because of the complex nature of the antigens used in complement fixation tests for helminthic and protozoan disease, the tests are often unreliable, a result due mainly to the anticomplementary effect of the antigen. The method described here eliminates most of the difficulties previously encountered. This test is similar in nature to the technics of Wadsworth,[2] Wadsworth, Maltaner, and Maltaner,[3] and Kent, Bukantz, and Rein.[4] The complement titer is determined on the basis of that amount which will give 50 per cent hemolysis when compared to the color standard. The test is conducted in a total volume of 1 c.c. in which 4 or these 50 per cent units are used.

Reagents.—

2 Per Cent Cell Suspension.—

In order to determine the end point for 50 per cent hemolysis, it is necessary, before the optimal hemolysin titer is determined, to prepare a 2 per cent suspension of cells from which a color standard is made.

Collect sheep cells by using sodium citrate, or by defibrinization. If the cells are to be held over 3 days, remove a portion from the original collecting container and wash 4 times with physiologic saline. If it is necessary to perform titrations with the same cell suspension for a period of several weeks, it is advisable to use Alsever and Ainslie's[5] solution as recommended by Bukantz, Rein, and Kent[6] for the preservation of cells to reduce fragility and consequent hemolysis. After the final washing, fill a 15 c.c. graduated conical centrifuge tube with washed cells and centrifuge at 2,000 r.p.m. for 10 minutes. Measure the quantity of packed cells and multiply the volume occupied by the cells by a factor of 50 to make a 2 per cent suspension. This gives the total volume which must be made up with saline. Thus, if the volume of packed cells is 1.5 c.c., 1.5 × 50 = 75 c.c. Pour the contents of the tube into a graduated cylinder and wash the centrifuge tube with saline, adding the washings to the graduated cylinder. Add saline until a volume of 75 c.c. is reached.

[6] J. Lab. & Clin. Med. 31: 394, 1946.

Hemoglobin Standard.—

Pipette 10 c.c. of the 2 per cent cell suspension into a graduated centrifuge tube and pack in the centrifuge at 2000 r.p.m. for 10 minutes. Without disturbing the cells withdraw most of the supernatant fluid by means of a capillary pipette. Add distilled water up to the mark 9.5, lake the cells completely by shaking, and add 0.5 c.c. of a stock buffer solution or 0.5 c.c. of a 17 per cent saline solution to restore tonicity.

Stock Buffer Solution.—

Sodium chloride (NaCl)	17.00 gm.
Sodium phosphate, dibasic (Na_2HPO_4)	1.13 gm.
Potassium phosphate, monobasic (KH_2PO_4)	0.27 gm.
Distilled water to make	100 c.c.

This stock solution may be used in place of saline as a diluent for all the reagents by adding 1 part of the stock solution to 20 parts of distilled water.

Color Standard.—

Prepare the color standard from the standard hemoglobin solution in tubes of the same diameter as those which are to be used in the test proper.

Note.—Since the total volume in the test is 1 c.c., all the titrations are conducted on the same volume and the measurements of the reagents given in all the tables are in tenths of a cubic centimeter.

TABLE 173.—PREPARATION OF COLOR STANDARD

	PER CENT OF HEMOLYSIS										
	0	10	20	30	40	50	60	70	80	90	100
Saline	0.80	0.80	0.80	0.80	0.80	0.80	0.80	0.80	0.80	0.80	0.80
Standard hemoglobin	0.00	0.02	0.04	0.06	0.08	0.10	0.12	0.14	0.16	0.18	0.20
2 per cent red cells	0.20	0.18	0.16	0.14	0.12	0.10	0.08	0.06	0.04	0.02	0.00

Shake the tubes and label according to the degree of hemolysis. Then centrifuge at 2,000 r.p.m. for 10 minutes.

Titration of Hemolysin.—

It is advisable to begin the titration of hemolysin with a 1:2000 dilution for, if the pooled hemolysin does not attain this titer, it is not satisfactory and the animals should be given further immunization. To prepare the sensitized cells for this titration, make up the hemolysin dilution desired in 10 c.c. amounts and add an equal volume of the 2 per cent cell suspension. The "sensitized cells" must be prepared 15 minutes before using them in the test. Prepare a 1:100 dilution of complement from the pooled sera of several guinea pigs. Arrange the tubes from the initial titration of hemolysin according to Table 174. In this preliminary titration of hemolysin, the complement titration is performed at the same time.

TABLE 174.—HEMOLYSIN TITRATION

	TUBE NUMBERS									
	1	2	3	4	5	6	7	8	9	10
Saline	0.55	0.50	0.45	0.40	0.35	0.30	0.25	0.20	0.15	0.10
Complement	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50
Sensitized Cells	0.40	0.40	0.40	0.40	0.40	0.40	0.40	0.40	0.40	0.40

Make this arrangement for each dilution of hemolysin to be tested. Place the rack in a 37° C. water bath for 30 minutes, remove, and centrifuge the tubes at 2,000 r.p.m. for 10 minutes. Compare each tube with the color standard tubes and record the results in per cent of hemolysis according to the plan given in Table 175.

The optimal dilution of hemolysin as defined by Wadsworth[2] is that dilution beyond which further increase in the concentration of hemolysin does not appreciably change the quantity of complement required for 50 per cent hemolysis. Therefore, from this titration it is apparent that the optimal dilution of hemolysin is 1:3000. This concentration is used henceforth for the daily titration of complement and for the sensitization of red cells for the test proper. This titration serves a dual purpose in this instance, in that both the complement and hemolysin titration are conducted at the same time.

Titration of Complement.—Titrate the complement daily with the optimal dilution of amboceptor as indicated in Table 175. Dilute fresh pooled sera, obtained from several guinea pigs, 1:100 and titrate according to Table 174. In this titration use only the optimal dilution of hemolysin. After incubation and centrifugation, compare each tube in the test to the 50 per cent hemolysis tube in the color standard. The color standard must be prepared fresh daily with a portion of the cells from the same lot which is to be used in the test proper. If the color standard tube containing the 50 per cent hemolysis matches exactly Tube 3 of the titrations containing 0.15 c.c. of 1:100 complement, Tube 3 is regarded as 1 unit of complement. If the 50 per cent color standard falls between 2 tubes, it is necessary to interpolate the 1 unit of complement. Since 4 units of complement are required in each 0.20 c.c., make the dilution of complement according to the following formula:

TABLE 175.—READING OF THE HEMOLYSIN TITRATION

HEMOLYSIN DILUTIONS	TUBES									
	1	2	3	4	5	6	7	8	9	10
1:7000	0	0	0	0	5	10	20	25	35	45
1:6500	0	0	0	8	20	30	40	55	65	68
1:6000	0	0	3	10	25	35	50	60	65	70
1:5500	0	0	5	15	35	45	55	70	80	85
1:5000	0	0	8	30	50	60	80	85	90	95
1:4500	0	0	20	40	60	70	85	88	95	98
1:4000	0	0	25	50	75	80	85	90	95	100
1:3500	0	10	30	60	80	85	95	100	100	100
1:3000	0	30	55	80	90	95	98	100	100	100
1:2500	0	35	60	85	93	98	100	100	100	100
1:2000	2	37	65	90	95	100	100	100	100	100

4 × 0.15 = 0.60 c.c. of 1:100 complement. Consequently $\frac{0.60}{100} = \frac{0.20}{X}$. $X = 33.3$. Therefore, 0.20 c.c. of a 1:33.3 dilution of complement will be required for the test. This dilution is also used in the controls in order to determine quantitatively the amount of complement which may deteriorate in the presence of serum, antigen, and saline alone.

Technic of Diagnostic Test.—

Inactivate the serum for 30 minutes at 56° C. just prior to use. If the serum was inactivated the day before, it is advisable to reheat it at this temperature for about 5 minutes before using it. Use two dilutions of serum in the test, 1:5 and 1:10. Arrange the tubes and add the reagents in the order given in Table 176.

TABLE 176.—THE TEST PROPER

REAGENTS	TUBE NUMBERS										
	1	2	3	4	5	6	7	8	9	10	11
Saline*	---	---	0.30	0.25	0.20	0.30	0.25	0.20	0.30	0.25	0.20
Serum 1:5	0.20	---	0.20	0.20	0.20	---	---	---	---	---	---
Serum 1:10	---	0.20	---	---	---	0.20	0.20	0.20	---	---	---
Complement 4 units	0.20	0.20	0.10	0.15	0.20	0.10	0.15	0.20	0.10	0.15	0.20
Antigen	0.20	0.20	---	---	---	---	---	---	0.20	0.20	0.20

*Or diluted buffer.

Place the tubes in the refrigerator overnight (15 to 18 hours) at 5° C. The next day, add to each tube 0.40 c.c. of sheep cells which have been sensitized 15 minutes previously. Incubate in a 37° C. water bath for 30 minutes. Remove and read.

Endamoeba histolytica antigen is prepared by a modification of the technic of Rees, Bozicevich, Reardon, and Jones.[1] It is used for the complement fixation test for amebiasis and has proved to be useful in the differential diagnosis of liver abscesses and questionable cases of liver involvement.

Interpretation of Results.—

In the usual complement fixation technic, according to Bozicevich and associates,[1] the amount of complement which will deteriorate overnight in the presence of serum or antigen is not taken into consideration. With the method described here, it can be seen that the amount of deterioration which might occur with any given serum sample is taken into consideration in evaluating the final results of the test. For the purpose of convenience this deteriorating factor is called the binding power of the serum or of the antigen. In Table 176, Tubes 3, 4, and 5 contain, respectively, 2, 3, and 4 50-per cent units of complement to determine the binding power of the 1:5 serum dilution. Tubes 6, 7, and 8 containing, respectively, 2, 3, and 4 50-per cent units of complement should give the amount of complement bound in the 1:10 serum dilution. Tubes 9, 10, and 11 should show the quantity of complement bound by the antigen used in the test. Thus, it can be seen that the binding power is determined for both dilutions of serum and the antigen used in the test if any binding should exist. It is necessary to conduct binding powers on every single serum used in the test, but it is necessary to conduct only one set of binding powers for the antigen for the particular day that the antigen is used.

Remove the tubes containing 30, 50, 70, and 100 per cent cells, respectively, of the color standard and shake thoroughly. Regard any tube in the test matching the tube containing 30 per cent cells or more as a positive, and any tube showing less than 30 per cent fixation as negative.

Bozicevich and associates[2] give a few examples to demonstrate the advantage of the present method of conducting the complement fixation test. If a serum should give the following fixation results, it is apparent from Tubes 3, 4, and 5 that the serum itself will bind 3 units of complement. Yet with the usual methods, Tube 5 would be the control tube and the test would have been regarded as satisfactory. However, the second serum dilution 1:10 also has some binding power as disclosed by Tube 7. This serum is regarded as a negative when the present method of complement fixation is used. If the serum showing the binding displayed in the above example has any antibodies present the titer would be much higher.

TABLE 177

	TUBE NUMBERS										
	1	2	3	4	5	6	7	8	9	10	11
1:5 serum	++++		++++	+++	–						
1:10 serum		+				++++	+	–			
Antigen									–	–	–

At times, it has been found that antigen will begin to deteriorate and tests are made to guard against this feature as shown by Table 178.

TABLE 178

	TUBE NUMBERS										
	1	2	3	4	5	6	7	8	9	10	11
1:5 serum	++++		–	–	–						
1:10 serum		++++				–	–	–			
Antigen									++++	+++	–

In this case, it is apparent that the antigen, as disclosed by Tubes 9 and 10, binds at least 3 units of the complement by itself. Again, Tube 11, which is the usual control in other tests, is negative and the antigen would have been regarded as satisfactory. In this instance, it is necessary to repeat the test with a new and satisfactory antigen.

---

[1] Am. J. Trop. Med. 22: 581, 1942.

[2] See footnote, page 1831.

In the example, Table 179, the test is regarded as positive.

TABLE 179

	TUBE NUMBERS										
	1	2	3	4	5	6	7	8	9	10	11
1:5 serum	++++		++++	++	±						
1:10 serum		++++				+++	±	-			
Antigen									-	-	-

The test is regarded as positive because the serum gave good fixation in the 1:10 dilution and in this dilution the anticomplementary effect of the serum is practically removed. The 1:5 dilution could not be read safely because of the strong anticomplementary tendencies.

Another Complement Fixation Test for Amebiasis[1]

A micro-Kolmer technic as modified by Microbiology Reference Laboratory, Veterans Administration Hospital, Bronx, N. Y., is here described.

Reagents.—All glassware must be scrupulously clean.

Sheep Cell Suspension.—

Collect sheep cells in sodium citrate or by defibrination.

Wash four times in physiologic saline solution (see page 2048). If the cells are to be used for several weeks, use preserving solution.

Fill a 15 c.c. graduated conical centrifuge tube with washed cells and centrifuge at 2,000 r.p.m. for 10 minutes.

Measure the volume of packed cells after removing the supernatant fluid.

Multiply by 50 to obtain the total volume of diluent required to make a 2% suspension. Suspend in Kolmer saline.

Kolmer Saline.—

To every 1,000 c.c. of 0.85% sodium chloride solution
add 100 mg. of magnesium sulphate.

Serum.—

The serum must not be chylous. Preferably withdraw from a fasting patient. If the serum is to be stored in a freezer and thawed shortly before the test is run, aseptic technic is not essential. Repeated thawing and freezing will render the serum anticomplementary if it has not been aseptically collected.

After the blood has clotted, loosen the clot, centrifuge, and remove the supernatant serum.

Inactivate at 56° C. for 30 minutes to destroy the natural complement.

Antigen.—

Obtain *Endamoeba histolytica* antigen. At present this is in the experimental stage and is not available.

Dilute with Kolmer saline 1:5. Use only freshly prepared dilutions.

Complement.[2]—

Bleed guinea pigs from the heart. Do not use pregnant pigs.

Allow the blood to flow gently from the syringe into a saline-rinsed bottle. Avoid rupturing the cells.

Refrigerate for 4 to 6 hours.

Decant supernatant fluid and centrifuge to remove blood cells.

Decant the serum into small rubber-stoppered test tubes, each containing exactly 1 c.c.

Freeze and store in a frozen state for at least one day before titrating.

Carry out the titration as indicated below (page 1836).

---

[1] This test is still in the experimental stage. It is presented by permission of Michael Kenney, M.D.

[2] Prepared as for the Bengston technic, Pub. Health Rep. 59: 402, 1944, except that it is diluted 1:30 for hemolysin titration and 1:40 for complement titration.

For the hemolysin titration, dilute 1:30. Dilute 1:40 for the complement titration.

Perform the complement titration with the rack of tubes, the complement, antigen, and Kolmer saline all standing in an ice-water bath.

Deliver the Kolmer saline and the 1:40 complement with 0.2 c.c. pipettes, but never measure the volumes with the tip of the pipette.

Deliver the antigen and the amboceptor-red cell mixture with 1 c.c. pipettes.

To dilute the complement (the same stock as used in the hemolysin titration) 1:40, add 0.2 c.c. to 7.8 c.c. of cold Kolmer saline.

Sensitize the 2% sheep cells with the titrated hemolysin by mixing equal proportions of each, 15 minutes before needed, and placing in a refrigerator until used in the test.

Set up the complement titration in 10 by 75 mm. tubes.

Hemolysin.[3]—

Give rabbits 5 or 6 intravenous injections, at about 3-day intervals, of washed, packed sheep cells suspended in 10 c.c. of saline.

The initial dose is 0.5 c.c. of cells, followed by three doses of 1.0 c.c., and finally 1.5 c.c.

Bleed 7 to 9 days after the last injection of a preliminary titration gives a titer of 0.15 c.c. or more of the 1:250 dilution of hemolysin. (See page 2040 for method of bleeding a rabbit.)

Allow the blood to clot, and centrifuge.

Remove the supernatant serum (it need not be inactivated), and preserve with an equal part of best grade, neutral glycerin.

Store in a refrigerator.

For the titration, complement must be diluted 1:30 instead of 1:40.

Titration of Hemolysin

Prepare a 1:250 dilution of hemolysin by diluting 0.2 c.c. of the glycerinated serum to 50 c.c. with saline.

TUBE NUMBER	1	2	3	4	5	6	7	8	9	10
Hemolysin	0.05	0.1	0.15	0.2	0.25	0.3	0.35	0.4	0.45	0.5
Saline	0.55	0.5	0.45	0.4	0.35	0.3	0.25	0.2	0.15	0.1
2% Sheep cells	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2

Shake and allow to stand 10 minutes at room temperature.

Add 0.2 c.c. (1⅓ units) of complement to each tube; shake.

Incubate in a water bath at 37° C. for 1 hour.

Find the smallest quantity of hemolysin which produces complete hemolysis.

Divide this by the dilution 250, which gives the amount of hemolysin providing *one unit.* Two units, or twice this amount, are used in the test.

Dilute the hemolysin so that 2 units are contained in 0.2 c.c.

The amount of hemolysin providing 2 units × the number of doses needed for the test = the c.c. of hemolysin needed. The number of doses × 0.2 c.c. = the total volume of the dilution.

Titration of Complement

Dilute the complement 1:40.

TABLE 180

TUBE	1	2	3	4	5	6	7	8	9	10
Complement (c.c.)	0.10	0.09	0.08	0.07	0.06	0.05	0.04	0.03	0.02	0.00
Kolmer saline (c.c.)	0.05	0.06	0.07	0.08	0.09	0.10	0.11	0.12	0.13	0.15
Antigen (c.c.)	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10
Shake well and place in a water bath at 37° C. for 1 hour.										
Sensitized sheep cells (c.c.)	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10
Shake well and place in a water bath at 37° C. for 30 minutes.										

---

[3] Bengston technic except for the dilution of complement.

Read. Find the smallest amount of complement which gives complete hemolysis. If all the tubes other than the control show hemolysis, the complement is hyperactive and should not be used.

For the test, dilute the complement so that 2 exact units will be represented in 0.1 c.c., according to Table 181.

TABLE 181

TUBE NO.	COMPLEMENT 1 EXACT UNIT	COMPLEMENT 2 EXACT UNITS	DILUTION RATIO
1	0.10	0.20	1:20
2	0.09	0.18	1:22.2
3	0.08	0.16	1:25
4	0.07	0.14	1:28.6
5	0.06	0.12	1:33.3
6	0.05	0.10	1:40
7	0.04	0.08	1:50
8	0.03	0.06	1:66.6
9	0.02	0.04	1:100
10	Control	Control	Control

Note: The dilution (D) is calculated as follows:

$$D = \frac{40 \times 0.1}{2\ U} \text{ when } U = \text{the exact unit of complement.}$$

Example: If tube No. 7 is the exact unit, then

$$D = \frac{40 \times 0.1}{0.08} = \frac{4}{0.08} = 1{:}50 \text{ dilution.}$$

Technic of the Test

(A) **Preliminary Serum Dilutions.—**

Make serial twofold dilutions in 10 by 75 mm. tubes.

TUBE	1	2	3	4
Kolmer saline	0.2	0.2	0.2	0.2
Inactivated undiluted patient's serum	0.2	0.2 from tube 1	0.2 from tube 2	0.2 from tube 3
Dilution	1:2	1:4	1:8	1:16

Use a 1 c.c. pipette to measure the saline, and a 0.2 c.c. pipette for the serial transfers.

(B) **Final Quantitative Test.—**

All racks must be set in an ice bath while performing the test.

TABLE 182

TUBE	1	2	3	4	5	6	7	8	9	10
Patient's serum (c.c.)	0.05 undiluted	0.05 undiluted	0.05 of 1:2 dilution	0.05 of 1:4	0.05 of 1:8	0.05 of 1:16	---	---	---	---
Kolmer saline (c.c.)	0.10	---	---	---	---	---	0.05	0.15	0.15	0.25
Titrated complement (c.c.)	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	---	---
Antigen (c.c.)	---	0.10	0.10	0.10	0.10	0.10	0.10	---	0.10	0.10
Shake well and place in a refrigerator overnight.										
Sensitized sheep cells (c.c.)	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10	0.10
Shake well and place in a water bath at 37° C. for 30 minutes. Take first reading after 15 minutes.										

Tube 1 is the patient's serum control. It must show complete hemolysis.

Tube 7 is the antigen control and must show complete hemolysis.

Tube 8 is the hemolytic system control and must show complete hemolysis.

Tube 9 is the control to test for the hemolytic property in antigen and must NOT show hemolysis.

Tube 10 is the cell control and must NOT show hemolysis.

Controls 7 to 10 must be set up with every batch of tests.

Compare the readings with a **color scale** prepared by using different proportions of sheep cell dilution and hemolyzed sheep cells:

1 part of 2% sheep cells + 6 parts of Kolmer saline for the sheep cell dilution, and sparkling tubes from hemolysin titration for the hemolyzed sheep cells.
Color scale:

TUBE	1	2	3	4	5
Sheep cell dilution	0.4	0.2	0.1	0.04	---
Hemolyzed sheep cells	---	0.2	0.3	0.36	0.4
Reading	4 plus	3 plus	2 plus	1 plus	Negative

The complement fixation test for amebiasis, as presented here, was used by Kessel[1] with the following results in the first 100 cases thus tested. Positive stool and positive complement fixation tests were found in 48 patients, or 48 per cent. Negative stool and negative complement fixation test were found in 32 patients, or 32 per cent. Negative stool and positive complement fixation test were found in only 6 patients, or 6 per cent, and positive stool with negative complement fixation test in 14, or 14 per cent.

Of the 10 control cases, 8 or 80 per cent had negative stools and negative complement fixation tests; 2 or 20 per cent had negative stools and positive complement fixation tests.

These data demonstrate that in 80 per cent there is a correlation of stool findings and complement fixation results, while false positive complement fixation tests were present in only 6 per cent, and positive stools with negative complement fixation tests in 14 per cent.

To the best of our knowledge, this is the first time that a similar antigen has been prepared and used successfully with the 100 per cent hemolysis system (Bengston technic). The technic used by Rees and his associates has involved the use of the 50 per cent hemolysis system which is considerably more complicated than the Bengston technic.

Although only 100 cases have been completely studied thus far, Kessel has found 80 per cent positive correlation with stool examinations with only 6 per cent false positives. A false positive has been defined arbitrarily as one with a positive complement fixation test and three negative stools. Since it is common experience for amebae to be discovered only after 5 or more stools have been examined, as in the cases discussed, further stool examinations might have reduced even more the percentage of false positives. Most encouraging were those patients with ulcerative colitis who had negative stools and negative complement fixation tests with no false positives. In view of the relative high specificity, minimal false positive reactions, the simplicity of the technic, and the availability of the antigen, this technic is considered a valuable adjunct to the armamentarium in the diagnosis of amebiasis.

---

[1] Personal communication. For full details see Kessel, John J., Parrish, Margaret, and Parrish, Glenn: Am. J. Trop. Med. & Hyg. 3: 440, 1954.

MEDICAL PROTOZOOLOGY

Protozoa are unicellular animal organisms which are capable of carrying on in one cell all the biological phenomena necessary for life. **Metazoa,** on the other hand, are multicellular animal organisms which contain cells specialized for definite functions.

Protozoa are composed fundamentally of a protoplasmic mass containing one or more nuclei. The **cytoplasm** is fine or coarsely granular, and is composed of an external hyaline portion called **ectoplasm** and an internal granular portion or **endoplasm.** Distinct prolongations of the ectoplasm are closely related to the functions of movement and motility.

Pseudopodia are ectoplasmic projections which progressively increase in size, frequently becoming digitiform, within which granular endoplasm is projected.

Flagella are long delicate filaments, usually few are present, used by the flagellates for locomotion.

Cilia are short, usually numerous, filaments arising from the ectoplasm.

A **peristome** is a pit or depression in the ectoplasm, which leads to a cavity called the **cytostome** or mouth. This leads to a **cytopharynx** or esophagus.

Vegetative forms of protozoa are called **trophozoites.** The ectoplasm condenses and becomes more resistant, forming the wall of **cysts,** which are resistant forms assumed by the trophozoites in response to unfavorable environmental conditions or as a part of the life cycle.

Chromidia and **chromatoid bodies** are nutritional inclusions in the endoplasm.

The **nucleus** is the fundamental structure of the cell, which participates in the process of cellular multiplication. Not only does it maintain the life of the protozoa, but it is important in the process of reproduction. In many protozoa it is the essential element in morphologic diagnostic differentiation of otherwise similar genera and species, as in the case of amebae of the human intestine. Within the nucleus is a granule or a **chromatin mass.** It is of variable size and is situated excentrically. This **karyosome,** as it is called, stains intensely with iron-hematoxylin. **Chromatin granules,** smaller than the karyosome, are found deposited at the points of intersection of the **linin filaments** which are radial filaments extending in the direction of the **nuclear membrane** and interlacing to form the **linin net** which is impregnated with nuclear fluid.

The flagellates contain a **macronucleus,** or true nucleus, and a small nucleus or kinetoplast or micronucleus, composed of a spherical, ovoid, or bacillary body, called the **parabasal body.** Another smaller, spherical or ovoid body, called the **blepharoplast,** is near the parabasal body, and from this blepharoplast rises the **flagellum,** the initial portion of which is called the **axoneme.**

Classification of Protozoa

There are two subphyla in the phylum Protozoa, Plasmodroma and Ciliophora. Plasmodroma are divided into the classes Rhizopoda, Mastigophora, Sporozoa, Cnidosporidia; Ciliophora into Ciliata and Suctoria. The class Rhizopoda contains five orders, Amoebida, Heliozoa, Mycetozoa, Radiolaria, and Foraminifera. The Mastigophora are the flagellates. The Sporozoa include malarial parasites and coccidia. Of the Ciliophora, only the class Ciliata is of interest in human parasitology.

Order **AMOEBIDA** Calkins 1902

These are Rhizopoda composed of a cytoplasm with a shell or skeletal structure, moving by means of thick, temporary pseudopodia which may appear from any part of the body surface; usually one nucleus, sometimes two, or many. Cytoplasm is usually differentiated into ectoplasm and endoplasm. All the parasitic amebae of the digestive tract of man and animals are included in this order.

The order Amoebida contains the following four families: Amoebidae, Dimastigamoebidae, Rhizomastigidae, and Paramoebidae, with the following differential characteristics:

ORDER			FAMILY
AMOEBIDA	Incapable of forming flagella		Amoebidae
	Form flagella	In adult stage may form two or more flagella	Dimastigamoebidae
		Provided with only one flagellum during the greater part of their free-living existence	Rhizomastigidae
	In addition to a principal nucleus, possess an accessory body (Nebenkörper) which is divided with the nucleus during reproduction		Paramoebidae

Only the family Amoebidae is of interest for our purpose.

Family **AMOEBIDAE** Bronn 1859

This family includes free-living amebae the majority of which parasitize the digestive tract of man and lower animals. These do not have flagella at any period of their existence.

The family Amoebidae has been divided into well-defined parasitic groups, such as the genera Endamoeba, Endolimax, Iodamoeba, and Dientamoeba, and also into free-living groups, not well-defined as yet. Many of the "small" type, formerly all included under the *Amoeba limax,* have since been differentiated into definite genera such as Hartmanella, Vahlkampfia, Sappinia. Most of the "large" varieties are retained in the genus Amoeba until a better understanding of their morphologic and biologic characteristics are understood. The following chart gives a summary of the differential characteristics of the genera of the family Amoebidae.

The first five of these genera include free-living species, with trophozoites usually showing a contractile vacuole in the cytoplasm. They are not of interest in this text. The last four genera, however, Endamoeba, Endolimax,

FAMILY					GENUS
AMOEBIDAE	Trophozoites usually with contractile vacuole in the cytoplasm. Free-living	Small body		Usually, only one contractile vacuole. One nucleus	Amoeba
				Contractile vacuoles have not been observed with certainty; several or many nuclei	Pelomyxa
		Large body		Vesicular nucleus; large central karyosome; numerous chromatin granules in the periphery	Hartmannella
				Nucleus with large karyosome and peripheral chromatin; mononucleated cysts	Vahlkampfia
				Two nuclei closely associated	Sappinia
	Trophozoites without contractile vacuole in cytoplasm. Parasites	One nucleus	Provided with peripheral chromatin	Small central or excentric karyosome	Endamoeba
			Not provided with peripheral chromatin	Voluminous karyosome, usually central, at times excentric; trophozoites small; cysts usually oval, multinucleated; glycogen vacuole usually absent	Endolimax
				Voluminous karyosome, central, spherical, surrounded by a layer of achromatic granules; trophozoites are of medium size; cysts generally spherical or irregular, almost always mononucleated, sometimes binucleated; glycogen vacuole usually present	Iodamoeba
		Generally two nuclei		Not provided with peripheral chromatin; central granular karyosome; small trophozoites; cysts unknown	Dientamoeba

Iodamoeba, and Dientamoeba, include all the parasitic species of the digestive tract of man and are consequently of great importance (see Fig. 448). The species *Endamoeba histolytica, E. coli,* and *E. gingivalis; Endolimax nana; Iodamoeba butschlii;* and *Dientamoeba fragilis* are of interest. The characteristics of Endamoeba are described on the following pages.

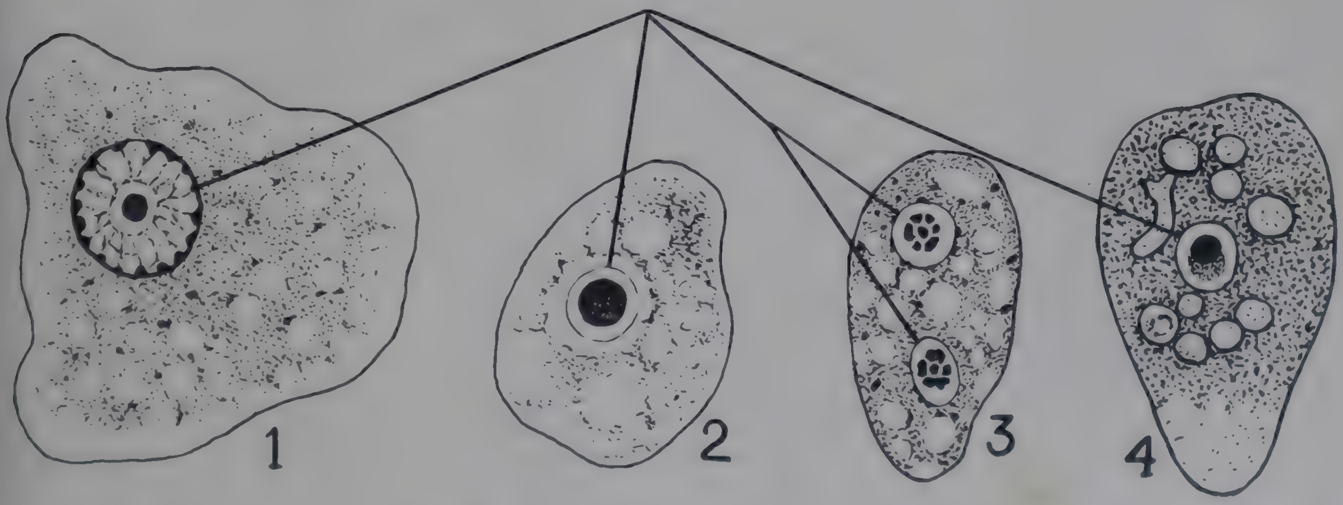

Fig. 448.—Genera of amebae. Nuclear characteristics; partly according to Brumpt and Dobell. *1,* Genus *Endamoeba:* small central or excentric karyosome and a denticulated layer of peripheral chromatin; *2,* genus *Endolimax:* voluminous karyosome, delicate nuclear membrane without peripheral chromatin; *3,* genus *Dientamoeba:* usually two nuclei with a delicate nuclear membrane without peripheral chromatin, and numerous karyosomes in rosette formation; *4, Iodamoeba* (*Pseudolimax*): voluminous central spherical karyosome surrounded by a layer of achromatic granules, crescent-shaped in the cysts, and a delicate nuclear membrane without peripheral chromatin. (Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Genus **Endamoeba** Leidy 1879

Characteristics.—Amoebidae with vesicular nucleus, fine but visible nuclear membrane, karyosome relatively small and situated in the center or near the center of the nucleus. Varying number of peripheral chromatin granules free or adherent to the inner surface of the nuclear membrane. Parasites of man, lower mammals, and invertebrates.

Nomenclature.—Some authors consider the genus Entamoeba as distinct from Endamoeba and include, in the former, the species *histolytica, coli,* and *gingivalis* which are all found in the digestive tract of man. Others believe that Entamoeba and Endamoeba are the same and have thus adopted the generic name Endamoeba since it is the older generic term; they use Entamoeba as a synonym. Using this last nomenclature the three species of this genus which parasitize the digestive tract of man are: *Endamoeba histolytica, Endamoeba coli,* and *Endamoeba gingivalis.*

Endamoeba Histolytica

(Schaudinn 1903) Hickson 1909

Endamoeba histolytica, from the point of view of frequency and of pathogenicity, is the most important of the protozoa which infect the digestive tract of man.

Living Endamoeba Histolytica in Fresh Unstained Preparations.—

Trophozoite.—The living trophozoite of *Endamoeba histolytica,* observed in unstained preparations, appears as a more or less rounded, colorless, refractive organism, 15 to 60 microns in diameter with an average size of 18 to 25 microns. The existence of large and small strains, producing large and small cysts, respectively, has been accepted since 1919 (Dobell). The trophozoite shows a hyaline ectoplasm and a finely granular endoplasm, usually well differentiated, especially when the protozoan is moving about. As a general rule, the nucleus is not observable in a fresh specimen, although at times it can be seen in the form of a ring of small refractive granules within the cytoplasm. In fresh feces the trophozoite contains neither bacteria nor nutritional vacuoles, but these may be present in the endoplasm of dead and degenerated forms. The presence of red blood cells in the endoplasm is almost pathognomonic in the differential diagnosis of this species since *E. coli* shows red blood cells in the endoplasm of its trophozoites only very exceptionally. In such cases the species might be confused with *E. histolytica.* The *E. histolytica* has a marked predilection for red blood cells.

Pseudopodia may be long and narrow (digitiform) or short and wide. They project rapidly. They are extensions of hyaline ectoplasm within which the granular endoplasm is thrown, so that motion results. This motion is so active in fresh feces that there is no clear differentiation between ectoplasm and endoplasm; the pseudopodia seem to be projections of total cytoplasm. As the feces cool, the movement of the ameba becomes slower and there may be seen, first, the projection of the hyaline ectoplasm which forms the pseudopodia, and second the projection of granular endoplasm into the pseudopodia. Later the ameba loses its motility or motility is very slow, until the protozoan dies and becomes rounded.

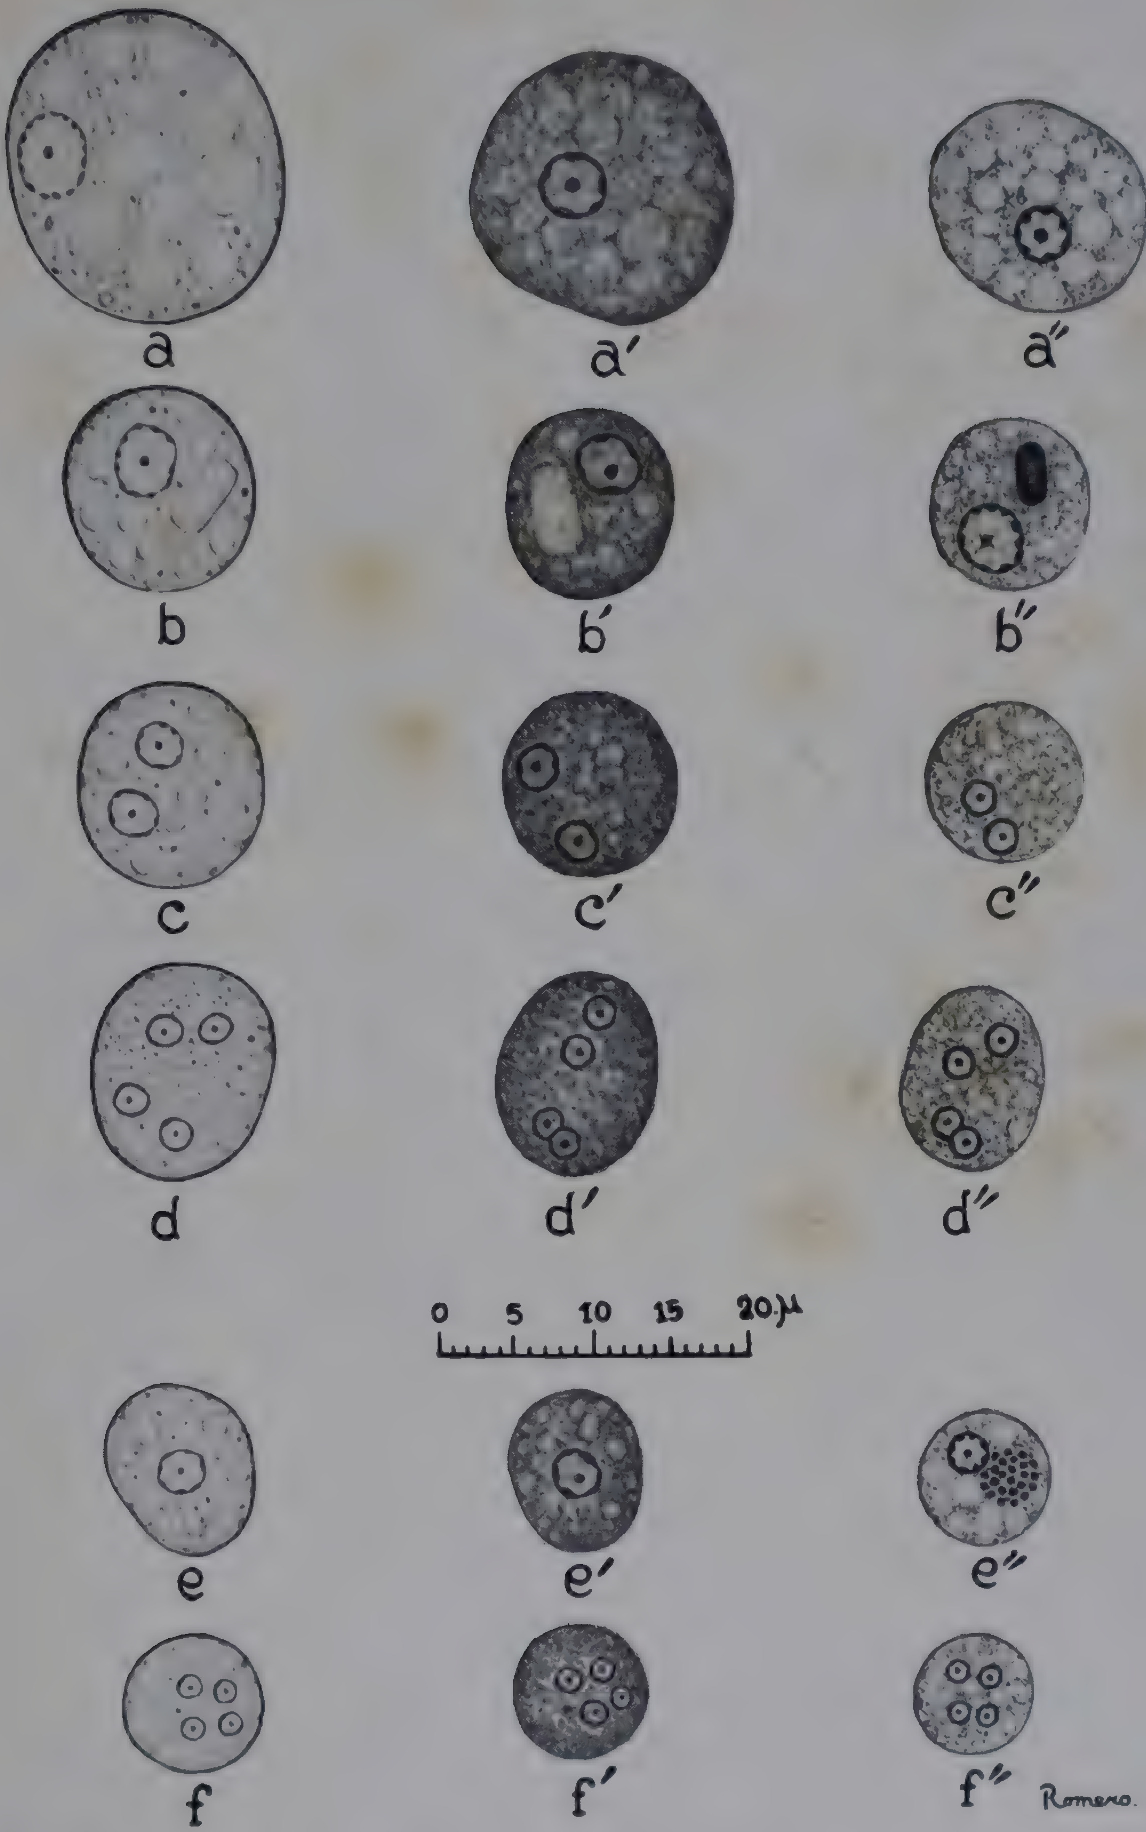

Fig. 449.—*Endamoeba histolytica*: *a* to *f*, fresh specimen; *a′* to *f′* stained with Lugol solution; *a″* to *f″* stained with iron-hematoxylin. *a*,*a′*,*a″*, Trophozoites. Note the peripheral nuclear chromatin, ring-shaped, denticulated on the inner edge, and the small central karyosome and cytoplasm without bacteria. *b*,*b′*,*b″*, Immature uninucleate cysts with a thick chromatoid body in the cytoplasm. *c*,*c′*,*c″*, Immature binucleate cysts. *d*,*d′*,*d″*, Mature quadrinucleate cysts. *e*,*e′*,*e″*, Small trophozoites and precystic forms, with a Sphaerita in the cytoplasm of *e″*. *f*,*f′*,*f″*, Small mature, quadrinucleate cysts. (Original, Kourí.)

Precysts.—In order to change to the precystic form, the ameba becomes immobilized, rounded, and reduced in size, expelling its nutritional contents. Precysts appear as colorless, refractive bodies, round or slightly ovoid. Though they do not present locomotion, they may, nevertheless, slowly project short, wide pseudopodia, which are as slowly withdrawn. The nucleus, when visible, may appear as a series of yellow-refractive granules, distributed in a circle or in the form of a rounded mass, yellow and refractive when viewed by artificial light. Oval or rod-shaped bodies are observed in the cytoplasm. These rods have rounded ends; they are of hyaline appearance similar to chromatoid, crystalloid bodies, chromidia, or rods frequently observed in the younger cyst forms of this species. A cyst wall is lacking.

Cysts.—The trophozoite and the precyst form have only one nucleus, while mature cysts have four and, exceptionally, eight nuclei. Consequently there are intermediate stages between the precyst form and the mature cyst, known as immature cysts, which have two or three nuclei. It is necessary to recognize these in practice.

Cysts appear as round, hyaline bodies, with a cyst membrane which is more refractive than the rest of the cytoplasm. Its dimensions vary widely from small types which produce cysts 3.5 to 12 microns in diameter, to large types which produce cysts 12 to 20 microns in diameter; they may range from 3.5 to 20 microns in diameter.

The nucleus of the cyst has the same appearance as that of the trophozoite. In newly formed cysts, only one nucleus is seen. After division, this nucleus forms two, and by the second division, four nuclei. This number is characteristic of mature cysts and predominates in specimens obtained from fecal matter.

In fresh specimens the nuclei are barely perceptible, the cytoplasm appears colorless and refractive, free of all nutritional inclusions, and in young or immature cysts glycogen vacuoles may be observed. When stained with Lugol solution, cysts are yellow, the cytoplasm loses its refractivity and appears finely granulated, nuclei stand out clearly, and the glycogen contained in the vacuoles stains a mahogany red color. The glycogen vacuole attains its maximum size in uninucleated cysts. These structural characteristics of cysts, trophozoites, and precystic forms are easily seen by use of the oil immersion objective, provided that the optimum amount of light is used.

Fig. 450.—*Endamoeba histolytica* stained with iron-hematoxylin. *1* to *21*, Trophozoites, precystic forms, immature cysts, and mature cysts, in human fecal material in six different cases of intestinal amebiasis (Kourí, Basnuevo, and Sotolongo). *22* to *25*, Trophozoites in pus from a case of amebic hepatic abscess (Case of Kourí and Basnuevo). *1*, Trophozoite with cytoplasm without inclusions; *2*, trophozoite with erythrocyte in the endoplasm; *3*, small trophozoite; *4*, uninucleate cyst with nucleus in activity, pushed back by a very large glycogen vacuole containing a small chromatoid body; *5*, uninucleate cyst with a thick chromatoid body; *5′*, with three chromatoid bodies; *6*, binucleate cyst with two chromatoid masses; *7*, smaller binucleate cyst with three chromatoid bodies; *8*, binucleate cyst without chromatoid bodies; *9*, uninucleate cyst with nucleus in activity, glycogen vacuole, and two chromatoid bodies; *10*, binucleate cyst with one chromatoid body; *11*, mature, quadrinucleate cyst with nuclei at rest, and without chromatoid bodies; *12* to *12″*, small trophozoite: a Sphaerita is seen in the cytoplasm of *12″*; *13* to *19*, uninucleate cysts, without chromatoid bodies and thick wall in *13* and *13′*; with three chromatoid bodies in *14* and *15*; with two Sphaeritas in *16*; with very wide glycogen vacuole in *17*, *18*, and *19*, with numerous chromatoid bodies in *17*; *20*, small binucleate cyst without chromatoid bodies; *21*, mature quadrinucleate cyst with one chromatoid body; *22*, observe the hyaline ectoplasm, very abundant in this typical specimen, with one erythrocyte in the process of being digested and without bacteria in the cytoplasm; in specimen *23*, there are three erythrocytes; in *24* there is one erythrocyte in the endoplasm; and *25*, projecting hyaline pseudopodia. (Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

Fig. 450.—*Endamoeba histolytica.* (*For legend see opposite page.*)

In immature cysts, ovoid or rod-shaped bodies are observed; these are called *chromatoid bodies*. The nature of these bodies has not been definitely determined. They stain a deep black with iron-hematoxylin. They usually disappear in older, mature cysts.

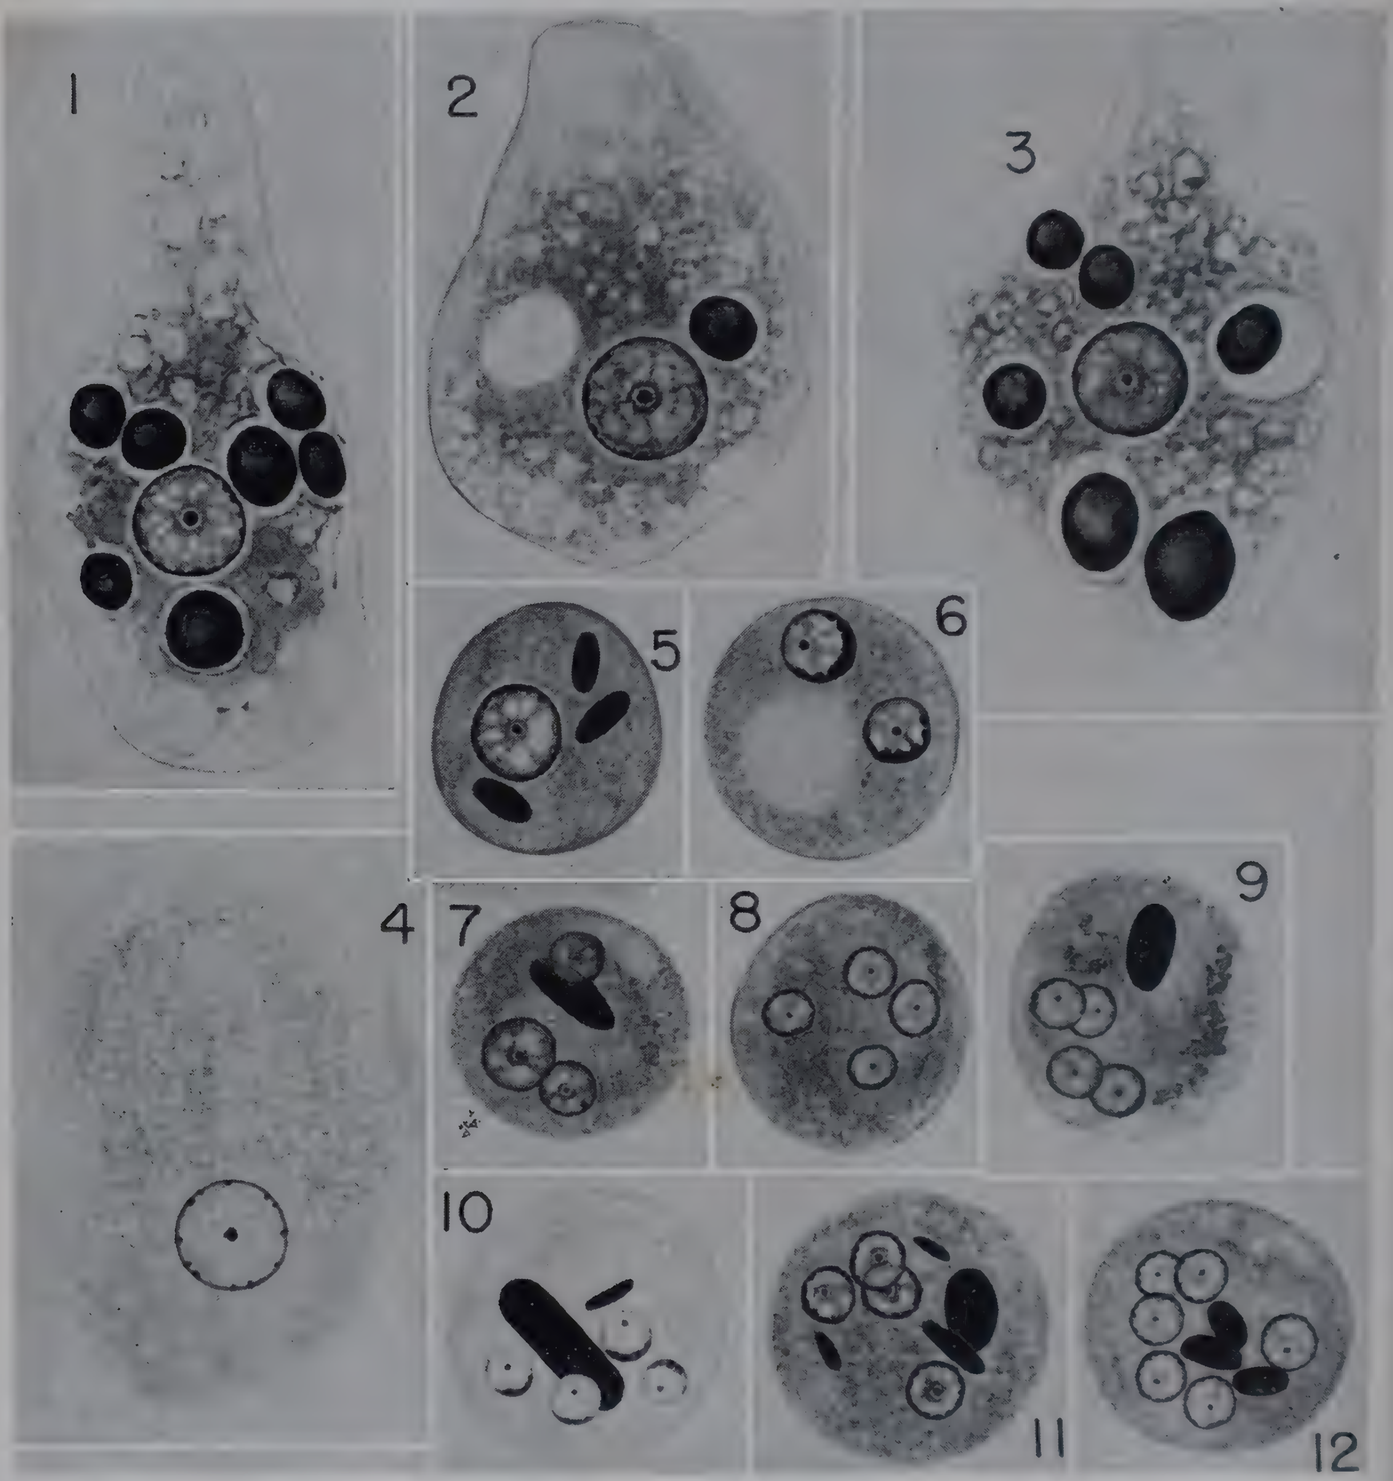

Fig. 451.—*Endamoeba histolytica.* *1* to *3*, Trophozoites from a single case, showing ingested red blood cells; *4*, trophozoite from another case showing delicate cytoplasm and typical nucelus; *5* to *12*, various cysts, with and without chromatoid bodies, showing 1, 2, 3, 4, and 6 nuclei of varying character. Chromatoid bodies are commonly present in young cysts, absent in older cysts. In exceptional cases, 8 nuclei are present. (Courtesy Winthrop-Stearns, Inc., copyright, 1946.)

A few points of difference between a nucleus in repose and a nucleus in the state of activity must be known so that a mature cyst can be differentiated from an immature cyst when the number of nuclei is such as to raise doubts about a differential diagnosis between the *histolytica* and *coli* species. The nucleus at rest is spherical and smaller than the nucleus in activity, which, in addition to being larger, may also be spherical. It is more frequently oval, elliptical, rather elongated, and infrequently fusiform according to the degree of karyokinetic activity at the time of observation. If the cyst is small, and the four nuclei are small and of equal size, it is almost certainly a mature four-nucleated cyst of Endamoeba, species *histolytica;* if the four nuclei are unequal in size and shape, it is probably an immature cyst which, upon maturing, will have eight nuclei, or, less frequently, a multiple of this number, and is almost certainly a cyst of *Endamoeba coli.*

Metacysts.—The cyst of *E. histolytica,* after reaching the lower portion of the ileum, de-encysts and releases an active trophozoite with four nuclei. This trophozoite divides into four trophozoites, one for each nucleus; these grow and invade the intestinal wall to continue their development. These four amebae which result from the de-encystment are called *metacystic trophozoites;* according to Dobell's experiments in vitro, there may be eight.

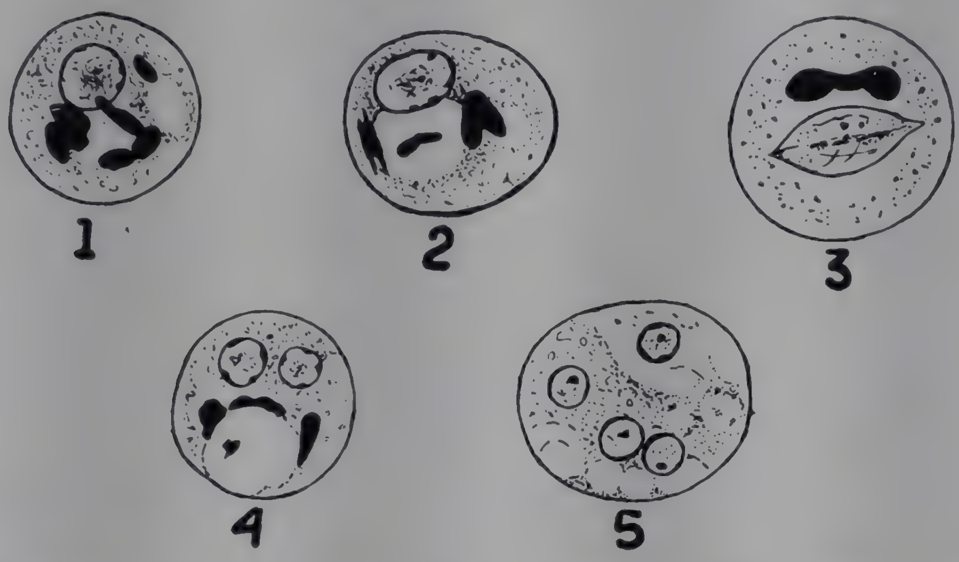

Fig. 452.—*Endamoeba histolytica.* *1* and *2,* Uninucleate cysts with glycogen vacuole and chromatoid bodies; *3,* nuclear karyokinesis in a uninucleate cyst with chromatoid bodies; *4,* binucleate cyst with glycogen vacuole and chromatoid bodies; *5,* mature quadrinucleate cysts. (Brumpt in Kourí and Basnuevo; Lecciones de Parasitología y Medicina Tropical.)

Endamoeba Histolytica Stained With Iron-Hematoxylin.—In well-stained preparations, the cytoplasm of the trophozoite stains grayish or violet and is granular in appearance, with an alveolar and spongy structure. If amebae are at their maximum activity, as in fresh feces, the cytoplasm does not contain bacteria, but red blood cells may be observed. The nucleus is an intense black, and stands out clearly in contrast to the gray or pale violet color of the cytoplasm. The **nuclear elements** are the nuclear membrane, chromatin granules on the inner surface of this membrane in the form of a cogged wheel, and the small karyosome, usually central, but at times slightly excentric, all stained an intense black. Sometimes there can be observed traces of a linin net, in the form of thin fibrils, sometimes radiating from the center to the periphery.

Cysts.—It is relatively easier to identify the cysts of *E. histolytica* in fresh preparations in moist Lugol-stained slides if the high dry objective is used with the 10× or 12× ocular. Staining, however, has certain advantages. It shows clearly the structural characteristics of protozoa, even in cases in which these characteristics might not have been observed in examination of the living specimen and in moist specimens stained by Lugol's. In preparations stained by iron-hematoxylin, the cysts show characteristic morphology and structure. They are spherical, or may be oval, and rarely irregular. The wall does not stain with hematoxylin, but appears as a colorless halo around the cyst. The cytoplasm stains a grayish-blue, while the nucleus and the chromatoid bodies are of a contrasting intense black color. The number of nuclei in mature cysts is usually 4, but some cysts have been observed with 6 or 8 nuclei.

De-encystment of Endamoeba Histolytica.—De-encystment of ingested cysts takes place in the distal portion of the ileum. This permits the young amebae to invade the ileocecal valve and to colonize in its mucosa. It is possible, however, that de-encystment may take place in the caput coli or in the ascending colon.

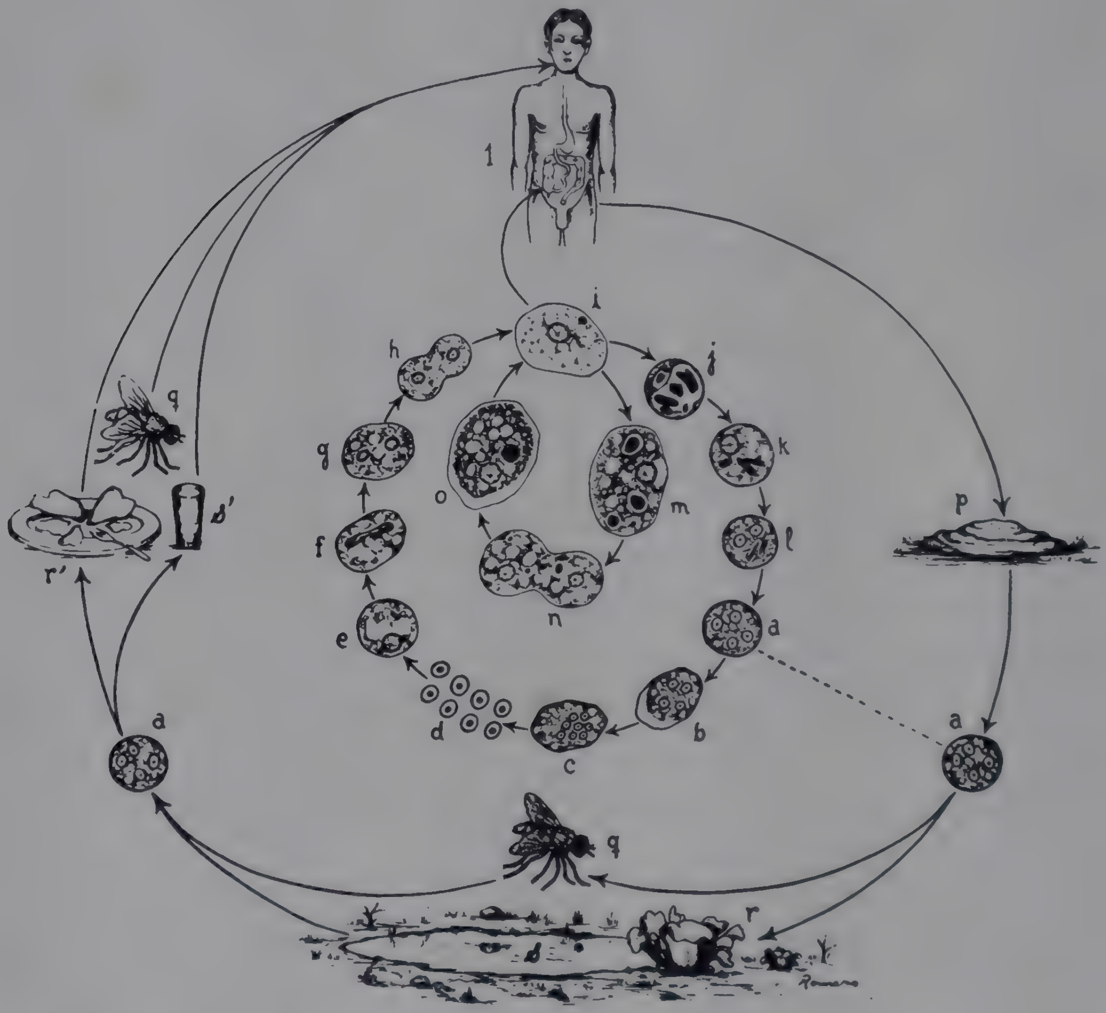

Fig. 453.—Life cycle of *Endamoeba histolytica.* The infective form, the mature cyst (*a*), is passed in the feces (*b*), is disseminated in nature, and contaminates vegetables and water (*r, s*), food for man (*r', s'*); flies (*q*); hands of patients and healthy and convalescent carriers. If the mature cyst (*a*) is ingested by man (*1*), in the intestines the cystic cover is dissolved and a quadrinucleate ameba is liberated (*b*) which, by nuclear division, is converted into an ameba with eight nuclei (*d*). Each develops into a vegetative ameba (*e*) which lives in the lumen of the intestine and reproduces repeatedly (*f,g,h,i,*) by karyokinetic division. In diarrheal or soft feces the vegetative forms (*e,f,g,h,i,*) appear; in hard or pasty stools the precystic forms are found. The immature cyst (*j,k,l*) and the mature cyst (*a*) are the infective forms. Normally the life cycle of *Endamoeba histolytica* is represented in the outer circle, *a* through *l*, without producing definite clinical symptoms. But when the host lacks resistance (*1*) dysenteric syndrome or acute inflammation of the intestines, or a hepatitis develops, and the histolytic forms of amebae (*m,n,o*) develop and bore through the tissue and produce the characteristic lesions of dysenteric amebiasis and its complications. (After Kourí and Basnuevo.)

Resistance of Cysts of Endamoeba Histolytica.—In a cool, moist place, the cysts of *E. histolytica* survive more than 12 days in the feces. In water, the period of survival depends upon the number of bacteria present, and upon the temperature of the water. Cysts survive from 9 to 30 days in indirect proportion to the number of organisms and the temperature. They have little resistance to desiccation and to higher temperatures.

Cysts resist for 15 minutes a 5 per cent solution of cresol, for 30 minutes a 1:2,500 solution of bichloride of mercury, 5 per cent Formalin, and 1 per cent phenol.

Cysts may be ingested by flies and eliminated with their excreta in a viable condition as long as 48 hours after ingestion.

Infective Forms of Cysts.—Mature or quadrinucleate cysts constitute the infective forms. These enter the human organism by way of the mouth, passing undamaged through the stomach, thence to the small intensine. Here the cyst wall softens and breaks, due to the action of digestive ferments, and a quadrinucleate ameba is released. The quadrinucleate ameba undergoes two cytoplasmic divisions without further nuclear division, giving rise to four active amebae. Occasionally nuclear division may also take place; this results in the production of eight very small amebae.

Life Cycle.—The metacystic amebae migrate into the large intestine and establish themselves in the walls, especially in the ileocecal region and in the first part of the ascending colon, as well as in the rectosigmoid. At these sites, at autopsy, there is seen a predominance of lesions caused by *E. histolytica*. The infection is very persistent; it may last throughout the life of the host.

While in the intestinal mucosa, the amebae multiply repeatedly by binary fission. For reasons as yet unexplained, some of these amebae that remain in the intestine expel their nutritional material, undergo reduction in size, possibly by division, and become rounded, constituting the so-called *precystic* forms. These precystic forms are later enveloped by a resistant membrane, forming the uninucleate cysts. When they mature, they are transformed into the quadrinucleate, infective forms. These forms, if ingested by the proper host, begin again the life cycle just described.

Mechanism of Transmission

Source of Infection.—*E. histolytica* is usually transmitted directly from person to person by food handlers, housekeepers, nurses, servants, etc., or by food or drink contaminated by excreta of parasitized persons. Although Faust succeeded in infecting young cats and dogs by feeding them trophozoites, nevertheless in nature the cyst is the usual infecting form. Since the so-called *normal carriers,* or better, *carriers without symptoms,* or with light symptoms without diarrhea or dysentery, regularly eliminate amebae in cyst form, while the diarrheal and dysenteric subjects eliminate the vegetative form of the parasite, the trophozoite, it is the mis-named *healthy carriers* who constitute the principal source of dissemination and contagion of *E. histolytica.*

Contamination of Food and Drinking Supplies Due to Inadequate Inspection of Water.—In cities where the water system is in bad condition, water pipes may permit contamination of drinking water. Installation of filters, chlorination of the water, and above all, boiling the water are indispensable in preventing infection. As an example of contamination by drinking water, we cite the classic example of amebic dysentery in Chicago, where 1,050 persons were infected by contaminated water or food used in two hotels in that city, and which resulted in 70 deaths.

In rural towns which have no centralized water works, drinking water from rivers, brooks, springs, wells, etc., is readily contaminated by human excrement which is often deposited upon the surface of the ground. When these rural towns are visited by whole families, armies, explorers, etc., who may find it necessary to drink from such sources, these people are exposed to infection by *E. histolytica* and by other parasites prevalent to the region which have the same mechanism of penetration.

Handling of Food by Infected Individuals.—In modern cities which enjoy the best general hygienic conditions, particularly a pure source of water supply, adequate disposal of human excrement, etc., incidence of amebiasis may still be high because of direct transmission of the organism from person to person. Such people as food handlers, cooks, waiters in public and private service, nursemaids, wet nurses, etc., should show a certificate of health which should include examination for intestinal parasitism. Vigilance should be maintained by periodic examination of their feces. These individuals present a source of danger as disseminators of the disease. They may be carriers without symptoms or with slight symptoms, the principal eliminators of cysts. These individuals may pass unnoticed since they do not present symptoms of amebiasis. It is important to discover these "normal carriers" and submit them to adequate treatment before permitting them to return to their work, especially if they handle food. In this respect, the work of Schoenleber (1940) demonstrating the importance of this method of transmission of *E. histolytica* is very significant. His report concerns the island of Aruba, near the coast of Venezuela, to which both drinking water and food were sent from the United States. Amebiasis was prevalent on this island, reaching 25 per cent of the population with 36 cases per 1000 with amebic colitis. These infections could not have been due to contaminated food or water, since these came from a safe source. It was later verified that the only possible means of contamination was through some 33 per cent of the Chinese "food handlers" who were infected by *E. histolytica*.

Once the handlers were isolated and cured of their amebic infection the total percentage of infected population dropped by 50 per cent in one year and 92 per cent in three years; at the same time incidence of amebic colitis decreased by 86 per cent in the first year and 92 per cent in three years, all other conditions remaining the same.

Excreta of Flies and Other Insects.—This mode of transmission is important in those areas in which the insect is abundant and where food is unprotected from them. If a cyst is deposited by a fly on liquid or solid food, the infection is transferred to the digestive tract of man. This type of transmission occurs particularly in crowded areas such as military camps, recreation camps, or work camps. As an example, Craig reported an epidemic of amebic dysentery in El Paso, Texas, widespread among the troops stationed there. This epidemic was due in all probability to food contaminated by excreta of flies. Faust (1943) cited a similar epidemic in Kuling, China (1921), caused by a plague of flies coming from a near-by region where there was a high percentage of ameba carriers.

Not only excreta, but also the body of the insect, the wings, and especially the feet and proboscis of the fly can transport cysts mechanically from the sources of infection to food.

Use of Human Excreta as Manure.—The custom of utilizing human excreta as manure is a common practice by farmers of the Far East. Due measures should be taken to stop this method of fertilization, since the cysts of *E. histolytica* remain alive for several days in moist fecal media.

Lack of Personal Hygiene, Crowding in Prisons, Nurseries, Asylums, Orphanages, Etc.—In such crowded areas as concentration camps, prisons, military camps, orphanages, schools, nurseries, hospitals, asylums, etc., crowding constitutes a great danger of propagation of *E. histolytica.* This danger is in direct proportion to the lowering of standards of personal hygiene. There is maximum danger when one considers that transmission from person to person is one of the most effective means of propagating amebae.

Physical cleanliness, bathing, frequent washing of the hands, especially after visiting the toilet and before eating, should be advised.

Susceptible Animals.—The following animals have been found infected with *E. histolytica* in their natural environment:

Monkeys, according to the studies of Dobell (1931) and Hegner (1934); mice—Chiang (1925) and Andrews (1934) found this ameba in the intestines of mice; cats; dogs (Faust 1930) in the United States; young rats, guinea pigs, hamsters, hogs in China, according to Kessell (1928).

The following animals have been experimentally infected: kittens, dogs, monkeys, guinea pigs, rats, rabbits, and hogs. Of these, kittens and dogs are most susceptible and suitable for experimental infection.

Distribution

Geographically, *E. histolytica* may be called a cosmopolitan parasite. Every region which keeps statistics on intestinal parasitism has reported such organisms. It is found more frequently in tropical and subtropical regions than in the temperate zones, although it may be frequent in these if sanitary conditions are bad.

Age.—According to Faust (1933) children under 5 years of age are less often infected than are those older than 5, and adults. The ages 26 to 30 years show the highest incidence of infection, the percentage declining after the age of 35 years. Lesser infection of infants is probably due to less exposure to contagion, while the decline in incidence after the age of 35 is probably due to immunity acquired by previous infections.

Pathologic Anatomy of Intestinal Lesions

Intestinal lesions vary from slight superficial erosion of the intestinal mucosa to extensive and deep lesions and remote extraintestinal complications, with formation of abscess in the liver and other viscera as well as lesions and ulcerations in various tissues not connected to the digestive tract.

There are three characteristic aspects of amebic lesions of the intestines: (1) nodular thickening in the vertex of the folds; (2) ulcers with irregular contour and excavated borders; (3) ulcers connected with each other beneath normal mucosa, which is undermined by tubules containing gelatinous and necrotic material, which show trophozoites of *E. histolytica;* (4) in less severe cases of amebic dysentery and in carriers, lesions starting with necrosis of the superficial portions of the mucosa, extending laterally and into the depths of the tissue, producing rounded or oval ulcers with congested and thickened but not undermined borders.

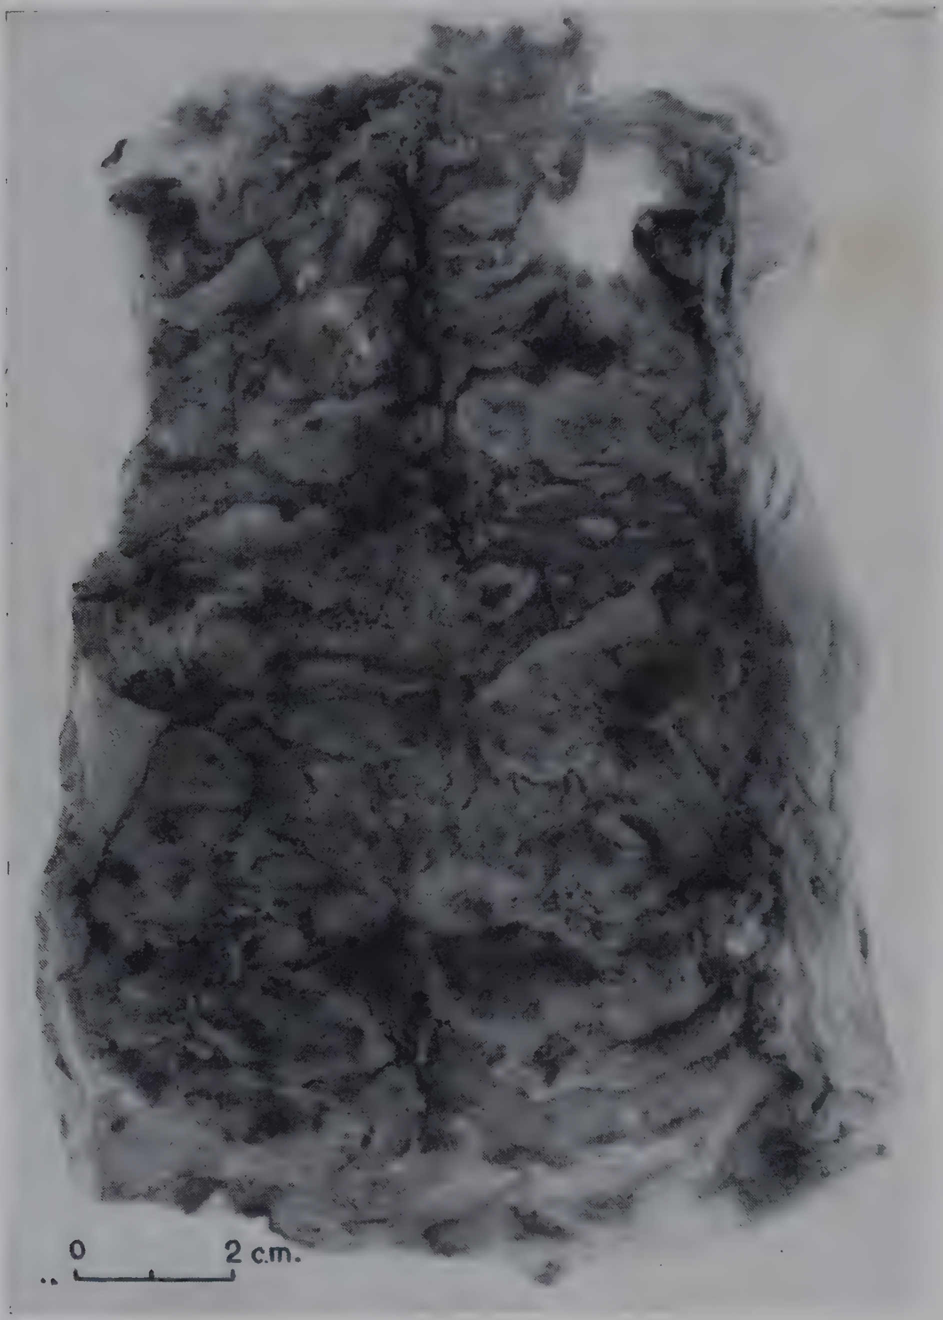

Fig. 454.—Intestinal amebiasis. Macroscopic appearance of the lesion. Note the extent, intensity, and severity of the lesions; ulcerations and necrosis. (Anatomical section No. 52, Finlay, Museum, Institute of Tropical Medicine, University of Havana.) (Original, Kourí.)

Hepatic Lesions

Invasion of the liver is known as amebic hepatitis. It is more than an inflammatory lesion; rather is it a necrotic affair, in multiple or small areas, round or oval, reddish gray, and of diffuse form. The foci coalesce, necrosis is complete, and an abscess is formed, with a cavity filled with necrotic tissue.

definite in contour, with a fibrous wall, generally localized in the right lobe. Occasionally the abscess may be multiple, smaller, and located anywhere in the liver parenchyma.

Other Lesions

The most frequent extraintestinal localization is the hepatic. Other localizations in the order of frequency are: **pulmonary,** primary abscess of the lung; secondary **pleuropulmonary** complications or those following upon rupture of an amebic hepatic abscess which opens into the pleural cavity or directly into the right pulmonary base by pre-established adhesions.

Amebic abscess of the **cerebrum** and amebic invasion of the **skin** are much less frequent than pulmonary amebiasis. Amebiasis of the **urinary and biliary systems** and **duodenal** localization of amebic lesions have also been reported by different authors.

Diagnosis

Sir Phillip Manson-Bahr has emphasized the need for the use of a proctoscope in the diagnosis of amebiasis. He advises the use of the Volkmann spoon with a long handle to obtain scrapings from the rectum. He states that it often succeeds when other methods fail. Manson-Bahr contends that ulcers in the rectum are quite unlike the appearances seen in textbooks: they are almost microscopic in size and protean in character. The acute stage looks like ulcerative colitis. Mucosa is friable and bleeds when swabbed with cotton wool. When scrapings are made from the surface, amebae are found in mosaic-like masses. In the acute stage it is possible to identify the tissue-invading trophozoites of *E. histolytica* moving between the cells, and in the more chronic stages to find cysts and precystic stages. Manson-Bahr does not believe that radiography as a means of diagnosis has much practical value.

Indirect Diagnosis by Means of the Complement Fixation Test

Complement fixation tests, according to Craig, give 90 per cent positive reactions in infections by *E. histolytica*. Bozicevich, Hoyem, and Walston[1] described a complement fixation test for amebiasis which eliminates most of the difficulty previously encountered in this test. Refer to pages 1831 and 1835.

Diagnosis by Means of Stains and Cultures

Staining methods for amebae are found on pages 1820 ff.

Collection of Specimens

The stool must be absolutely fresh. It should be examined within a few minutes after collection. If this basic rule of stool examination is not followed, the amebae disintegrate and sensitive microorganisms either die or are so outgrown by secondary microorganisms that they cannot be easily recovered.

The most suitable portion for examination is mucus. If no mucus is found, samples are taken from the surface and also from the inner portions of the specimen. Postcathartic stool must be examined when detecting carriers of *E. histolytica*. Such stools are collected after the patient has received 1 to 3 teaspoonfuls of sodium or magnesium sulphate in one-half glass of water before breakfast. The samples for examination are collected from the second bowel movement.

---

[1] Pub. Health Rep. **61**: 15, 1946; Lab. Digest **10**: Sept., 1946.

D'Antoni (1942) described a method which consists of a cleansing enema about 1 to 1½ hours before sigmoidoscopy. Then an enema with about 2 liters of tepid saline is given. The last part of the returned enema fluid is used for examination. Finally, aspiration samples are taken from the bowel walls through the sigmoidoscope. When a cathartic is given before the enemas, postcathartic stools may also be collected.

Another method for rectal examination is the swab of Hardy and Watt, which consists of a 10 to 12 cm. piece of rubber tubing of 0.18 cm. outside diameter, fitted over a regular throat swab. The throat swab is prepared from a wooden applicator with one end covered by rolling cotton tightly over it. Before use, the end of the applicator is inserted just inside the rubber tube. The end of the tube is lubricated and inserted for a distance of about 5 to 6 cm. into the rectum. The swab is then exposed by withdrawing the tube 2 or 3 cm. The swab is gently rotated, then withdrawn into the tube, and the whole is withdrawn from the patient. The tubing is discarded into a container and sterilized by boiling. The swab is used immediately to make permanent stained slides for examination for intestinal protozoa. Because of the lubricant, the fecal material on the swab cannot be used for saline and iodine-stained suspensions for direct examination.[1]

Endamoeba Coli (Grassi 1879)*

Endamoeba coli is frequently found in nature, lives in the lumen of the large intestine, and feeds on bacteria, food fragments, and protozoa and their cysts. It is somewhat similar to *E. histolytica.* It is usually described as being larger, from 20 to 40 microns.

The **ectoplasm** is much less hyaline and transparent than that of *E. histolytica* and is not well differentiated from the endoplasm. In the **endoplasm** there are a large number of vacuoles containing a variety of nutritional materials—bacteria, yeasts, cysts of other protozoa, etc. The **pseudopodia** are similar in shape to those of *E. histolytica* but frequently they are blunt and are not projected in any definite direction.

The **nucleus** is characterized by peripheral chromatin granules, coarser and more irregular than those of *E. histolytica.* They are more readily distinguishable, due to their refractile character. The karyosome, which is larger and less refractile, is excentrically located.

Precystic forms are about 20 microns and are similar to those of *E. histolytica,* from which they can be differentiated by nuclear characteristics.

The **cysts** are spherical or spheroidal, seldom irregular, and vary from 10 to 30 microns. The membrane which surrounds them presents a well-marked double contour. They are originally uninucleate; through successive division they form two, four, and eight nuclei, eight being considered typical of mature cysts. They contain a large amount of glycogen, which ac-counts for their dark brown color when tinged with iodine. They frequently lack **chromatoid bodies**; when present, these are needle-shaped and sometimes joined together, forming large or small clusters.

---

*After Beltrán, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, The C. V. Mosby Co.

[1] O. Felsenfeld, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine, The C. V. Mosby Co.

Life Cycle.—The life cycle is similar to that of *E. histolytica* except that this ameba, once established in the large intestine, lives within the lumen and feeds on bacteria and other material without invading the tissue, and is thus considered a commensal.

The **incidence** is high. It has been estimated that about 50 per cent of the entire population of the world harbors *E. coli.*

The mechanism of **transmission** is the same as that of *E. histolytica.*

This species is difficult to cultivate.

The parasite is not easily transmitted to animals.

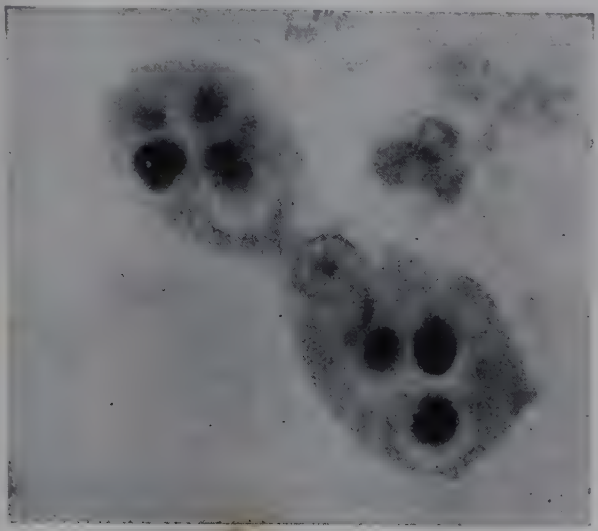

Fig. 455.—Trophozoite of *Endamoeba gingivalis,* stained with iron-hematoxylin. The nucleus is seen in the central portion, the remnants of ingested leukocytes in the food vacuoles. (×3,000.) (Original photomicrograph of E. Beltrán in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Differentiation Between Endamoeba Histolytica and Endamoeba Coli

The cysts and trophozoites of *E. histolytica* are usually smaller than those of *E. coli.* Size, alone, however, is not an absolute means of differentiation, since at times the sizes vary and cysts and trophozoites of *E. histolytica* are rather large.

In normal and vigorous living specimens, the most important means of identification is differentiation of the ectoplasm and endoplasm and the nature of the amebic movements.

The contents of the food vacuoles is very important: *E. histolytica* habitually shows only ingested erythrocytes, or completely lacks food vacuoles, whereas *E. coli* shows abundant food vacuoles containing a variety of material. In degenerated *E. histolytica* are seen vacuoles containing ingested bacteria, and there are some reported cases of *E. coli* containing ingested erythrocytes.

Cysts help differentiate the two species: the size, nature of the membrane, single in *E. histolytica,* double in *E. coli,* and the nature of the chromatoid bodies. Of greater importance is the structure of the nuclei which, as in the trophozoites, offers a more certain identification in stained slides. The number of nuclei is also a means of differentiation, but this is not always reliable. It appears that even though the number of supernucleate cysts of *E. coli* may be large, up to 20 per cent, this is of no particular importance in diagnosis, whereas the number of supernucleate cysts in *E. histolytica* which might cause serious confusion is barely 3 to 4 per cent.

Endamoeba Gingivalis (Gros 1849)

E. gingivalis, although not a true intestinal ameba, since it lives in the mouth, is mentioned here only because of its high incidence; it occurs in about 50 per cent of adults. Morphologically it resembles *E. histolytica* from which it differs in a few slight details of nuclear structure. The food vacuoles contain a variety of materials, such as bacteria and other microorganisms and the remnants of leukocytes.

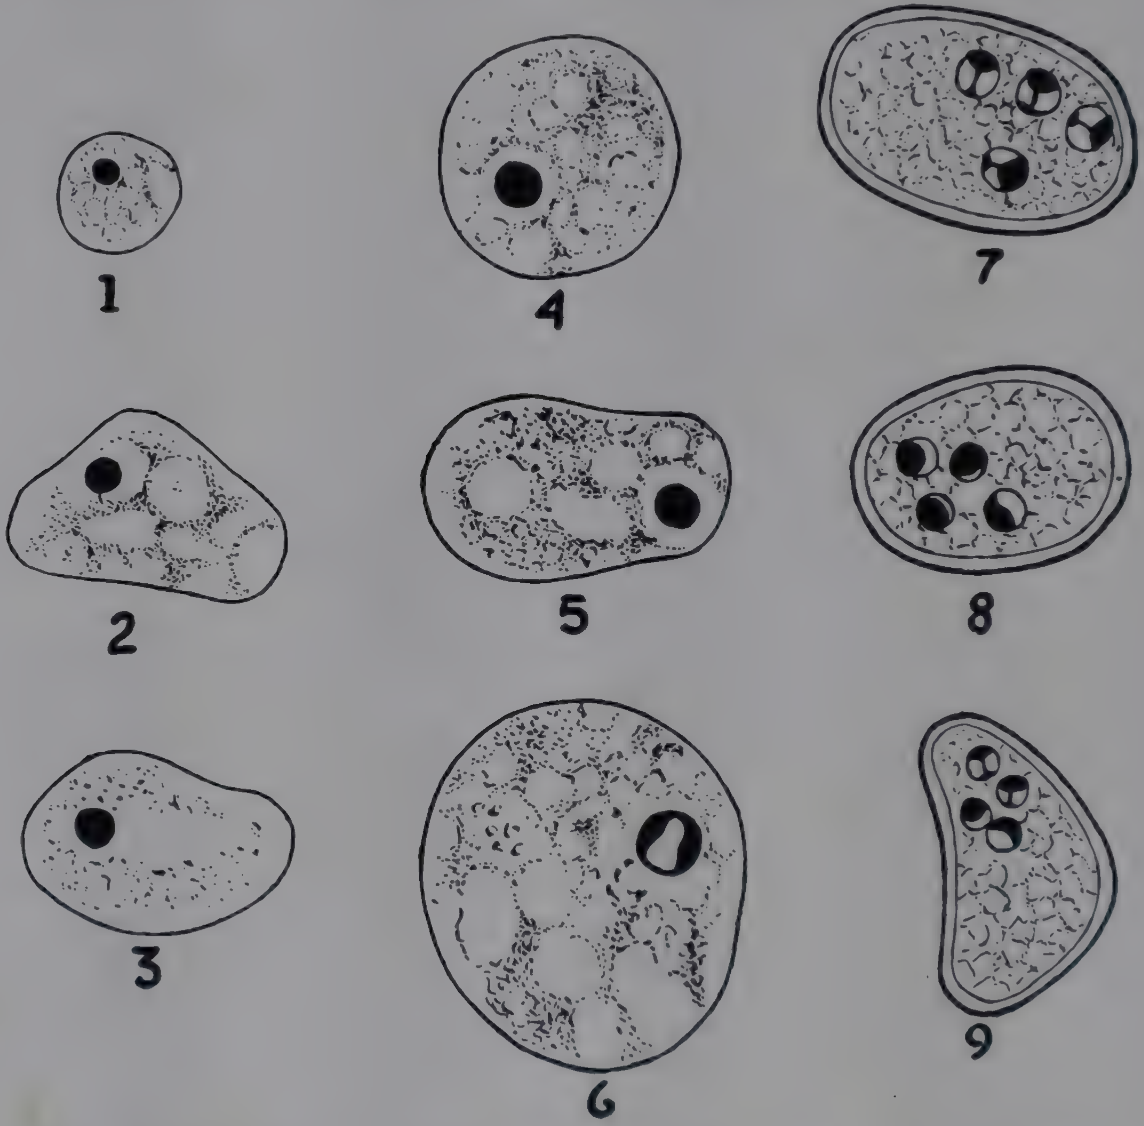

Fig. 456.—*Endolimax nana.* *1* to *6*, Trophozoites of different sizes, after Brumpt. *7* to *9*, Cysts. (After Wenyon and O'Connor in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

This species has no cystic form in its life cycle. It is assumed that transmission from person to person takes place by direct contact, especially through kissing.

Some authors consider it to be of etiological importance in pyorrhea alveolaris, although most contemporary authors do not accept this view.

Endolimax Nana (Weynon and O'Connor 1917)

Endolimax nana is a small ameba, varying from 6 to 12 microns. Differentiation between the ectoplasm and the endoplasm is variable; while perfectly marked in some, in others it is observed only with the greatest difficulty, or not at all. The karyosome is large, irregular, excentric, and without peripheral chromatin. The endoplasm contains abundant food vacuoles containing a variety of material. This fact, in conjunction with the characteristics of their movements, sluggish and in different directions, sometimes causes this species to be confused with small *E. coli*. The nucleus constitutes the most important diagnostic characteristic of the parasite.

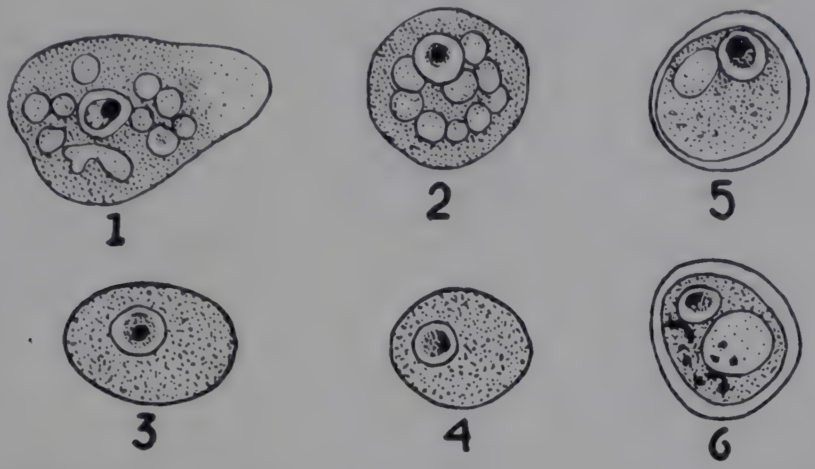

Fig. 457.—*Iodamoeba williamsi.* *1* and *2*, Trophozoites. *3* and *4*, Precystic forms. *5* and *6*, Mature cysts with glycogen vacuoles and a single nucleus. (Original figure of Brumpt in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

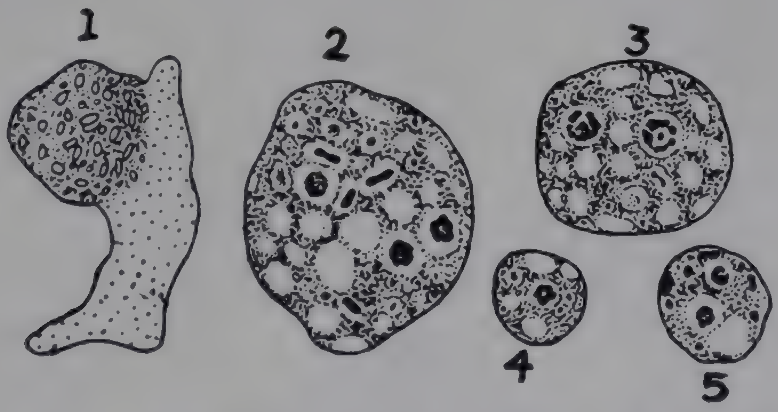

Fig. 458.—*Dientamoeba fragilis.* *1*, Living trophozoite. *2* to *5*, Trophozoites, fixed and stained. (After Jepps and Dobell in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Cysts are ovoid, less frequently spherical, with four nuclei in the mature state. The nuclei have the same characteristics as those found in the trophozoite, but they are barely visible in fresh specimens.

They measure approximately 8 to 10 microns along the longer axis. Young stages frequently show glycogen, distributed diffusely, or concentrated in vacuoles, which sometimes resemble those found in Iodamoeba. Dobell described the occasional presence of filaments which stain black with iron-hematoxylin.

The **life cycle** is similar to that of *E. coli.* It is a simple commensal.

Incidence is about 10 per cent; in Mexico, it is 8 to 32 per cent (Beltrán).

Endolimax nana disappears from the feces after oral administration of pentavalent arsenicals. It is frequently found parasitized by Sphaerita. It has been cultivated in the same media as that used for culture of *E. histolytica.*

Iodamoeba Williamsi (Prowazek 1911)

Synonym: *Iodamoeba bütschlii.*

Iodamoeba williamsi are small organisms, varying from 5 to 20 microns. The **nucleus** has a generally well-defined membrane enclosing a thick, spherical excentric karyosome surrounded by a mass of achromatic granules which, in the cyst, have a semilunar arrangement. The **ectoplasm** is not clearly differentiated from the endoplasm. The **endoplasm** contains numerous nutritional vacuoles with the most varied contents. Movement of the ameba is sluggish, frequently not directional.

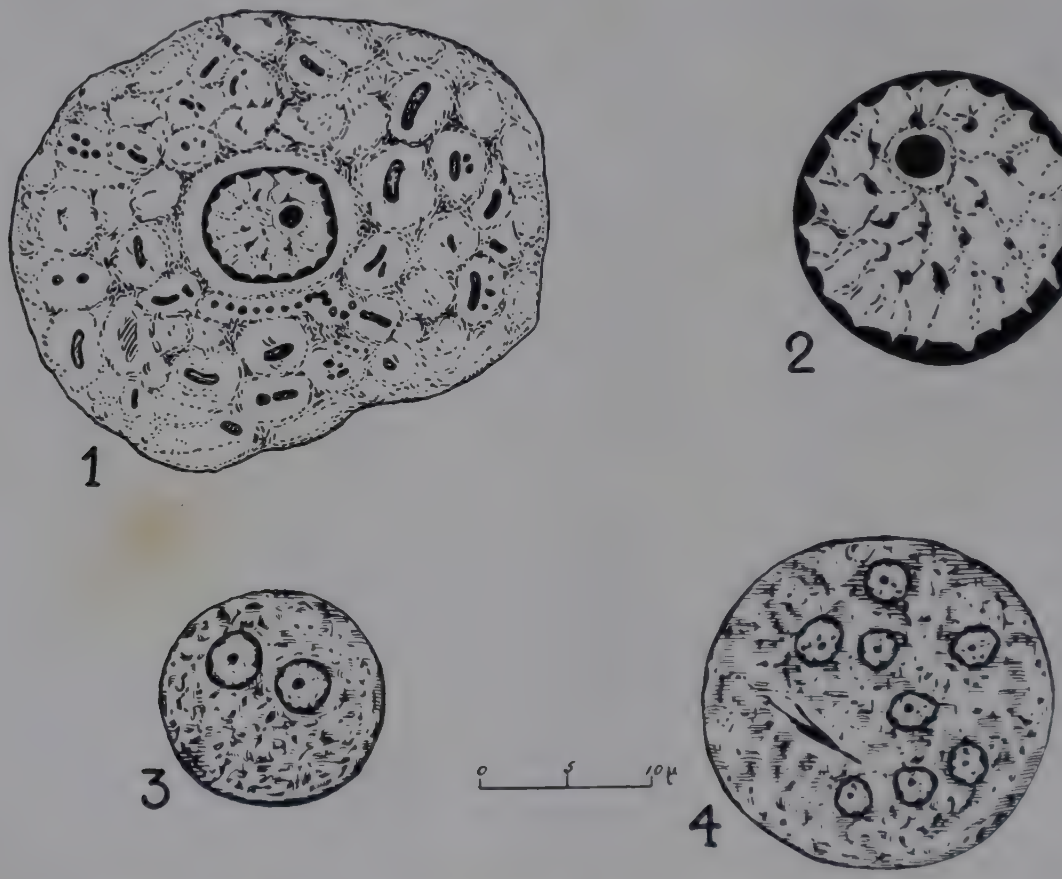

Fig. 459.—*Endamoeba coli.* Iron-hematoxylin stain. *1,* Trophozoite without hyaline ectoplasm, without erythrocytes in the endoplasm, but containing bacteria. Nucleus central with excentric karyosome and thicker than that of *E. histolytica. 2,* Nucleus greatly enlarged to show its characteristics. Thicker denticulated peripheral chromatin, excentric karyosome thicker than in *E. histolytica,* and small chromatic granules disposed in the spaces between the karyosome and the nuclear membrane. *3,* Small binucleate cyst. *4,* Normal size mature cyst with eight nuclei. (After Langeron and Rondeau du Noyer in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Cysts, 5 to 18 microns in diameter, are frequently uninucleate, sometimes binucleate. The nucleus is practically invisible in fresh specimens and barely detectable in preparations treated with iodine. The most notable characteristic is the great irregularity of outline. Another characteristic structure is the **glycogen vacuole** with its definitely limited outline, which occupies a large part of the cyst. In fresh specimens or in specimens stained with hematoxylin, it appears as a clear space, while in specimens stained with iodine it appears as a well-defined, mahogany-colored mass.

It has often been stated that the cysts are found in large numbers in infections due to this species, but that only rarely are the trophozoite forms

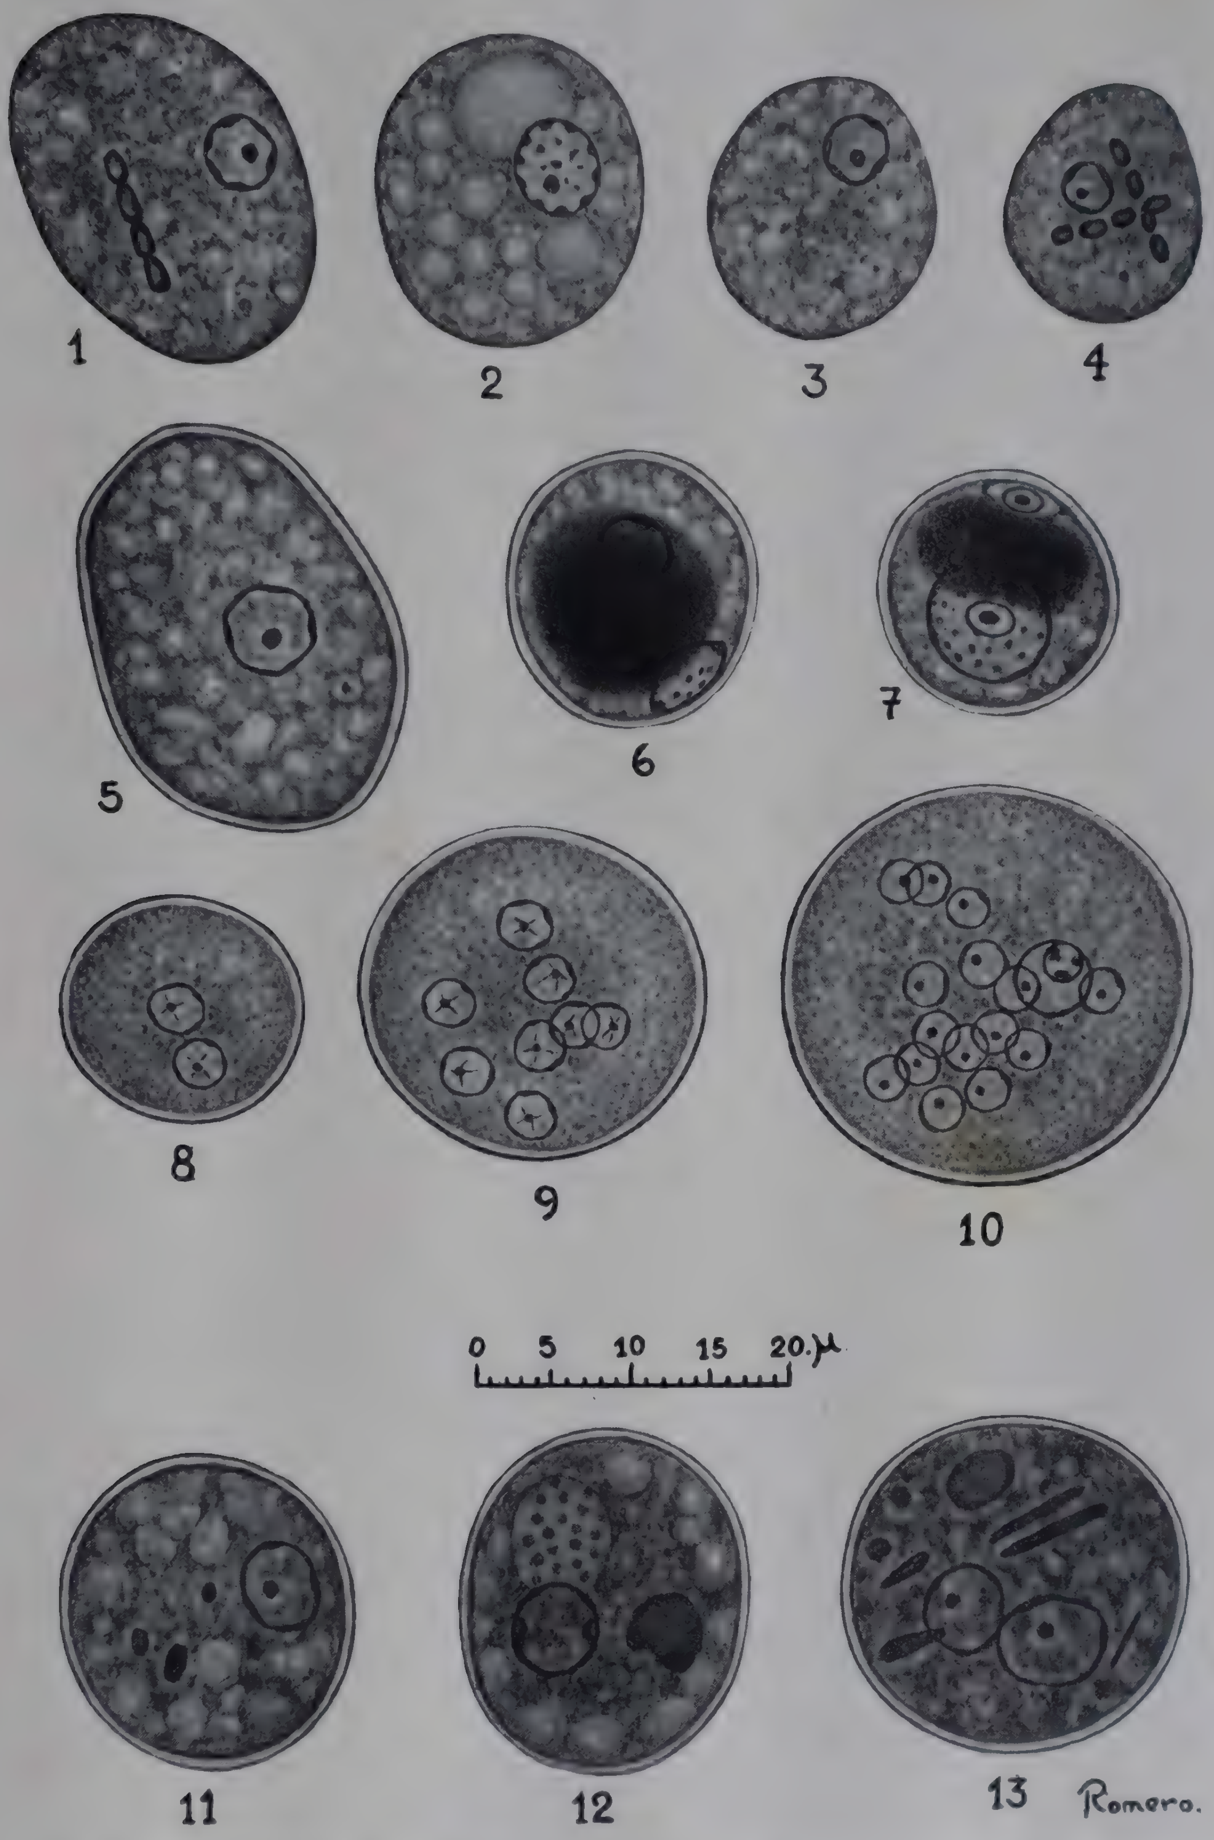

Fig. 460.—*Endamoeba coli.* Stained with Lugol solution. *1* to *4*, Trophozoites. Note bacteria in the cytoplasm of *1* and *4*, excentric karyosome in all four, and chromatic granules between the karyosome and the nuclear membrane in *2*. *5* to *7*, Precystic form and immature cysts with two nuclei and glycogen vacuole in *6* and *7*. *8*, Small immature binucleate cyst. *9*, Mature cyst with eight nuclei, normal size; and *10*, gigantic mature cyst with sixteen nuclei. *11* to *13*, Degenerative forms. (Original of Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical. Drawing by Romero, with 10 × ocular, oil immersion objective.)

found. Beltrán has found the vegetative forms sufficiently abundant in both liquid and formed stools.

The **life cycle** is similar to that of *Endolimax nana.* It is usually considered harmless to man. Incidence is about 7 to 31 per cent (Beltrán). It disappears after oral administration of pentavalent arsenicals. At times it is parasitized by Sphaerita. It can be cultivated in the same media as used for *E. histolytica.*

Dientamoeba Fragilis (Jepps and Dobell 1918)

These parasites are easily destroyed, for which reason the name *fragilis* has been given to this species. They disintegrate readily in fresh specimens and in Lugol preparations. They are very small, 4 to 12 microns. The ectoplasm and endoplasm are clearly differentiated. They project hyaline, transparent pseudopodia which resemble those of *E. histolytica,* although they are not formed with the same rapidity.

The **nucleus** is the most outstanding characteristic. There are often two nuclei, which are vesiculated, with delicate, nuclear membrane, without peripheral chromatin, with central karyosomes formed by dense chromatin granules. **Cysts** are unknown.

The **life cycle** differs from other parasitic amebae of man, with the exception of *E. gingivalis,* in that no cysts are known. Because of this, details of the transmission are still obscure.

Most authors agree that this is the least frequent of the amebae of man. Beltrán has found an incidence of 9 per cent.

Most authors agree that this organism is not pathogenic for man, but this point has not as yet been determined.

Degenerated forms are similar to those of *Blastocystis hominis,* with which it is sometimes confused.

These amebae die readily in an outside environment.

Dientamoeba fragilis has been cultivated in the same media as those used for *E. histolytica.* It is inoculable into cats. It disappears from the feces after ingestion of pentavalent arsenicals.

MASTIGOPHORA

Mastigophora are characterized by having, as organs of locomotion, long vibratory whiplike appendages, called **flagella,** from which is derived the name "flagellates," commonly applied to them.

Certain flagellates live in the blood and the tissues; these are called *hemoflagellates.* Another group lives in the intestine; these are called *intestinal flagellates.* Generally included in this group, although they are not, strictly speaking, intestinal inhabitants, are species found in the mouth and in the vagina.

Polymastiginia, one of the four orders into which this class is divided, is characterized by three to eight flagella, with the exception of the family Polymonadinae, which has more. In some species there is an undulating membrane. They have one or more nuclei of the vesicular type. Certain forms which feed upon solid particles have a cytostome for ingestion, while others lack such orifices and derive their nourishment by absorbing nutritive materials through the entire body surface. Some form both trophozites and cysts, while others have no cystic stage. There are a great number of species of both free-living and parasitic forms.

The Flagellates

There are five species of flagellates which can parasitize the intestines of human beings: (1) *Giardia lamblia* or *Giardia intestinalis;* (2) *Chilomastix mesnili;* (3) *Trichomonas hominis* or *Trichomonas intestinalis;* (4) *Embadomonas intestinalis;* and (5) *Enteromonas hominis.*

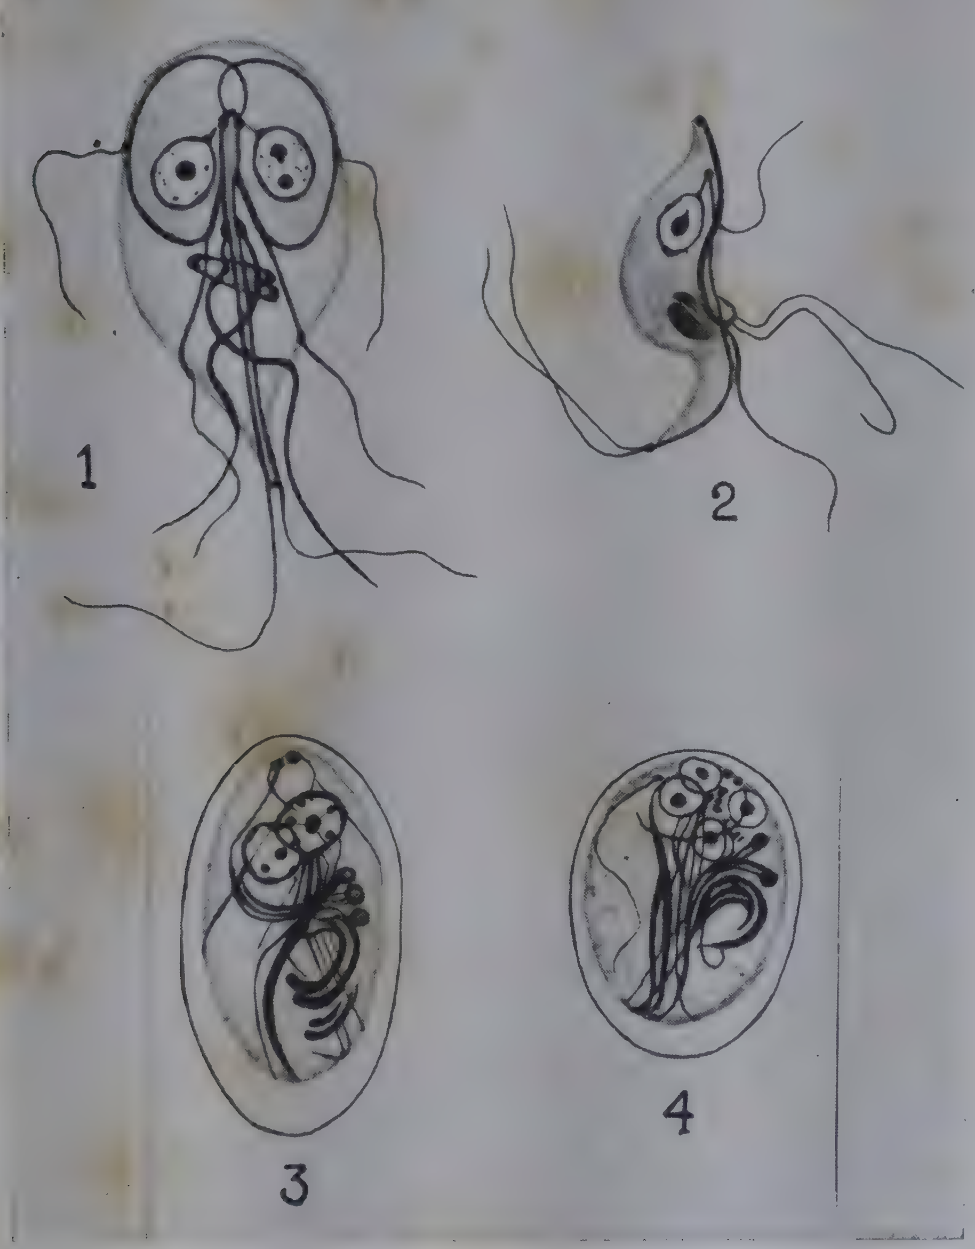

Fig. 461.—*Giardia lamblia.* *1,* Trophozoite or vegetative form, front view; *2* side view. *3,* Cystic form with two nuclei. *4,* Mature quadrinucleate cyst. (Adapted from Dobell and O'Connor by Kourí in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Family **OCTOMITIDAE**

Giardia Lamblia Stiles (1915)

The **trophozoites** or vegetative forms of *Giardia lamblia* are pyriform, bilaterally symmetrical flagellates with a broad anterior extremity and a pointed posterior end. From the suctorial disc arise six symmetrical flagella, three on each side. There is also a pair of flagella which arises from the pointed posterior end of the organism.

Cysts are ovoid with resistant covering, nonretractile, and with double contour. They have two to four paired nuclei, each with a fine central or excentric karyosome, round, and located in one of the poles. The cysts are 8 to 12 microns long and 7 to 10 microns wide.

Diagnosis is made by microscopic examination of stools when vegetative or trophozoite forms abound in the diarrheal liquid stools, and when cystic forms are found, often in large numbers, in pasty or hard stools. There are negative phases, which may last several days.

Examination of bile obtained by duodenal intubation enables one to find flagellates during these negative coprologic phases.

Staining with iron-hematoxylin is not necessary to distinguish the cysts of Giardia. Direct examination suffices, using Lugol or Gram stain.

Family **CHILOMASTIGIDAE**

The family Chilomastigidae includes flagellates with oval or pyriform bodies and four flagella, three of which are anterior and one posterior, directed backward, with the long axis parallel to the cytostome. Cysts are pyriform or lemon-shaped and are uninucleate.

Chilomastix Mesnili (Wenyon 1910) Alexeieff 1922

Chilomastix mesnili is a small flagellate with a pyriform trophozoite, 10 to 15 microns long and 5 to 7 microns wide. The broad anterior end shows three free flagella. The body is frequently twisted.

Cysts are small, 7.5 or 8.5 microns, pear-shaped, almost spherical, refractive, and colorless. They have a double-contoured wall, a nucleus, parts of their flagella, and a cytostome. As with Giardia, at times one sees gray or blue cysts of *C. mesnili* in microscopic preparations of stools stained with Lugol solution.

Some individuals are carriers of this parasite without symptoms. Others show functional changes in the digestive system.

Diagnosis.—Trophozoites are found in liquid and soft stools, while the precystic and cystic forms appear in semisolid and solid stools. Trophozoites are found primarily in recently passed stools.

It might be confusing for beginners to differentiate the trophozoites, but by using the oil immersion objective and examining only fresh preparations, this flagellate can be differentiated from *Trichomonas hominis*.

Culture.—*C. mesnili* can be cultivated in a medium composed of 1 part of inactivated human blood serum and 4 parts of Locke's solution containing a small amount of glucose.

Family **TRICHOMONADIDAE**

Trichomonadidae are flagellates characterized by a definite cystostome, a variable number of flagella, and an axostyle, a canelike structure, which arises from the blepharoplast and passes through the body to the posterior end, through which it usually protrudes. Only the human parasite, the genus Trichomonas, is of interest in human parasitology.

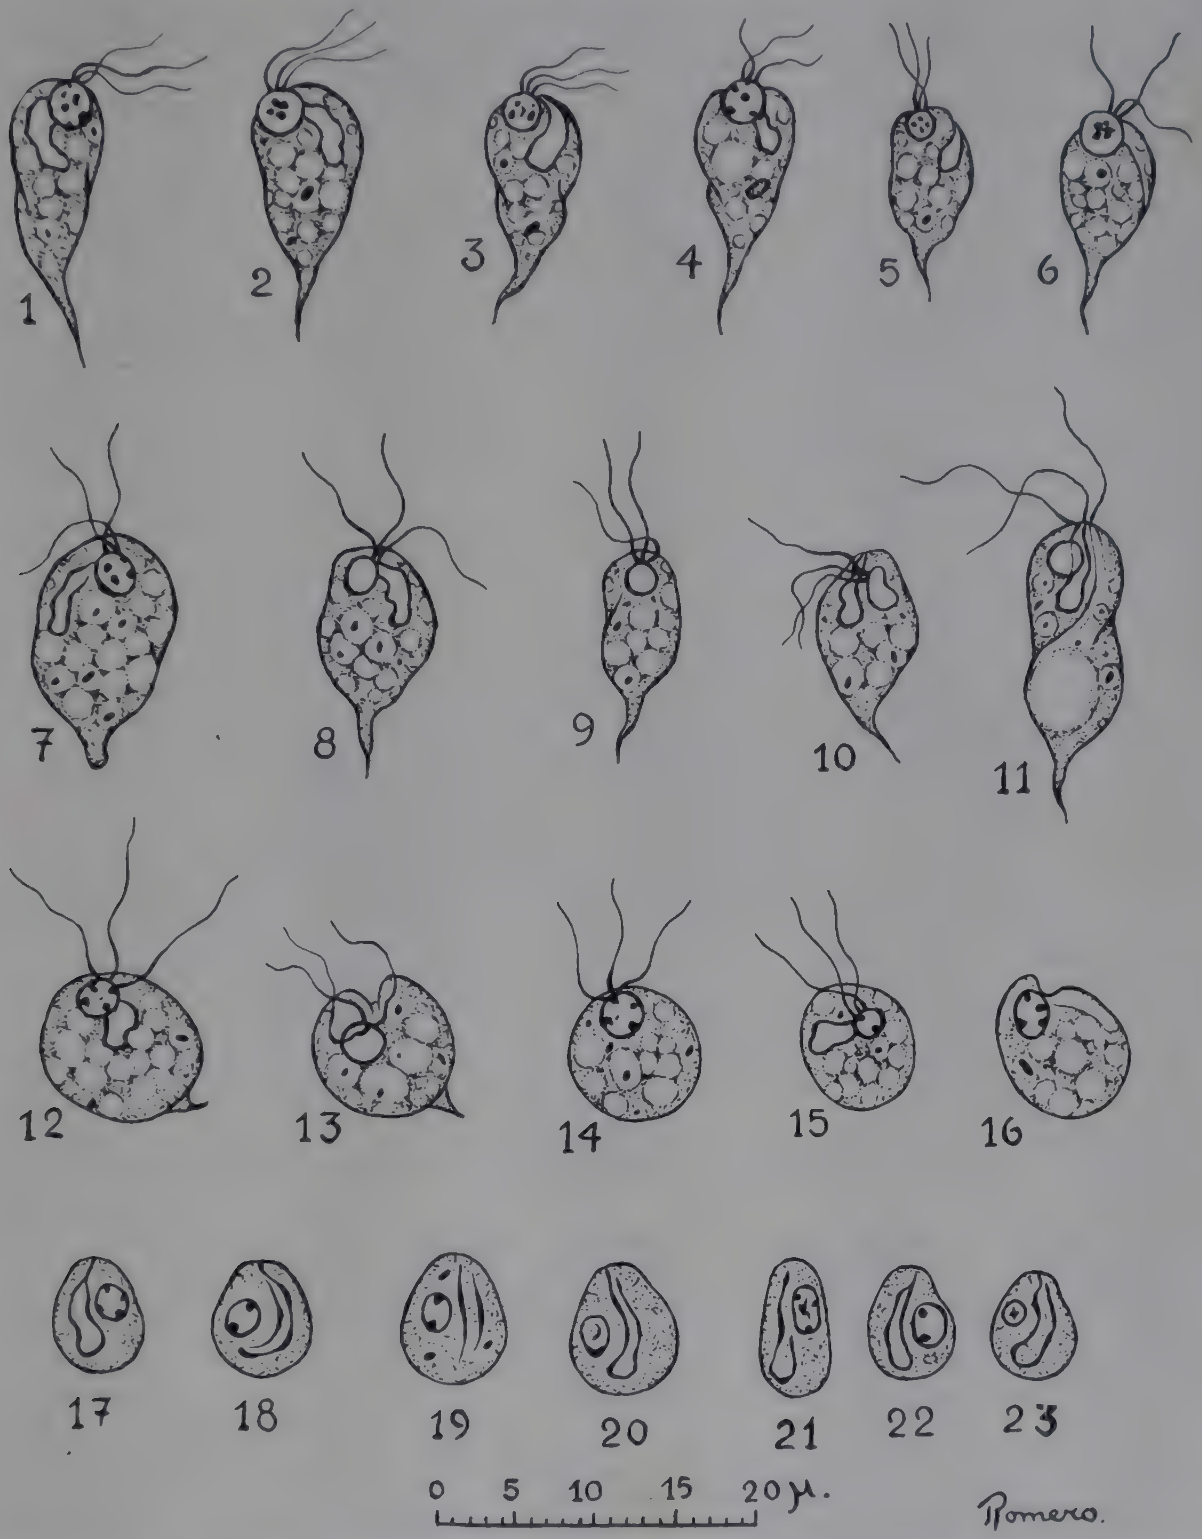

Fig. 462.—*Chilomastix mesnili.* *1* to *11*, Trophozoites. *12* to *16*, Rounded or spherical trophozoites in the process of dying. *17* to *23*, Cysts. Iron-hematoxylin stain. (After Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Trichomonas Hominis (Davaine 1860) Leuckart 1879

The *Trichomonas hominis* has no cysts. The trophozoites are almost round, 10 to 15 microns long, by 7 to 10 microns wide. They show three to five anterior flagella. In addition, there is a large and adherent posterior flagellum which forms the border of the undulating membrane as it passes down the body of the organism toward the posterior end, where it is often continued beyond the membrane.

The Trichomonades are usually considered by most authors as inoffensive parasites of the digestive canal. They are found in great numbers in the alkaline diarrheas, although they may be found as well in acid diarrheas. They can produce a chronic catarrhal disorder of the intestines.

Diagnosis is made by microscopic examination of diarrheal stools or of liquid stools after a saline purgative.

Trichomonas Vaginalis Donné 1837

Morphologically, the *T. vaginalis* and the *T. hominis* are identical except for variations which appear to be dependent upon certain conditions of the medium in which these species develop—the intestines for one and the vagina for the other. *T. vaginalis* can be seen in the abnormal secretions of the vagina, in the urine of both men and women, and also in prostatic secretions.

In **cultures,** *T. vaginalis* has the same morphology as the living form seen in the vagina. Cystic forms are also found in cultures.

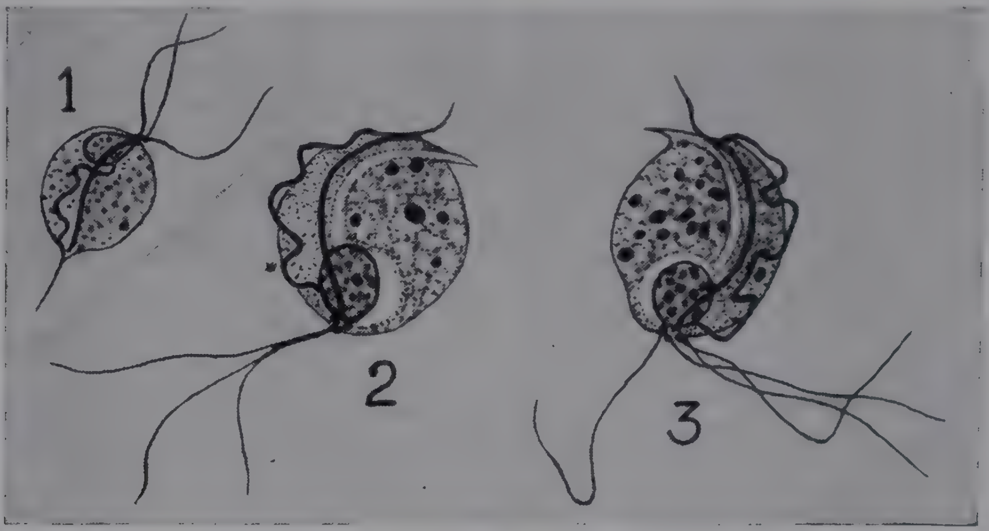

Fig. 463.—*Trichomonas hominis.* *1,* Small specimen with three anterior flagella. *2,* Large specimen with three anterior flagella. *3,* Specimen with four anterior flagella. (After Dobell and O'Connor in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

The method of **transmission** is not definitely known. It is frequently found associated with vaginitis, never in the normal vagina, so that most gynecologists consider it the causative agent of this type of vaginitis; there is much controversy on this point. It is believed that males are the carriers of *T. vaginalis* and transport this organism to women.

Diagnosis is made from direct microscopic examination, by concentration with centrifugation in salt solution, and by cultures of the vaginal secretions.

Since one of the first requirements for the establishment of a base line of efficacy of drugs and other measures in the therapy of *T. vaginalis* is a reliable criterion for cure, it is necessary to evaluate all different methods used in the diagnosis of trichomoniasis.

Kean and Day[1] have outlined the following methods for establishing this criterion of cure:

Methods.—

Patients are instructed not to douche for 24 to 48 hours prior to coming for an examination. Vaginal secretion is obtained by introducing a vaginal speculum and swabbing the mucosa with two cotton swabs. Most of the material is derived from the posterior fornix although some secretions from other portions of the vagina are also utilized.

---

[1] Am. J. Obst. & Gynec. 68: 1510, 1954.

I. **Hanging Drop.**—

Introduce one swab immediately into a test tube containing 0.1 c.c. of physiologic saline at a temperature of 37° C., and mix the contents thoroughly.

Prepare hanging drops using the depressed slides in the usual manner and examine immediately. Study 3 hanging drops for a total of 10 minutes before rendering a negative report.

II. **Cultures.**—

Introduce the second cotton applicator into a test tube containing a culture medium which has been left in an incubator for 2 hours at 37° C. Rotate the swab in the medium and drop it into the test tube and leave at room temperature for 2 to 3 hours.

Place the tube in an incubator for 48 hours.

Subculture.

Examine the original cultures twice: first after 48 hours of incubation when subcultures are made, and again after 96 hours.

Make transfers by withdrawing 2 c.c. of suspension with a sterile pipette.

Use the simplified trypticase serum medium described by Kupferberg and associates[2] to which has been added penicillin and streptomycin:

Maltose	1 gm.
Bacto-agar	1 gm.
Distilled water	400 c.c.

Heat in an autoclave at 10 pounds pressure for 10 minutes to dissolve the agar, and filter.

Add	Trypticase	20 gm.
	Cysteine HCl	1.5 gm.
	0.5% Methylene blue	0.48 c.c.
	Distilled water to	600 c.c.

Adjust the reaction to pH 6.0 with 5 N sodium hydroxide. Dilute to volume (1,000 c.c.) with distilled water.

Tube in 8 c.c. amounts.

Autoclave at 15 pounds pressure for 15 minutes and cool to room temperature.

Add 0.5 c.c. sterile serum (100%) which has been adjusted to pH 6.0.

To each 8.5 c.c. tube add 2,500 units of crystalline penicillin G in 0.5 c.c. of distilled water

and 10 mg. of streptomycin in 1 c.c. of distilled water.

The final amount in each tube is 10 c.c.

No subculturing is necessary. If the seeded tube is examined after 48 hours and is negative, re-examine after 96 hours' incubation; in this way, all positives will be detected.

III. **Papanicolaou Technic.**—

Prepare vaginal and cervical smears taken routinely for the detection of cancer, and read for the presence or absence of *T. vaginalis* as follows:

Vaginal Smears:

The vaginal secretion is aspirated from the posterior fornix of the vagina by means of a glass pipette (6 inches long with a strong bulb).

Expel the secretion onto a dry glass slide and spread with the end of the pipette.

Immerse the slide immediately in fixative: equal parts of ether and 95% alcohol.

Cervical Smears:

Insert speculum into the vagina without the use of a lubricant.

Take smears with cotton applicator from the surface of the cervix, and spread this material on a slide.

Fix immediately in ether-alcohol, equal parts.

Leave the vaginal and cervical smears in the fixative for at least 1 hour, then stain by the Papanicolaou method.

---

[2] Proc. Soc. Exper. Biol. & Med. 67: 304, 1948.

Kean and Day found that the Papanicolaou method is the least satisfactory for the diagnosis of *T. vaginalis.* It has the only advantages of permanence of material and opportunity for delayed reading. An inclusion of diagnosis of trichomoniasis is part of another routine, namely, cancer diagnosis, but no additional expense or effort is involved. It also correlates infection with cytologic changes produced by parasites.

Summarizing, these technics for the diagnosis of vaginal trichomoniasis indicate that a simple culture method is superior to the hanging drop and the Papanicolaou smears. The Papanicolaou method is as effective as the hanging drop, but requires too much technical skill for routine diagnosis of *T. vaginalis.* The prevalence of the parasite as determined by the culture method on a single examination was 6.5 per cent in asymptomatic ''cancer survey'' patients, 15 per cent in obstetric patients, and 26 per cent in gynecologic patients.

Family **CERCOMONADIDAE**

The family Cercomonadidae includes flagellates which have one or more anterior flagella and one posterior flagellum attached to the superficial part of the body, in a longitudinal direction.

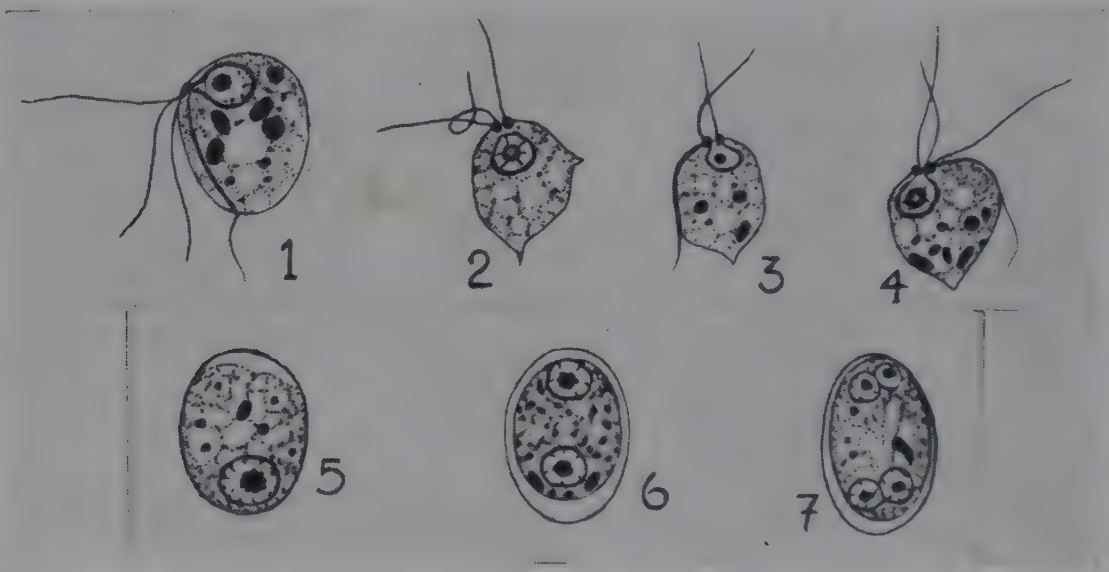

Fig. 464.—*Enteromonas hominis.* *1,* Typical form of trophozoite with four flagella, three free and one recurrent. *2,* The recurrent flagellum is not clearly visible. *3,* Only the two anterior flagella are visible. *4,* Typical form showing two blepharoplasts. *5* to *7,* Cysts uninucleate, binucleate, and quadrinucleate (mature), respectively. (In Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Enteromonas Hominis da Fonseca 1915

These flagellates are very small, pear-shaped, round, or oval, flat on one side, 4 to 10 microns long, and 3 to 6 microns wide. They have a rather voluminous anterior nucleus with dense karyosomes. There are four flagella, three of which are free; the fourth, sometimes not seen, is directed backward and adherent to the body of the parasite and terminates as a free flagellum on the posterior end of the parasite. Cysts are oval, have double-contoured walls, and are 6 to 8 microns long and half as wide. They show one or two nuclei when the cysts are immature, with four in the fully developed cysts. Two of these nuclei are in each pole. They have distinct karyosomes. Staining with iron-hematoxylin is necessary to make out the structural details.

Family EMBADOMONADIDAE

The species in the family Embadomonadidae are oval, have one nucleus anteriorly situated, a cytostome, two blepharoplasts, one anterior flagellum, and one posterior flagellum both rising from the blepharoplast in contact with the nuclear membrane. The posterior flagellum is usually contained within the cytostome before it becomes free.

Embadomonas Intestinalis Wenyon and O'Connor 1917

The *Embadomonas intestinalis* is a very small flagellate, about 4 to 9 microns long and 3 to 4 microns wide. It is usually round, although at times it is pyriform with a pointed posterior extremity. It has two anterior flagella, one of which is larger than the other, directed posteriorly and adherent to the cytostome. The other is free. In the anterior portion there is a cytostome and a rather large nucleus with a thick karyosome. The cysts are very small, 4 to 7 microns by 3 to 4 microns, pyriform.

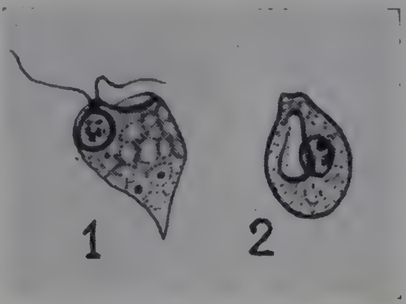

Fig. 465.—*Embadomonas intestinalis.* *1*, Trophozoite; *2*, cyst. (Adapted by Kourí from Dobell and O'Connor, in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Flagellates of the Blood and Human Tissues

Order PROTOMONADIDA

Family Trypanosomidae

In the family Trypanosomidae, genus Trypanosoma, there are three species: *T. gambiense, T. rhodesiense,* and *T. cruzi.*

In the genus Leishmania, there are three species: *L. donovani, L. tropica,* and *L. braziliensis.*

Trypanosomes cause human trypanosomiasis. Two important species, *T. gambiense* and *T. rhodesiense,* are specific agents of African sleeping sickness or trypanosomiasis africana. The first is found in West Africa, the second in East Africa.

T. cruzi is the agent of trypanosomiasis americana or Chagas' disease.

Species of the genus Leishmania are the cause of human leishmaniasis, which occurs in three forms. (1) Visceral leishmaniasis affects the spleen; it is called "kala azar." It is endemic in tropical Asia. Infantile kala azar, or infantile splenic leishmaniasis, is found along the Mediterranean littoral. Both types are caused by *L. donovani.* (2) The cutaneous forms of leishmaniasis are found in the Near East, are known there as "oriental boil," and are caused by *L. tropica;* in America (3), it is known as "leishmaniasis americana." This is characterized by mucocutaneous ulcerations affecting especially the mouth, the nose, and pharynx.

Trypanosomes

Trypanosomes are hemoflagellates. They show a nucleus and a blepharoplast, from which proceeds a flagellum with an undulating membrane. The flagellum projects out from the forward end.

These trypanosomes are found in the blood stream of infected animals. They are transmitted through the intermediation of other animals, such as blood-sucking worms, insects, and flies. There are certain forms found at times among trypanosomes, known as Crithidia, where the blepharoplast lies ahead of, instead of behind, the nucleus. It is an insect form found in the tsetse fly, and a normal inhabitant or parasite of the mosquito.

Division of trypanosomes in mammalian animals takes place in the blood stream. This is characterized by division of the nucleus. The cytoplasmic body swells and the blepharoplast divides.

In certain types of trypanosome infections, it is very difficult to find these parasites in the blood. Especially is this the case with the nonpathogenic beef trypanosomes called the *T. theileri* and the sheep trypanosome called the *T. melophagium*. The latter form can be seen in the circulation of the so-called "sheep louse," which is found on most sheep. It is a curious fact, however, that while these sheep lice will apparently communicate this *T. melophagium* to sheep, it is very difficult to find them in their blood. Various organs of the body will show trypanosomes, the lymph vessel system, the spleen, liver, kidneys, bone marrow, and brain. The brain particularly is an object of investigation in seeking for the trypanosomes of African sleeping sickness of man. The skin and mucosa show changes.

Cultivation Methods

Successful cultivation of *T. gambiense* and *T. rhodesiense* is possible but often is a failure. It is not necessary to utilize it unless blood spread and juice examinations fail.

It is in Chagas' disease that cultivation methods offer most brilliant promise of success.

It is likewise true that animal inoculation affords a better chance of success in Chagas' disease than in East or West African sleeping sickness. Even though no *T. cruzi* are found in the blood examination, inoculation of guinea pigs will often bring success in proving the existence of Chagas' disease. The method is to inoculate from 0.5 to 1.0 c.c. of blood from the patient intraperitoneally into several pigs.

The various methods advocated by different workers for cultivating trypanosomes are as follows:

Artificial Culture Methods

Cultivation of certain trypanosomes upon artificial culture media is very successful. We have not been successful in cultivating the trypanosome of African sleeping sickness. It must be noted that, in cultures, a great many of the Crithidia forms are seen. The best temperature for cultivation is a high room temperature. The ordinary incubator temperature of 37° C. is too high for their growth.

The culture media are as follows:

1. **Blood Broth** was originated by Miyajima in 1907. To 10 parts of ordinary weak alkaline, weak acid, or neutral broth, add 2 to 10 parts of defibrinated blood. This blood can come from the infected animal or from a noninfected animal.

2. **Blood-Corpuscle-Free Bouillon**, by Noller's method, 1913. Pipette off the clear part of the above-noted blood bouillon and use this.

3. **Fluid Medium of Row**, 1912—one part of sterile, defibrinated rabbit blood to 8 or 10 parts of sterile water. After hemolysis has taken place, to every 100 c.c., add 0.8 gram of sterilized sodium chloride.

PLATE XLVII.

4. **Hypotonic Rabbit Blood,** by Ponsel, 1923. One part of sterile fluid defibrinated rabbit blood is mixed with one part redistilled water. Place in test tubes and inactivate for half hour at 60° C.

5. **Medium of Wenyon and Noguchi,** 1921: To 270 c.c. of 0.85% physiologic salt solution (reaction pH 7.6) add 30 c.c. of ordinary 2% nutrient agar. After mixing, place 10 c.c. in test tube. Autoclave at 120° C. and after cooling to 50° C. add 20 drops of fresh rabbit blood from the disinfected ear of the rabbit to each test tube. Mix without shaking and incubate at 37° C. for 24 hours to determine sterility. Then use the tubes.

6. A solid culture medium which is much used is the blood agar medium of Novy and McNeal, 1903. This is the so-called **N. N. Agar.** Infuse 125 grams of chopped-up beef in 1,000 c.c. of distilled water, strain, add agar 20 grams, peptone 20 grams, sodium chloride 5 grams, normal sodium carbonate solution, 10 c.c. The agar is placed in tubes and mixed with blood at 55° C. The blood volume should be about one-fifth of the agar volume.

7. **Grape Sugar Blood Agar Medium of Hagestermeister:** Hagestermeister used the N. N. Medium with 0.5% sodium chloride and 1% peptone, weakly alkaline, with 2% grape sugar added to this. He used defibrinated horse blood.

8. **Blood Agar Medium of Novy, McNeal, and Nicolle (N. N. N. Medium).** This is especially designed for Leishmania cultivation but it is also good for trypanosomes. Nicolle, in 1908, described it as follows: Agar 14 grams, salt 6 grams, distilled water 900 c.c.

It is made just like N. N. Agar. Add rabbit blood when the agar has cooled to 52° C., usually one-fifth as much blood as agar.

9. **Kelser's Medium.** This medium has been described by Kelser and is a modification of that previously described by Bonacci. Prepare it as follows:

Bacto-peptone	12.5 gm.
Sodium chloride	3.5 gm.
Agar (Bacto-agar, granular)	5.0 gm.
Bacto-beef, dehydrated	25.0 gm.
Distilled water	500.0 c.c.

Add the beef to the 500 c.c. of water and place over a water bath at 55° C. for one hour. Now add the peptone and the sodium chloride. Bring the mixture to the boiling point and hold it there for five minutes. Shake and filter through cotton. Neutralize to litmus by using N/1 sodium hydroxide.

Make it 1 per cent agar. After the agar has dissolved, place in test tubes or Erlenmeyer flasks, sterilize at 12 pounds in the autoclave, and it is ready for use. Use by melting in water bath, keeping the temperature at 50° C. Add to each tube 0.25 c.c. of a sterile 1 per cent dextrose solution and 0.25 c.c. of fresh, sterile, defibrinated guinea pig blood.

Slant the tubes so as to have a deep butt and a short slant. If such media are kept on hand and become dried out, add a little of the dextrose broth solution when ready for use. This dextrose broth solution to overcome loss of water of condensation is made by adding one part of sterile 1 per cent dextrose solution to ten parts of peptone broth prepared as described above. According to Kelser's technic, maintain a stock culture of *T. cruzi* by covering cotton plugs with rubber cap to prevent evaporation.

Inoculate medium by means of sterile glass capillary pipettes closed with cotton air filters, equipped with rubber nipples. Transfer cultures every ten days.

Trypanosoma Gambiense—Trypanosoma Rhodesiense African Sleeping Sickness*

Sleeping sickness or African trypanosomiasis is often designated as "African sleeping sickness," to distinguish it from Economo's lethargic encephalitis which also formerly was called "sleeping sickness." It is a disease caused by trypanosomes, and is characterized by chronic fever, more or less intensive glandular enlargement, and, in many cases, a cerebral stage with fatal outcome.

---

*After O. Felsenfeld in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine. 1948. The C. V. Mosby Co.

Geographical Distribution.—The geography of sleeping sickness follows the African belt of the tsetse flies (Glossina), mainly of *Glossina palpalis, G. tachinoides, G. morsitans,* and *G. swynnertoni,* the most frequent insect vectors of the disease. The northern boundary of sleeping sickness approximately follows a line drawn from St. Louis to the Lake Chad, then along the Shari and the southern part of Anglo-Egyptian Sudan. Abyssinia and Italian Somaliland are free from it. Southwest Africa and the Zambezi River, with the exception of two foci, are the southern boundaries, while in West Africa, along the Gulf of Guinea, in the Congo, in Angola, Sudan, Uganda, and Kenya, the classic type ascribed to *Trypanosoma gambiense* prevails, and the Rhodesian type ascribed to *T. rhodesiense* is found in Tanganyika, Mozambique, Nyasaland, and Rhodesia.

Etiology.—Sleeping sickness is caused by trypanosomes. These organisms are similar to *Trypanosoma brucei,* the agent of the animal disease "nagana." Two types of trypanosomes have been described as the cause of sleeping sickness: *T. gambiense* and *T. rhodesiense.* It is not possible to differentiate between these types morphologically or by animal experiments, except by production of keratitis in goats by *T. rhodesiense.* It was formerly believed that the forms of *T. rhodesiense* in the blood of injected mice or rats more frequently have their nuclei located more posteriorly than do forms of *T. gambiense* under similar experimental conditions. Some authors consider *T. rhodesiense* a human-adapted variant of *T. brucei.* Others ascribe the difference in clinical types of sleeping sickness to the adaptation of the trypanosomes to various species of Glossina.

The organisms appear irregularly in the blood but are usually present during the periods of fever. They are most easily found in enlarged lymph glands, later occurring in body fluids, principally the cerebrospinal fluid. Aside from elongated, slender trypanosomes, rather short, broad forms with smaller flagella and posterior nuclei may be observed. After the organisms enter the tsetse fly by feeding on a patient who harbors trypanosomes, they multiply in the midgut, later in the hindgut, of the Glossina. After 12 to 36 days, depending on the temperature, humidity, and other factors, the infective metacyclic forms reach the salivary glands of the fly and may be injected into a susceptible host during a blood meal.

Trypanosomes of sleeping sickness are difficult to cultivate. They are, however, easily transferred to laboratory animals, chiefly to mice, rats, and guinea pigs.

Vector and Animal Reservoirs.—The trypanosomes are usually transferred by tsetse flies after they have gone through a cyclic evolution in these insects. There is, however, a possibility of purely mechanical transfer by Glossinae and other biting insects from person to person under certain circumstances.

The principal species of Glossina which transfer sleeping sickness are *G. palpalis* and *G. tachinoides* for *T. gambiense,* and *G. morsitans* and *G. swynnertoni* for *T. rhodesiense.*

Most species of Glossina require shade and proximity of water. Glossinae which live in southwest Arabia are not infected with trypanosomes. The organisms are not transferred to the larvae of the flies. No repellent effective against tsetse flies is known.

Resistance.—There is no racial predisposition to sleeping sickness. Neither does the disease prefer people of one sex or of a certain age group. Trypanosomes are not, as a rule, transferred from mother to fetus, but some exceptions have been described.

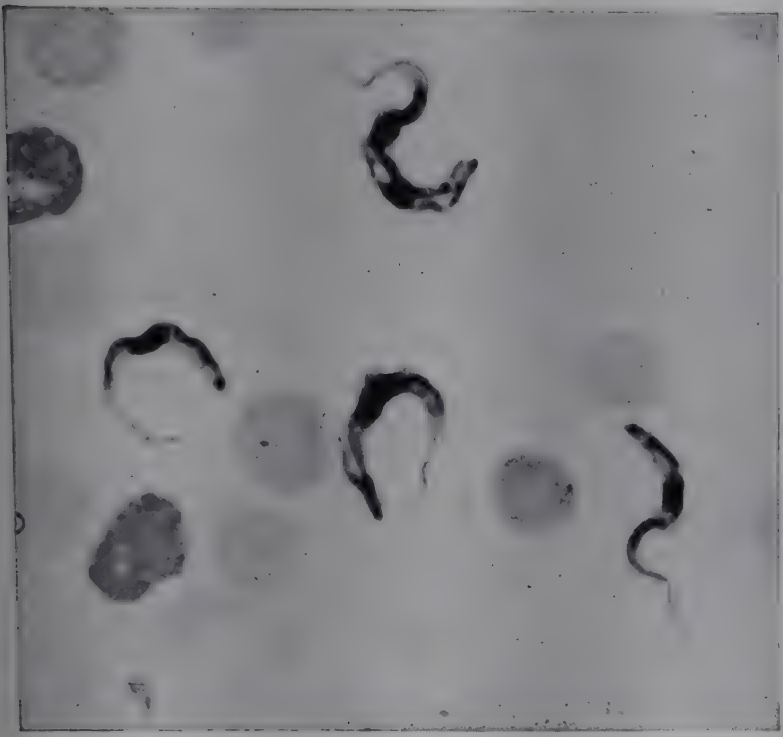

Fig. 466.

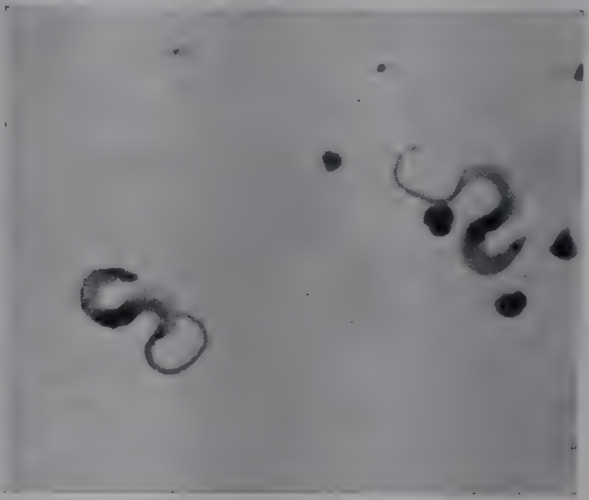

Fig. 467.

Fig. 466.—*Trypanosoma gambiense* in peripheral blood. (O. Felsenfeld, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Fig. 467.—*Trypanosoma rhodesiense* in peripheral blood. (O. Felsenfeld, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Laboratory Diagnosis.—The number of parasites in the peripheral blood undergoes considerable fluctuation. The parasites are not easily recovered from the cerebrospinal fluid in every case. Gland puncture is the method of choice for recovering the parasites if there is enlargement of the lymphatic glands.

(A) THE PERIPHERAL BLOOD

Cultivation of the trypanosomes is not as yet practical for diagnostic purposes.

For animal inoculation, guinea pigs are used most often. Inject 5 or 10 c.c. of blood intraperitoneally.

For examination of the blood for trypanosomes, use the thick drop method (pages 650 ff.), or centrifuge citrated blood and examine the sediment.

Both stained and unstained preparations are examined. The Giemsa method and its modification by Field are the recommended methods of staining.

(B) THE LYMPH GLANDS

Puncture the lymph glands after massage, using a relatively strong needle and a 10 or 20 c.c. syringe.

Prepare spreads and stain by the Giemsa or Field method.

Strict asepsis is necessary for this operation, but no anesthesia is needed. The lateral cervical glands are easily accessible, particularly when they are enlarged. Massage of the glands during puncture enhances the operation.

Examine both stained and unstained spreads.

(C) CEREBROSPINAL FLUID

Centrifuge the spinal fluid and observe the sediment microscopically.

The sediment can be used for injection into guinea pigs, or for cultivation.

Trypanosomes are often recovered from the fluid gathered through suboccipital puncture and also from sternal puncture material.

(D) SEROLOGIC REACTIONS

The so-called ''adhesion reaction'' is sometimes used for diagnostic purposes. This consists of the adhesion of human red blood cells to trypanosomes, when trypanosomes are mixed with immune serum, complement, and red blood cells. In the presence of a nonspecific serum, no such clumping or adhesions occur. Serologic reactions, however, have not as yet attained an important place in the diagnosis of sleeping sickness.

(E) MISCELLANEOUS

The **blood picture** shows secondary anemia. The number of white blood cells is within normal limits in the beginning of the disease. Leukocytosis appears during the later stages of sleeping sickness. There is a relative increase of lymphocytes and monocytes.

Autoagglutinins occur often, causing rouleaux formation of the red blood cells. Cold agglutinins have not been found.

Blood Chemistry.—The blood sugar and the alkali reserve of the blood decrease during the disease. The serum is depleted of proteins, chiefly of the albumin fraction. The albumin-globulin ratio is low. Nonprotein nitrogen, urea, and creatinine increase in the terminal stage, while the cholesterol usually decreases.

Spinal Fluid.—During the cerebral stage, the spinal fluid contains many cells, mostly lymphocytes and plasmacytes. The occurrence of plasmacytes in the cerebrospinal fluid is of diagnostic value.

A considerable amount of globulin is usually present in the spinal fluid. Pandy, Nonne-Apelt, and Weichbrodt reactions are positive. The colloidal gold curve shows the paretic type.

Trypanosoma Cruzi
Chagas' Disease or Trypanosomiasis Cruzi

The term ''trypanosomiasis americana'' is incorrect in describing this disease, since the parasite has been found in primates in Java and the vector has a wide geographical distribution.

Trypanosoma cruzi is about 15 microns long, with the blepharoplast situated near the outer point. Dividing forms are not found in the blood stream, but are found in the tissues, without flagella, in this way simulating the form of the organism of kala azar, but are larger than the Leishmaniae of kala azar.

T. cruzi can easily be grown in blood agar. It is pathogenic for monkeys, cats, guinea pigs, dogs, and mice.

Infection is carried through a large bug, the *Triatoma megista*. This triatome is 3 to 3.5 cm. by 1 cm. Light red bands are seen over the abdominal segments. The thorax shows similar stripes or bands. All stages in the development of this bug suck blood.

Chagas' disease is an acute disease with anemia and nervous, cardiac, and myxedematous symptoms.

Diagnosis.—Diagnosis is made by direct or indirect examination.

Direct Examination

Fresh Specimen.—The fresh specimen is very seldom used. It can be useful, however, in very acute cases with heavy parasitism. The parasites should be searched for with high magnification. The serpentine movements of the parasite can be observed as it rapidly traverses the microscopic field.

Thin Blood Film or Thick Drop.—The thin film is not recommended except in acute cases or in heavy parasitism of animals where intact forms of the trypanosomes can be attained. The thick drop is indicated because it increases the probability of finding the parasites. Ross states that in a thin drop of blood only one parasite might be found when in reality there may be as many as 150,000,000 parasites present.

Thick Drop of Blood (Ross) (Errecart's Modification).—This is the best method of examining stained specimens of blood and is very useful for epidemiologic studies. The parasites are fragile and are easily deformed during the examination. In order to prevent breaking the parasite, the following solution should be used.

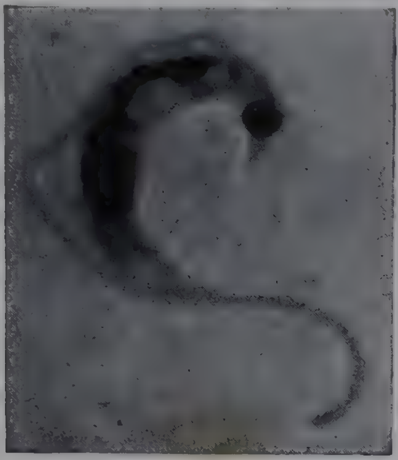

Fig. 468.—*Trypanosoma cruzi* in human blood. Giemsa stain. (×2,000.) (Mazza, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Errecart Solution

Formaldehyde, 40%	1 c.c.
Acetic acid	0.2 c.c.
Physiologic saline	100 c.c.

Gently mix, with a loop, 3 or 4 drops of blood with 1 drop of the solution. Make a very thin spread from this.

Dry in the air, but take care to protect it from flies, dirt, etc.

Dehemoglobinize with distilled water. If dehemoglobinization is not complete, use a solution of 0.2 to 0.5 per cent acetic acid. If the 0.5 per cent solution is used, wash with distilled water several times.

Stain with Giemsa stain diluted 1 drop to each c.c. of neutral distilled water, for 20 minutes.

Renew the Giemsa stain and continue staining for 70 minutes more.

Wash and dry.

Cultures.—Many culture media have been proposed for *Trypanosoma cruzi:*

Geiman Medium, Modified by Groot and Hernández (used also in the cultivation of *Bartonella bacilliformis*).—

Proteose-peptone No. 3.	20 gm.
Bacto agar	20 gm.
Sodium chloride	5 gm.
Distilled water	1000 c.c.

Dissolve and adjust the reaction to pH 7.6 to 7.8 and sterilize in the autoclave. To 75 c.c. of this medium, liquefied and cooled to 45° C., add 25 c.c. of fresh rabbit blood and 0.2 c.c. of the following mixture sterilized by filtration:

Ascorbic acid	10 mg.
Glutathione	40 mg.
Ringer's solution	20 c.c.

The modification consists of adding water of condensation, 2 to 5 c.c., to the tubes, according to the size of the tubes. This is the solution which is usually added to the Kesler medium:

Bacto-peptone, Difco	12.5 gm.
Sodium chloride	2.5 gm.
Bacto-beef, dehydrated	25.0 gm.
Glucose	2.5 gm.
Distilled water	750 c.c.

Inoculate each tube with 0.5 c.c. to 1.5 c.c. of blood and incubate at 22 to 30° C. Some advise defibrinating the blood or placing it in an anticoagulant like sodium citrate. The material may be concentrated by centrifuging. Hernández and Groot found leishmanial forms after nine days, and two or three days later the Trypanosoma appeared, passing through the intermediate leptomonas and crithidia forms. They advise replanting every ten days.

Direct Method of Examination of Living Tissues.—

Biopsy of Glands (Method of Mazza-Talice).—

Select a neighboring gland which gives a 90% positive Leishmania finding, or any lymphatic gland which gives 30% positive findings.

Infiltrate a local anesthetic, 1% Novocain.

Cut the gland in half and rub against a slide.

Fix, and stain with one of the Romanowsky stains; or fix the section in 10 to 15% Formalin, and stain cut sections with iron-hematoxylin-eosin.

Cutaneous and conjunctival biopsy is easily carried out.

Cardiac and hepatic viscerotomy is a method recommended by Mazza for the diagnosis of Chagas' disease. It is similar to that used in the diagnosis of yellow fever. A small block of tissue, 1 cm. by 1 cm., may be obtained by means of an apparatus called "viscerotome," so that the cadaver need not be opened too much. In Venezuela, several chronic cases of this disease have been diagnosed by this procedure.

Mazza proposed that this method be used as a systematic procedure in all endemic zones, or in regions which show a high infestation rate with the winged bedbug.

Indirect Examination

The **complement fixation test** in the diagnosis of Chagas' disease is quite reliable. It has been especially recommended by Kelser, of the United States Army, who used the antigen prepared by making an extract of cultures grown on Kelser's medium.

Make cultures of *T. cruzi* on Kelser's medium and incubate.
Add 0.75 c.c. of sterile distilled water to each tube.
Mix with the surface growth by means of a sterile glass pipette.
Collect the mixtures from these tubes into a 15 c.c. conical centrifuge tube.
Centrifuge for one-half hour at 4,000 r.p.m.
Pipette off the supernatant fluid.
Add 8 c.c. of sterile physiologic saline.
Repeat the centrifugalization to wash the trypanosomes. Pipette off the saline.
Add 2 volumes of 50% glycerin in physiologic saline.
Mix the trypanosomes gently with a platinum loop.
This is the stock antigen and must be kept in a refrigerator.

Leishmania and Leishmaniasis

Leishmanias are small protozoa belonging to the family Trypanosomidae. They are round, oval, or cigar-shaped, 1.5 microns at the shortest diameter and 5 microns at the longest. Besides a relatively large nucleus excentrically placed, there is a parabasal body at an angle to it, and a kinetoplast. Near this is the rhizoplast which represents the axoneme of the flagellate form. With Giemsa or Wright stain, the cytoplasm is a faint blue; all other structures are red or purple.

Leishmanias are found in nature in the blood and reticuloendothelial cells of various mammals and also in sandflies in which the flagellated leptomonas forms develop. They can be cultivated in citrated blood, hemoglobin liver broth, and in the condensation water above N.N.N. medium. In cultures, they elongate, and the large flagellum grows from the kinetoplast at the blunt anterior end. Multiplication of these leptomonas continues by longitudinal fission, whereas the intracellular leishmanias in the mammalian host reproduce by binary fission.

There are three principal species:

Leishmania braziliensis causes mucocutaneous leishmaniasis, mostly in South America, and espundia, or uta.

Leishmania tropica causes cutaneous leishmaniasis and oriental sore.

Leishmania donovani causes visceral leishmaniasis, kala azar, and infantile kala azar.

Animal reservoirs are dogs, cats, and possibly the hamster. Laboratory animals in order of susceptibility are hamsters, monkeys, mice and rats, guinea pigs, and rabbits which are often refractory.

Leishmania Braziliensis

Mucocutaneous Leishmaniasis* (Espundia or Uta)

The etiological agent of mucocutaneous leishmaniasis is the *Leishmania braziliensis*. The nonflagellate or leishmania form is found in the human tissues and in animals susceptible to inoculation with the parasite; the flagellae or leptomonas form is found in the digestive tube of the vector host and in cultures. At times the nonflagellate form is found in the invertebrate host and the flagellate type might be seen, very rarely, in the vertebrate host.

Forms in the Vertebrate Host.—The leishmania forms appear often within the cells of the reticuloendothelial system; in smears they generally appear outside the cells, due to rupture of the cells while preparing the slides. The typical leishmanias are oval, with one extremity more rounded than the other. They measure from 2 to 4 microns by 1.5 to 2.5 microns. This form is susceptible to variations. The distinguishing features of the parasite are the cytoplasm, the nucleus, and the kinetoplast.

Forms in the Insect Vector.—In the insect vector, the leishmania forms rapidly evolve to produce the flagellate form.

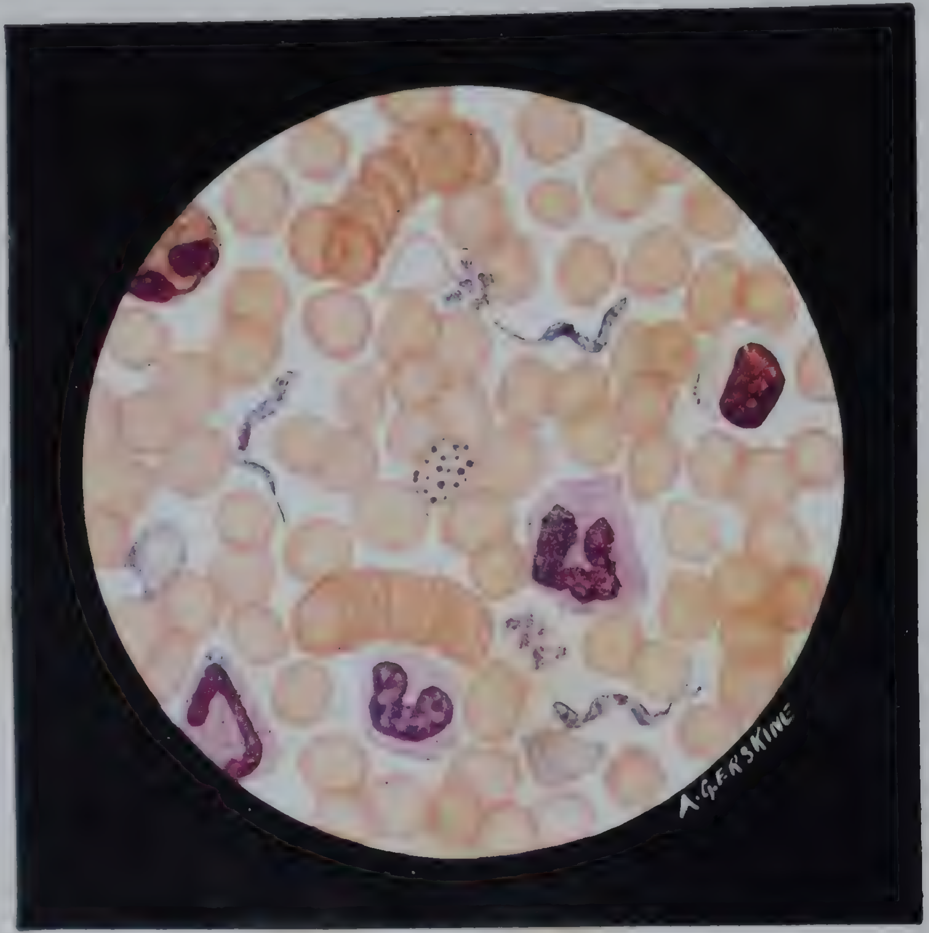
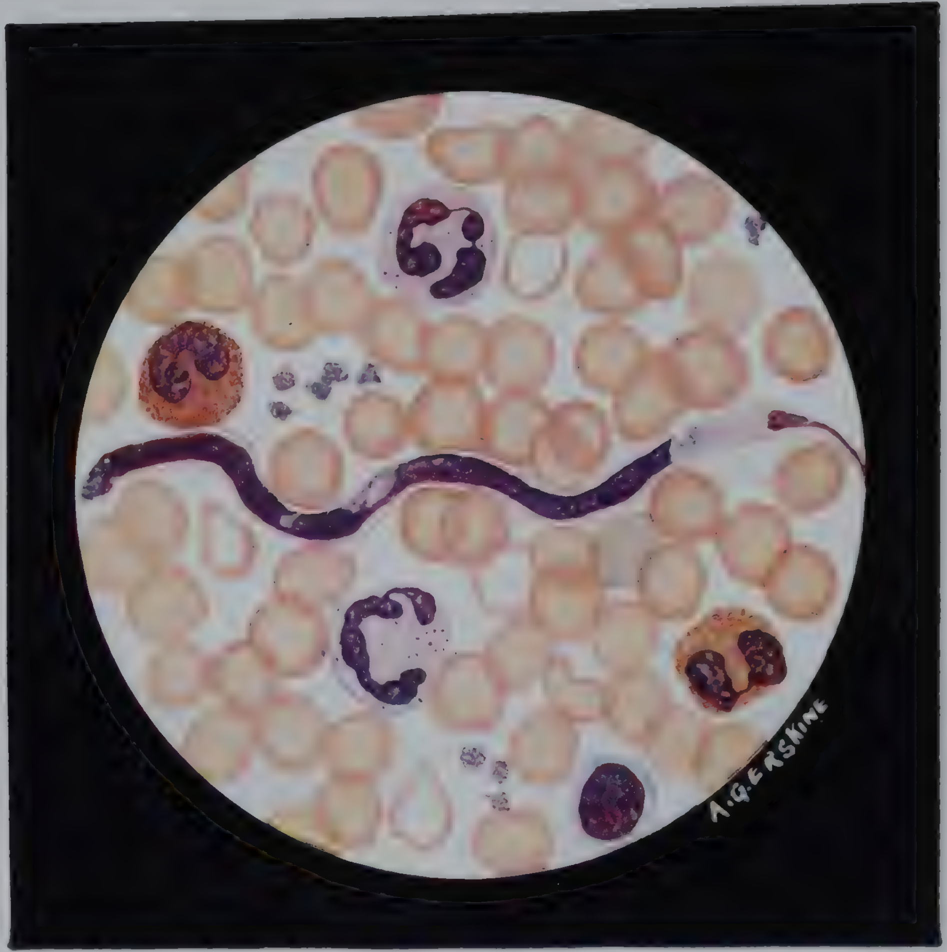
PLATE XLVIII

BLOOD FILMS

GIEMSA STAIN X 950



TRYPANOSOMA GAMBIENSE



WUCHERERIA BANCROFTI

PLATE XLVIII.

Geographical Distribution.—Mucocutaneous leishmaniasis has been found throughout most of Latin America, from Mexico to the northern part of Argentina, with a high incidence of the disease in parts of Peru and Brazil. In Brazil, the disease is most frequent in São Paulo.

Culture.—*L. braziliensis* can be cultivated in N.N.N. medium. The organisms grow in the water of condensation.

Transmission.—The intimate relationship between the incidence of Phlebotomus and mucocutaneous leishmaniasis has been noted for many years. The species which seem to play a predominant role in the dissemination of the disease are *Phlebotomus whitmani, P. pessoai,* and *P. migonei.* The *P. fischeri* seems to be the transmitter in regions of sporadic cases.

After feeding on individuals or animals infected with *L. braziliensis,* the Phlebotomus becomes infected. About 0.22 per cent seem to be naturally infected.

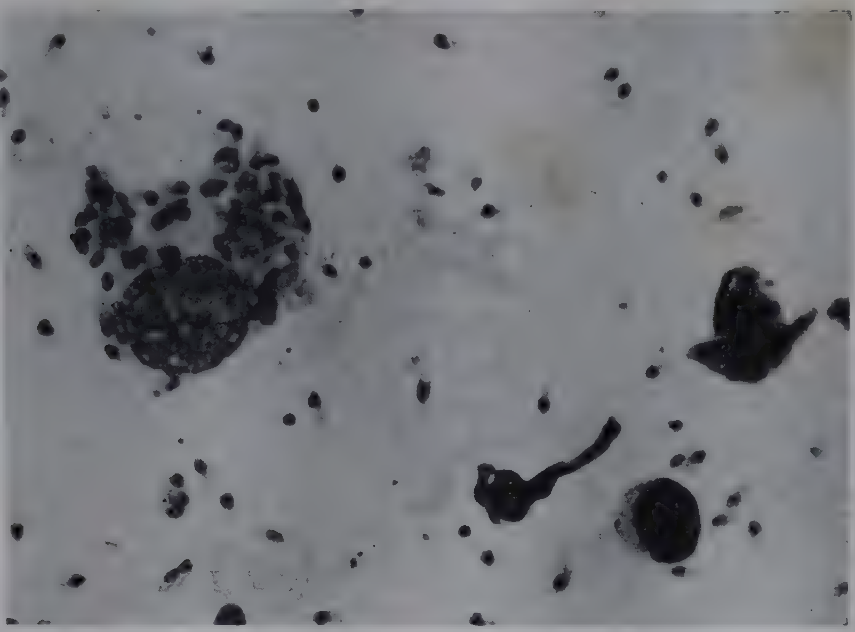


Fig. 469.—Smear of material obtained from puncture of a nonulcerative lesion of mucocutaneous leishmaniasis; a macrophage containing 62 leishmanias may be observed. (Giemsa stain.) (After Pessôa and Barretto in I. Meeting of Derm. Syphil., Brazil, 1944.) (From Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

The possibility of transmission by direct contact has been accepted by several authors.

Nonhematophagous arthropods have been incriminated as the transmitters of the disease, but this idea is not accepted. American leishmaniasis is a disease acquired in the forests, where flies are not as abundant as in cities. The disease is endemic only in certain definite regions, whereas the housefly and other flies can be found everywhere.

The Phlebotomus is probably the only hematophagous arthropod which plays an important role in the transmission of American leishmaniasis.

Laboratory Diagnosis.—The most important laboratory test is the demonstration of the parasite by direct methods: finding it in the ulcers, glands, or by culture. Curettage, puncture, or biopsy may be used to demonstrate the parasites in material taken from lesions of the skin and mucosa as well as from glands.

Place the material immediately in culture media (N.N.N. agar), or fix and section for microscopic examination. In closed lesions, puncture with a large needle is advisable.

To find the parasites in the **nasal mucosa,** curettage must be performed after anesthesia with Neotutocaine. The material obtained must be spread on slides and fixed and stained by the Giemsa method.

Cultures increase the possibility of finding the parasite. It must be kept in mind that leishmanias do not grow in the presence of other microorganisms, so that several tubes must be used to make the culture.

Complement fixation tests are complicated and not satisfactory because of lack of a good antigen.

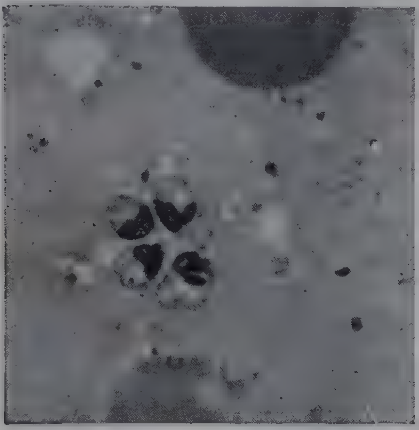

Fig. 470.

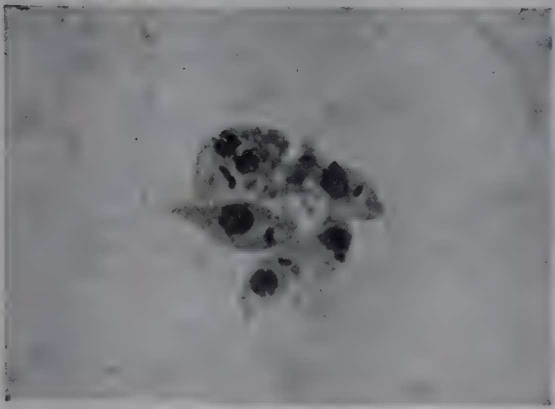

Fig. 471.

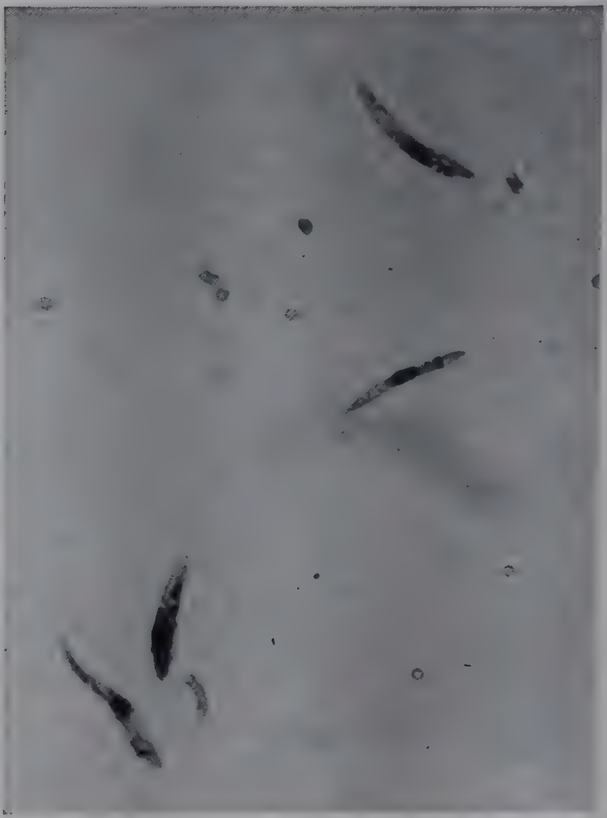

Fig. 472.

Fig. 470.—*Leishmania braziliensis.* Parasites in rosette pattern. Smear from an ulcer. (Pessôa in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Fig. 471.—Leptomonas stages in a culture of *Leishmania braziliensis* in N.N.N. medium. (Pessôa in Clinical Tropical Medicine.)

Fig. 472.—*Leishmania braziliensis,* leptomonas stages, found in the pharynx of *Phlebotomus whitmani* naturally infected. (Pessôa in Clinical Tropical Medicine.)

The Montenegro Test.—The Montenegro test is an intradermal allergic reaction. The antigen is a suspension of leptomonas in phenolized saline solution.

Inject intradermally in dosage of 0.1 to 0.2 c.c.

Positive reactions show the formation of a specific papule, which attains maximum development in 48 hours, remains 4 or 5 days, and then regresses and disappears in about 4 days, more or less, according to its intensity.

This test gives about 95 per cent positive results. It may be negative in early cases, but in such cases the parasites can always be found.

Leishmania Tropica (Cunningham 1885, Wright 1903)
Cutaneous Leishmaniasis (Oriental Sore)

The etiological agent of cutaneous leishmaniasis or oriental sore is the *Leishmania tropica.* Morphologically it is identical to *L. braziliensis.*

Geographical Distribution.—Cutaneous leishmaniasis is endemic in Italy, Greece, Spain, Morocco, Algeria, Tunis, Tripoli, and Egypt. It is also found in Abyssinia, Nigeria, French Congo, etc. It is common in Syria, Israel, Saudi Arabia, Iraq, and other countries of Asia Minor, as well as in certain regions of the U.S.S.R., as in the Caucasus and Southern Russia. There are many cases in India and Indochina.

Cultivation.—*L. tropica* can be cultivated in N.N.N. medium. The forms and development are identical with those of *L. braziliensis.*

Transmission.—It is believed that transmission in nature is effected chiefly through the bite of the Phlebotomus, *P. papatasii, P. sergenti,* and *P. caucasicus.*

Diagnosis.—Diagnosis is made by demonstrating the parasite in lesions by smear or by culture, as described above.

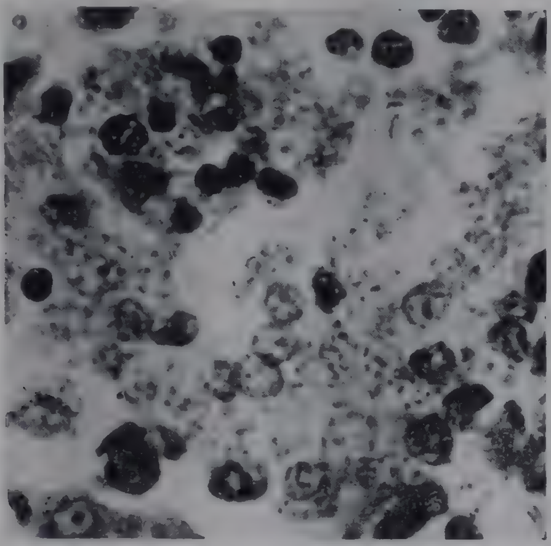

Fig. 473.—*Leishmania donovani* spleen puncture. (O. Felsenfeld, in Clinical Tropical Medicine.)

Leishmania Donovani (Leishman and Donovan 1903)
Visceral Leishmaniasis (Kala-Azar)

The **etiological agent** of visceral leishmaniasis is the *Leishmania donovani.* It is similar in morphology to the *L. braziliensis* and the *L. tropica.*

The disease is known in India as "kala-azar," "black fever," "dumdum fever," or "tropical splenomegaly"; in the Mediterranean as "infantile kala-azar" or "splenic anemia of children"; and in South America as "American visceral leishmaniasis" or "American kala-azar."

Cultivation.—Cultures of *L. donovani* may be obtained from the spleen or from some other organ in which the parasites exist. They have been cultivated from centrifuged urine.

The behavior and morphology of this species in cultures are the same as those of *L. braziliensis.*

Laboratory Diagnosis.—Laboratory methods may be direct, by examination for the parasites, or indirect, by serologic reaction. Microscopic preparations can be used to demonstrate the parasites in the blood, the spleen, the bone marrow, or the liver. These preparations should be fixed in methyl alcohol and stained with Giemsa stain.

The leukopenia may be of great diagnostic value.

Examination of the **peripheral blood** reveals parasites in the leukocytes. Since these are difficult to find, the blood should be diluted with an oxalate solution and immediately centrifuged in a special container. After sedimentation, the layer of leukocytes is drawn off with a pipette. Histiocytes containing many organisms are easily found. A blood culture may be made.

Puncture of the spleen is the method of choice in the search for leishmanias.

To make the puncture, introduce a needle 10 cm. long and 2 mm. in diameter below the costal margin and at a distance which varies with the type of spleen.

Generally parasites are found in smears from the splenic pulp, in great numbers when the case is recent. In the period of the "state of disease," leishmanias are less numerous and, for the most part, extracellular. The pulp may be used to prepare cultures of the parasites.

Resort to **puncture of the liver** is less frequent than splenic puncture, since hepatomegaly occurs later in the disease than does splenomegaly. Finding parasites in the liver is more difficult than finding them in the spleen.

The sternum is usually selected when a search for parasites is to be made in the **bone marrow.** They are frequently found.

Formol-Gel Test (Aldehyde Reaction)*

Place 1 c.c. of the patient's serum, free from erythrocytes, in a 9 mm. test tube. Add 1 drop of 40% (commercial) formaldehyde.

A positive result is indicated by complete coagulation of the serum. Coagulation is complete if the serum does not move when the tube is inverted or shaken. One hour is allowed for the coagulation process.

It has been noted that the serum of a patient with kala-azar becomes coagulated in a few seconds, and not in a few hours.

This test, like other serologic tests, is not absolutely specific. While it is always negative in normal individuals, solidification of the serum takes place in other diseases besides kala-azar: malaria, leprosy, bouba, and alastrim, although the process takes a long time. In American visceral leishmaniasis, the reaction is slow in the early stages, but increases in rapidity with the degree of infection. It is useful in the diagnosis of American visceral leishmaniasis in the early stages and also it can be used for evaluating the results of therapy.

Brahmachari Test (Reaction of Ray)

The Brahmachari test consists of the formation of a turbid ring at the point of contact between the serum and distilled water.

Allow 2 or 3 c.c. of distilled water to flow slowly along the walls of a test tube containing 1 c.c. of serum.

A turbid ring forms at the point of contact in positive cases; the stronger the reaction, the more definite the ring.

---

*Spackman, Col. W. C.: Brit. M. J. 2: 266, 1921.

The reaction is due to increase of globulin, principally euglobulin, in the serum, with corresponding reduction in albumin. The reaction is not specific for kala-azar, but occurs as well in malaria.

Complement Fixation Tests

Antigen for complement fixation tests for visceral leishmaniasis are cultures of leishmanias washed in physiologic solutions by centrifugation, and preserved in acetone for a few days. After evaporation of the acetone, the leishmanias which remain are triturated and mixed with ethyl alcohol. Positive results have been obtained with this antigen, not only for visceral and cutaneous leishmaniasis, but also for Chagas' disease. This has been interpreted as the result of a group reaction. This is a delicate test and is not readily adaptable as a routine measure.

Recently antigens prepared from acid-fast organisms have been used for complement fixation tests.

For **intradermal skin tests**, see Mucocutaneous Leishmaniasis.

SUBPHYLUM CILIOPHORA Doflein 1901

Subphylum Çiliophora includes protozoa provided with cilia which serve as organs of locomotion and for taking food. It has two classes, Ciliata and Suctoria.

Ciliophora contain both a macronucleus and a micronucleus. Most of the Ciliophora are free-living, but the class includes a number of parasitic forms.

Class **CILIATA** Butschlii

Order **HETEROTRICHIDA** Stein

Family **Bürsariidae**

All species have cilia or cirri during the vegetative or trophozoite life. Only the genus Balantidium is of interest in medical protozoology.

Balantidium Coli (Malmsten 1857) Stein 1862

The trophozoite of *Balantidium coli* is usually very large. There are also small forms. In the stools, the size varies from 50 to 100 microns in length and 40 to 70 microns in width; some forms are 50 to 80 microns long and 40 to 60 microns wide. The parasite is ovoid and is covered with cilia, which are in constant motion. There are two nuclei, the larger one situated in the midportion of the body, the smaller one usually hidden under the concavity of the macronucleus. A large vacuole is seen in the middle portion and a small vacuole in the posterior end.

B. coli may engulf bacteria, erythrocytes, or other foreign bodies.

Cysts are spherical or ovoid, and large, 45 to 65 microns in diameter, with a thick cystic wall of double contour. It is probable that the cysts which contain the moving trophozoites are viable and that the older cysts are degenerated and dead forms.

Hogs, various species of monkeys, and man can be parasitized by *B. coli*.

The parasites can produce ulcerative lesions in the mucosa of the large intestine.

B. coli has been cultivated on various media.

Man is infected through ingestion of the cysts, either in contaminated food or on the contaminated hands of individuals who slaughter or handle hogs, or by butchers. More than 25 per cent of the reported cases of human balantidiasis give history of direct antecedent contact with hogs.

Diagnosis is made by direct microscopic examination of fresh stools, unstained and stained by Lugol solution. The organisms can be cultivated on a medium composed of 1 part of inactivated human serum and 16 parts of 0.5 per cent saline.

FUNGI, SPIROCHETES, AND INTESTINAL BACTERIA

In addition to the protozoan intestinal fauna of man there are frequently seen in the microscopic examination of stools a certain number of intestinal vegetable microorganisms belonging to the classes of fungi, spirochetes, and bacteria, some of which demand the attention of the microscopist. These organisms are of particular importance in teaching students or beginners. Certain elements such as the *Blastocystis hominis* are often sources of error in diagnosis of intestinal protozooses, particularly amebiasis.

Among the fungi the *Blastocystis hominis* must be considered as the principal artefact; in second position are yeasts, monilias, and fungi, often due to external contamination of fecal material. As to the *Spirochaeta intestinalis,* Kourí and Basnuevo[1] published a description of four types based on their morphology in human stools.

---

[1] Crón. méd. quir. de la Habana 59: 349, 1933.

Certain bacteria, because of their size, form, and abundance, frequently call attention to their presence under the microscope, for example, the *Clostridium iodophilum*. These organisms are spherical or oval, relatively large, grouped in bunches, refractile in fresh specimens, and blue when stained with iodine. They form a part of the normal flora of the colon. They are very abundant in liquid stools after the use of laxatives which cause rapid emptying of the colon. They are not usually found in the formed stools of normal movements or in the hard stools of constipation.

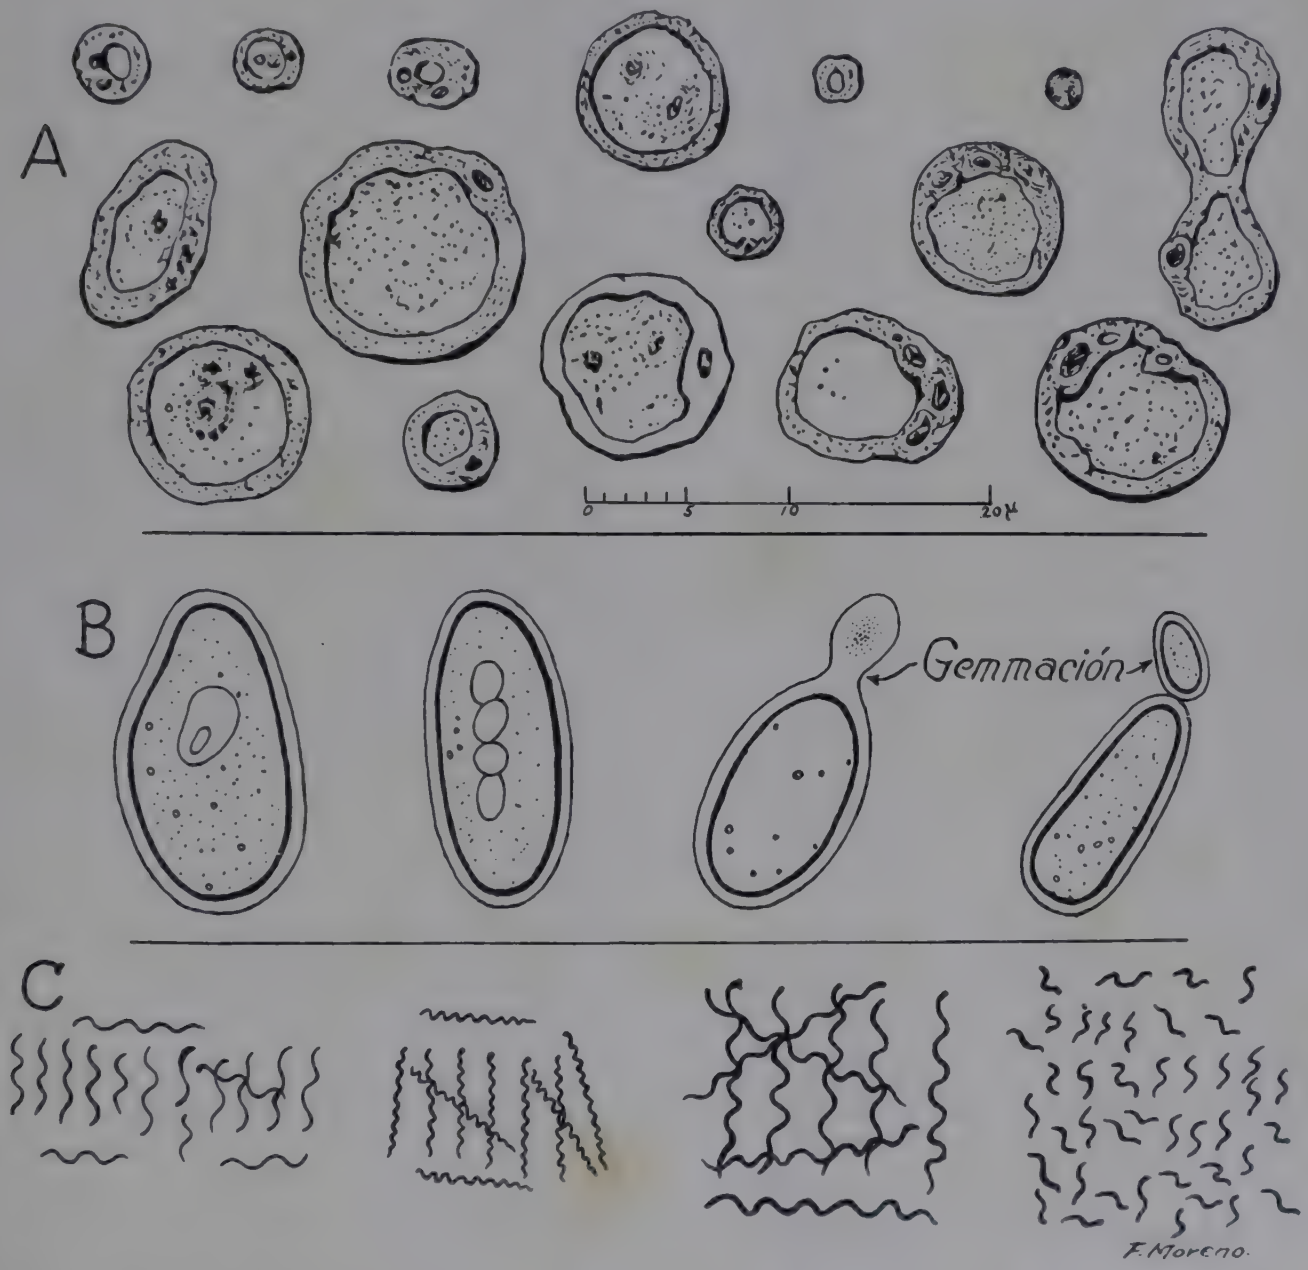

Fig. 475.—*A*, *Blastocystis hominis*, after Langeron and Rondeau du Noyer. *B*, Yeasts, after Troissier and Achalme. *C*, Intestinal spirochetes. All these elements are found frequently in human feces. (After Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

Blastocystis Hominis Brumpt, 1912

Blastocystis hominis appears in the stools as a spherical body, colorless and refractile, varying in size from 2 to 15 microns in length (see Fig. 475). In some specimens only the small forms are seen, while in others medium-sized forms are found, and in still others, the very large forms. The small forms are frequently confused by beginners with cysts of amebae.

When stained with Lugol, the characteristic structure can be seen very well. It has a relatively thick peripheral ring of protoplasm in which may be seen one or more nuclei with dense karyosome, and a central or slightly excentric vacuole. It stains well by Gram stain (Kourí 1930) and by iron-hematoxylin. At times they may be seen in binary fission, biscuit-shaped, or in figure of eight. They are frequently seen in individuals with slight intestinal disturbances, or even with no such disturbances. They are seen at times in considerable numbers in diarrheal or dysenteric stools, often associated with true intestinal protozoa and spirochetes.

It is usually regarded as nonpathogenic but when seen in large numbers in diarrheal or dysenteric states, alone or associated with spirochetes, in patients in whom it is otherwise impossible to ascertain any other cause for the disturbance—a disturbance which disappears with the disappearance of the Blastocystis when pentavalent arsenicals are administered by mouth—there is a possibility that it may be able to cause such symptoms, or that it has contributed at least in their production or maintenance. In other words, in such cases the *Blastocystis hominis* might be the cause and not the consequence of these symptoms, especially when they occur in great numbers.

Yeasts, Monilias, and Other Fungi in Human Stools

Yeasts are oval, mammilated elements, hyaline and refractile, with a diameter not exceeding 6 to 7 microns. They are frequently found in stools. When found in large quantity they are generally due to ingestion of brewer's yeast. These yeasts must not be confused with Clostridia which are also oval, but which are much smaller and which stain very light blue with Lugol. True yeasts take on the yellow color of Lugol. Finding of yeasts in stools concentrated by Telemann's method is quite common. Most of them are gram-negative. See Fig. 475.

Other fungi found in stools are the Monilias, which appear as filamentous forms composed of segments with rounded extremities, distended and very fragile, with an oval blastospore like the yeasts, but generally wider and more easily broken off. In cultures of stools on Sabouraud's medium, monilias and yeasts frequently develop. Stools that have been exposed to the air are frequently contaminated by fungi from outside the body. Do not consider these fungi as parasites coming from the intestinal canal.

Intestinal Spirochetes

Different types of spirochetes are found frequently in stools. They are found in large numbers in diarrheal conditions, at times in dysenteric syndromes, alone or associated with Blastocystis or other intestinal protozoa.

SPOROZOA

Coccidiosis of Man

Coccidia are protozoa which are widely distributed usually in the animal kingdom. They show a complicated development, and multiply by sexual and asexual methods. They have been found in the stool in cystic form, the so-called oöcysts.

Eimeria stiedae is a rabbit coccidium which has been reported in a number of cases in man. Silcock, of London, in 1890 reported a fatal case in man with intestinal disturbances, anemia, and fever, showing at autopsy a marked enlargement of the liver with numerous ulcerative caseous areas filled with coccidia. Dresler and Craig report a case with liver nodules filled with coccidia.

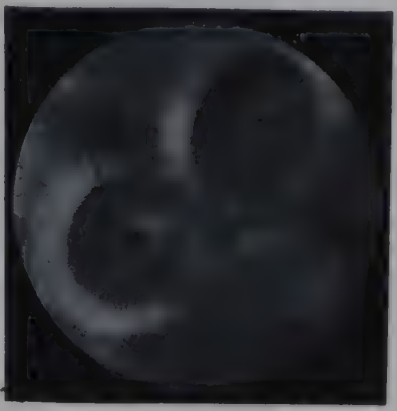

Fig. 476.—Coccidiosis of man, *Isospora bigemina* (×950).

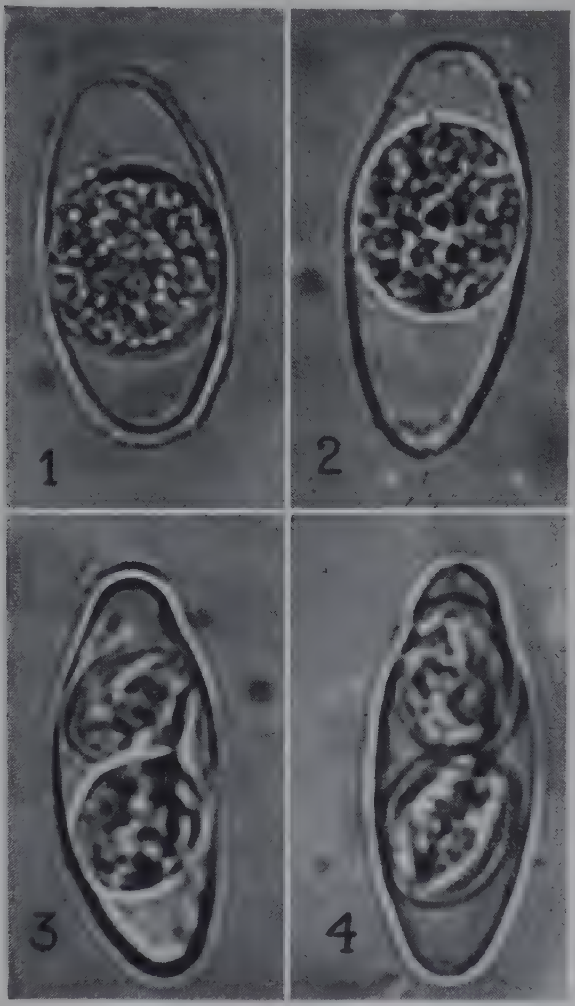

Fig. 477.—Human coccidia: *Isospora hominis.* *1* and *2*, Oöcysts with one sporoblast, in a concentrated specimen, method of Willis; fresh feces recently passed. *3* and *4*, Oöcysts with two sporocysts, from a 48-hour culture of fecal material concentrated by the method of Willis. Each sporocyst produces four sporozoites. Thus, 2 sporocysts × 4 sporozoites = 8 sporozoites. (After Kourí and Basnuevo in Revista de Medicina Tropical y Parasitología, 1937, and Lecciones de Parasitología y Medicina Tropical.)

Isospora Hominis.—These cases have shown the typical oöcysts in the stool. These oöcysts were found in conjunction with a dysenteric condition. There has also been described in man as well as in cats and dogs a special type of isosporocyst known as the *Isospora bigemina.* Reichenow, with whom the author worked at the Hamburg Institute of Tropical Medicine, presented him with the specimen which is photographed here. (Fig. 476.)

Eimeria Oxyspora Dobell, Eimeria Wenyoni.—In these cases we find the characteristic Eimeria oöcysts in the stool of the infected patient. The *Eimeria wenyoni* seems to be identical with the *Eimeria clupearum* which has been recovered from the liver of herring and other fish.

TOXOPLASMOSIS

Toxoplasma Gondii (Nicolle and Manceaux)

Many reports on toxoplasmosis have appeared since the original discovery of toxoplasma by Nicolle and Manceaux, in 1908, in North Africa, and by Splendore in the same year, in Brazil. Nicolle and Manceaux first observed intracellular parasites in smears of the spleen and other organs of the North African rodent, the gondi (*Ctenodactylus gondi*). They were impressed by its resemblance to Leishmania. They recognized the absence of a kinetoplast and later, in 1909, placed the parasite in the new genus Toxoplasma. They described it fully, even to the point of recognizing its mode of division as longitudinal bipartition. In accordance with the laws of priority for binomial nomenclature, the proper name for all strains of Toxoplasma is *Toxoplasma gondii* (Nicolle and Manceaux).

With the first strain they isolated, they were successful in producing acute toxoplasmosis in the gondi and the guinea pig, but failed with macaques and rats. Splendore, in 1909, reported that he was able to transmit the parasite to guinea pigs and to sparrows and other birds. Carini, in 1909, was able to infect pigeons with the parasite from rabbits, as well as guinea pigs and white rats, but not dogs or chickens. Nicolle and Conor (1913) found mice to be most susceptible, but they failed to infect white rats, a young dog, monkeys, frogs, or toads. Mello, in 1910, in the meantime described a spontaneous case of toxoplasmosis in a dog, and Carini, in 1911, and Carini and Maciel, in 1913, also discovered natural infections in dogs and pigeons and transmitted the parasite to other animals. Carini and Migliano, in 1916, found natural infection also in guinea pigs from which they inoculated pigeons successfully. Chatton and Blanc, in 1917, were able to infect a cat with a parasite from the gondi. It thus became clear that Toxoplasma was a parasite without host specificity among warm-blooded vertebrates, and Chatton and Blanc expressed the view that the organisms found naturally in the various hosts were all members of the same species. This was substantiated on immunologic grounds as well by Sabin in 1939. The discrepancies in some of the early reports regarding the susceptibility of various animals to Toxoplasma may be attributed to variations in host response and in strain virulence.

Leon Jacobs[1] discussed the biology of toxoplasmas fully. Toxoplasmosis has been found in the gondi, the mouse, the vole, rat, rabbit, guinea pig, squirrel, and marmot. Among carnivores, the dog, cat, and chinchilla have been found naturally infected. There are also reports of infections in sheep and in swine. Among primates, it has been found in the baboon and chimpanzee as well as in man. Forty-five species of birds have been reported as harboring this parasite. The pigeon has been definitely shown to harbor Toxoplasma.

Morphology.—Toxoplasma resembles the merozoite of a coccidian. It is crescent-shaped, with one end attenuated, the other more rounded. It is 2 to

---

[1] Am. J. Trop. Med. & Hyg. 2: 365, 1953.

4 microns wide by 4 to 7 microns long. The nucleus is nearer the rounded end. No centrosome or kinetoplast is visible, but in some specimens there may be a chromatic granule between the nucleus and the attenuated end. At times the parasite appears oval rather than crescentic, and this stage is considered preliminary to cell division. No pigment is present in any stage. The organism stains well with Wright or Giemsa stain, with a pale blue cytoplasm and a red nucleus.

Agglomeration of the parasites within muscle cells has given rise to reports that the Toxoplasma reproduces by schizogony as well as by longitudinal division, but no intermediate stages representative of schizogony have ever been described.

Culture.—Toxoplasma requires an intracellular situation to grow and multiply. Sabin and Olitsky, in 1937, pointed out that as an obligate intracellular parasite it is similar to a filtrable virus in behavior and in the host reactions it induces. It has never been cultivated in artificial media, but it has been propagated successfully in suspensions of minced embryonic tissues by Sabin and Olitsky (1937) and in Maximow slide cultures of chick embryonic tissues by Guimaraes and Meyer (1942) and by Jacobs.

Inoculation into the yolk sac of a developing chick results in dissemination of the parasite, which can be recovered from chorio-allantoic and other membranes and from the embryonic tissues in one week or less. The virulence of the parasites following over 13 serial passages in chick embryos remains unchanged, and Jacobs states that this may be extended to include a much longer period, two to three years. He also states that a chick embryo appears to be a good host in which to maintain Toxoplasma strains of low virulence.

Transmission.—Intracerebral inoculation of Toxoplasma into mice, rabbits, hamsters, guinea pigs, pigeons, and other hosts generally results fatally within one week, even with Toxoplasma strains of low virulence, and in hosts such as the rat which manifests little evidence of infection following peripheral inoculation even with virulent strains.

Pathogenicity.—It appears that neonatal toxoplasmosis could result from transfer to the child of toxoplasmas in milk of mothers experiencing the initial acute stage of the infection after parturition. It is unlikely that this could occur in chronic infections. On the basis of clinical and laboratory findings, the likelihood of congenital transmission of toxoplasmosis from the chronically infected mother is low.
